Abstract—Semantic segmentation of road scenes plays a crucial role in many fields such as autonomous driving, intelligent transportation systems and urban planning. Through the precise identification and segmentation of elements such as roads, pedestrians, vehicles, and traffic signs, the system can better understand the surrounding environment and make safe and effective decisions. However, the existing semantic segmentation technology still faces many challenges in the face of complex road scenes, such as lighting changes, weather effects, different viewing angles and the existence of occlusions. Combined with the actual road scene image, this paper improves DeeplabV3+ network and applies it to semantic segmentation of road scene image, and proposes a semantic segmentation method of road scene image based on improved DeeplabV3+ network. By adding enhancement strategies for road scene images and hyperparameter adjustment, the method improves the training process of DeeplabV3+ network, and uses SK attention mechanism to improve the feature fusion module in DeeplabV3+, so as to improve the segmentation effect of road scene images. After the validation of Cityscapes and other data sets, the segmentation accuracy index mIoU of the proposed method reaches 79.8%, which can predict better semantic style effect, effectively improve the segmentation performance and accuracy of the model, and achieve better segmentation index results in the comparison network, and the subjective visual effect of the segmentation is also better.

Keywords—Image enhancement; attention mechanism; semantic segmentation; road scene images

I. INTRODUCTION

Image semantic segmentation [1] aims to provide richer image semantic information for pixel-level image classification tasks. The need for semantic segmentation is crucial for applications in scenarios that require high-precision target segmentation, such as autonomous driving [2-4], environmental monitoring [5-7], augmented reality [8-10], and security surveillance [11-13]. By accurately segmenting objects in an image, more accurate scene analysis, target recognition and decision making can be achieved, thus enhancing system performance and application experience.

In recent years, the field of automatic driving is constantly developing, and the semantic segmentation technology of road scene plays an important role in the automatic driving system. Image semantic segmentation provides the autonomous driving system with rich road information and high-level

understanding of the image, including the classification and accurate positioning of the target, so that the autonomous vehicle can fully understand the complex traffic situation around. However, there are still some specific problems in the existing road scene semantic segmentation technology, such as: insufficient robustness under different lighting conditions, which leads to the deviation of segmentation results. Due to the influence of bad weather (such as rain, snow, fog), the segmentation accuracy decreases significantly. And in crowded and dynamic scenes, it is easy to appear occlusion and confusion. These deficiencies limit the decision-making ability of autonomous vehicles in complex environments, and further research is needed to address these challenges to improve system safety and reliability.

With the continuous development of hardware level and computing power, the rapid development and application of deep learning technology provides new ideas for semantic segmentation research, and deep learning methods can significantly improve the accuracy of semantic segmentation. Full Convolutional Network (FCN) [14] is an important method to deal with image segmentation tasks using deep learning technology, which opens a new era of achieving high-precision semantic segmentation with deep learning as the core technology. However, FCN still has some shortcomings, for example, the relationship between pixels is not fully utilized and the results obtained are still not fine enough. Researchers have gone on to propose many network models with better segmentation results based on different technical features. Badrinarayanan et al. proposed SegNet [15] based on the structure of codec [16]. The innovation of SegNet network is that it reduces the number of fully-connected layers as well as the number of parameters and storage space of the streamlined model, and also outputs the indexing information in the pooling process to improve the image segmentation accuracy and efficiency of the decoding process. Noh et al. proposed DeconvNet [17], which improves the segmentation performance by introducing an inverse convolution layer at the decoder side to recover the resolution of the feature map through the coding-decoding structure. Olaf Ronneberger et al. proposed U-Net [18], whose symmetric coding and decoding network structure captures semantic information at different levels, pinpoints feature map information during up and down sampling, and preserves more information about the original image.

Fig. 1. DeeplabV3+ network architecture.

PSPNet [19] uses the ResNet [20] network as a backbone network, with modifications that use an additional auxiliary loss function, and two losses are assigned different weights, which promotes rapid convergence of the model. Overall, the traditional symmetric coding and decoding structure has more training parameters and complex structure, so it is less effective for the application of scenarios with real-time requirements.

The Deeplab network was proposed by the Google Brain team to solve the problems of category imbalance, voids, and edge details that are difficult to handle in semantic segmentation. Nowadays, Deeplab has developed a series of networks that are constantly employing new techniques and structural optimization algorithms to enhance their performance in various domains. DeepLabV1 [21] utilizes dilated convolutions to expand the receptive field and employs a fully connected conditional random field to enhance detail capturing capability, refining the segmentation object edges. DeepLabV2 [22] introduces the ASPP module on the basis of DeeplabV1, utilizing dilated convolutions with different dilation rates to extract feature information at different scales, enhancing the model's adaptability to objects of different scales, and also incorporating inverse convolutions and batch normalization techniques. DeeplabV3 [23] further expands the depth and width of the network on the basis of V2, adopts cascading or parallel mode to arrange cavity convolution with different cavity rates, optimizes ASPP module, and captures multi-scale features more effectively. DeeplabV3+ [24] extends DeepLabV3 by adopting an encoder-decoder structure to achieve better semantic segmentation performance. This paper proposes a semantic segmentation method for road scene images based on improved DeeplabV3+ network. The backbone network uses lightweight MobileNetV2, combined with the actual application of road scene image, to enhance

image data and hyperparameter adjustment, aiming at improving the accuracy and efficiency of semantic segmentation of road scene image. We introduced SK attention module to optimize the feature fusion module in DeeplabV3+ to enhance the model's ability to capture key features. This improvement not only improves segmentation accuracy, especially in complex environments such as bright light, shadows, and dynamic scenes, but also helps reduce computational costs.

The main contributions of this paper are summarized as follows:

- This paper proposes a road scene image semantic segmentation method based on improved DeeplabV3+ network. To reduce the complexity of DeeplabV3+ network, lightweight MobileNetV2 is used as the backbone network.
- Increase the diversity of training data through image enhancement strategies, optimize the generalization of DeeplabV3+ network, and optimize the training process through hyperparameter adjustment.
- By introducing SK attention mechanism to optimize the feature fusion module in DeeplabV3+, adjust the feature weights and improve the accuracy of semantic segmentation.

The rest of this article is structured as follows: Section II describes the network structure of DeeplabV3+. In Section III, the semantic segmentation method of road scene image based on the improved DeeplabV3+ network is introduced in detail. Section IV describes the experimental setup of this paper and the experimental results with other methods. The final conclusion is given in Section V.

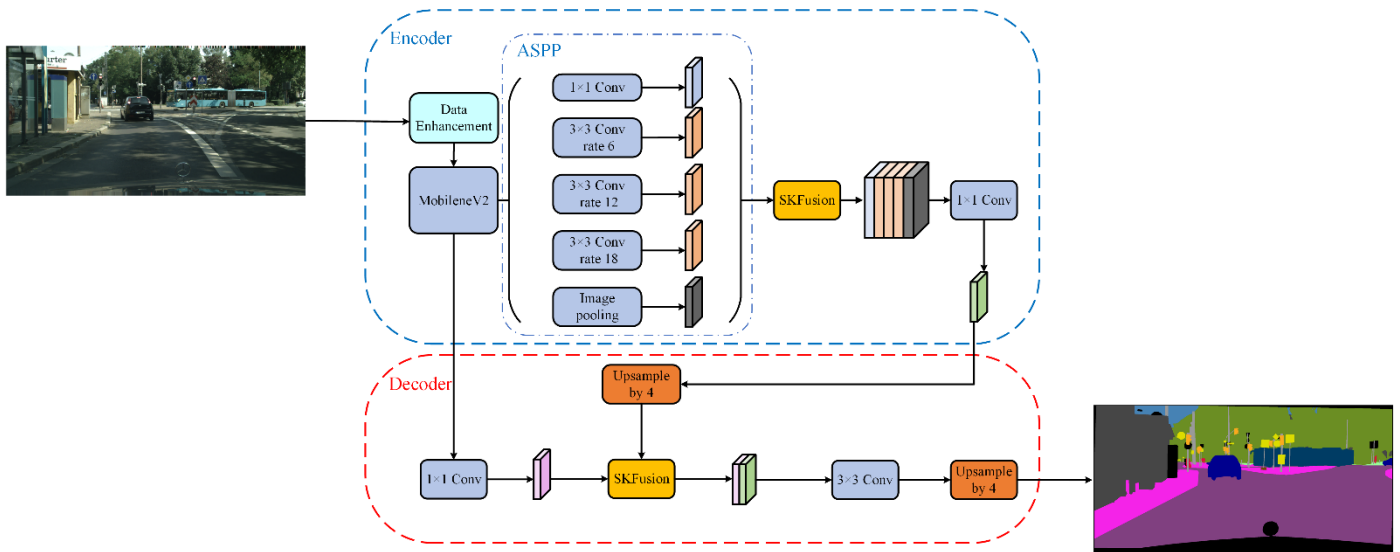

Fig. 2. Overall framework of road scene semantic segmentation based on improved DeeplabV3+.

II. DEEPLABV3+ NETWORK

The DeepLabv3+ network architecture is shown in Fig. 1. DeepLabv3+ uses an encoder-decoder structure to improve DeepLabv3. The encoder uses Atrous Spatial Pyramid Pooling (ASPP) to capture context information at different scales, while the decoder refines the target boundary to improve segmentation results. The ASPP module is used to capture semantic information of different scales, splice the feature information after multiple empty convolution operations with different sampling rates, and obtain the feature after 1×1 convolution. Another branch of the Deep Convolutional Neural Network (DCNN) uses 1×1 convolution to process the underlying features of the image to obtain the underlying features of the image. Then the feature is fused with the feature that has been subsampled four times, and the semantic segmentation prediction image is obtained after 3×3 convolution and four times subsampling.

III. A SEMANTIC SEGMENTATION METHOD FOR ROAD SCENE IMAGES BASED ON IMPROVED DEEPLABV3+ NETWORK

A. The Overall Framework of the Proposed Methodology

In this paper, DeepLabv3+ model is used to improve image semantic segmentation in road scenes. In the semantic segmentation of road scene image based on DeepLabv3+ network, lightweight MobileNetV2 is adopted as the backbone in this paper. In the training process, the data is enriched by image enhancement. After passing through MobileNetV2 network, ASPP method is used to extract multi-scale feature information from images by different sampling rates. SK attention mechanism [25] is introduced to improve the feature fusion module, and feature fusion is performed on the feature mapping obtained by ASPP module to improve DeepLabv3+ network. The SK feature fusion module is also used in the later feature fusion of encoder and decoder. The improved Deeplabv3+ model is shown in Fig. 2.

B. Image Enhancement

Image enhancement refers to the process of generating new training samples through a series of transformation operations on the original image during image processing or pattern recognition tasks. Through image enhancement, the diversity of training data can be increased, which helps to improve the generalization ability and robustness of the model. The operation process of image enhancement in this paper is shown in Fig. 3.

1) *Random left-right flip*: In order to increase the diversity of data and make the model have better generalization ability and segmentation effect, the left and right flip of all the training set images is carried out with 50% probability. The same original image was randomly flipped left and right twice, and the resulting image was shown in Fig. 4.

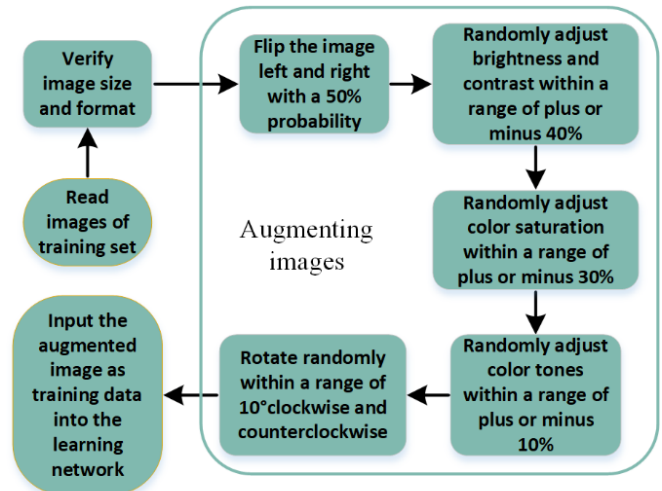

Fig. 3. Improved image augmentation operation process.

(a) Example 1 of result image after randomly flipping

(b) Example 1 of result image after randomly flipping

Fig. 4. Schematic diagram of random left-right flip.

2) *Random color adjustment*: In the actual road scene image, may encounter a variety of different weather during driving, or due to the impact of camera shooting, resulting in a large difference in the brightness of the input image, so you need to adjust the image brightness, contrast, saturation and tone to increase the generalization ability of color. The pre-processed images are color-adjusted, the brightness and contrast are randomly adjusted within the range of plus or minus 40%, the color saturation is randomly adjusted within the range of plus or minus 30%, and the hue is randomly adjusted within the range of plus or minus 10%. Two random color adjustments were made to the same original training image, and the results were shown in Fig. 5.

(a) Example 1 of result image after randomly adjusting color

(b) Example 2 of result image after randomly adjusting color

Fig. 5. Schematic diagram of random color adjustment.

(a) Example 1 of result image from random rotation

(b) Example 2 of result image from random rotation

Fig. 6. Schematic diagram of random rotation angle.

3) *Random rotation angle*: In order to increase the generalization ability of oblique images, this paper added the processing of random rotation Angle, set the center of the image as the rotation center, and rotate the image randomly within the range of 10° clockwise and counter clockwise. The same picture was randomly rotated for two times, and the result was shown in Fig. 6.

C. SKFusion

When people observe things, they will selectively pay attention to the more important information, which is called attention. By continuously focusing on this key location to get more information and ignoring other useless information, this visual attention mechanism greatly improves the efficiency and accuracy of our processing on information. The attention mechanism in deep learning is similar to the attention mechanism in human vision, which is to focus attention on the important points with more information, select the key information, and ignore other unimportant information.

SKFusion in the improved DeepLabv3+ network is to adjust the weight of the feature map by using the SK attention mechanism after the concatenated features. The operation process is shown in Fig. 7. We first splice n features together by Concat operation, as shown in formula (1):

$$X = \text{Concat}(x_1, \dots, x_n) \quad (1)$$

where, (x_1, \dots, x_n) a is n eigenvectors.

Fig. 7. SKFusion network architecture.

Then the obtained feature X is processed using the SK attention mechanism, and the processed feature is obtained, as shown in formula (2):

$$V = SKAttention(X) \quad (2)$$

SK attention mechanism [25] is mainly divided into three operations: Split, Fuse and Select. The Split operator produces multiple paths of different kernel sizes. The Fuse operators combine and aggregate information from multiple paths to obtain a global and comprehensive representation for selecting weights. The Select operator aggregates feature maps of cores of different sizes based on selection weights.

a) Split: Convolve the input feature graph X through a cavity of different receptive fields. Fig. 7 represents two groups of convolution operations, one with a convolution kernel of 3×3 to obtain the feature graph, and the other with a convolution kernel of 5×5 to obtain the convolution kernel, as shown in formulas (3) and (4):

$$\tilde{U} = Conv_{3 \times 3}(X) \quad (3)$$

$$\hat{U} = Conv_{5 \times 5}(X) \quad (4)$$

b) Fuse: To ensure that the information flow from multiple branches carries information of different sizes into the next layer of neurons, first fuse the results of multiple branches (two branches in Fig. 7) by summing the elements, as shown in formula (5):

$$U = \tilde{U} + \hat{U} \quad (5)$$

Then, the global average pooling of U is performed to obtain s , and the dimensionality is reduced by the fully connected layer to improve the efficiency and z is obtained, as shown in formulas (6) and (7):

$$s = F_{gp}(U) = \frac{1}{H \times W} \sum_{i=1}^H \sum_{j=1}^W U(i, j) \quad (6)$$

$$z = F_{fc}(s) \quad (7)$$

Where, F_{gp} represents the global average pooling operation,

$H \times W$ is the spatial dimension size, and F_{fc} represents the fully connected layer.

c) Select: A new feature map computed from convolution kernels with different weights. First do softmax to calculate the weight of each convolution kernel, if there are two convolution cores, then $a+b=1$. Then, the final feature graph V is obtained by multiplying the weight elements of each convolution kernel, as shown in formula (8):

$$V = a \cdot \tilde{U} + b \cdot \hat{U}, a+b=1 \quad (8)$$

D. Hyperparameter Adjustment

In the original training hyperparameters of the model, the batch size was set to 16. However, considering that there is still room for expansion in the memory of the graphics card, we have increased the batch size. Increasing the batch size has three following benefits. Firstly, the memory utilization is increased, and the parallelization efficiency of the large matrix multiplication is increased. Secondly, with the same amount of data, the number of iterations required to run through a training round is reduced, further increasing the processing speed. Thirdly, increasing the batch size within a certain range can make the determined descent direction more accurate, thus reducing training oscillations.

When the batch size increases to a certain extent, its determined descent direction may have been largely unchanged. However, since the accuracy of the final convergence is affected by a variety of factors, such as network structure, learning rate, etc., it does not mean that the larger batch size will necessarily get better results. In practice, when the batch size is increased to some extent, to achieve the optimal convergence accuracy, factors such as iteration need to be considered. So the adjustment strategy of our proposed method is to increase the batch size to 32.

For the epoch hyperparameter, the epoch was set to 30 in the initial experiment, which still has room for improvement. The complete process of running the model to complete one forward propagation and back propagation on all the data is called 1 training round, in other words, it means that all the training samples in the dataset have been trained once.

Fig. 8. Loss fluctuation per training set round.

Fig. 9. Loss fluctuation per validation set round.

In the training process of gradient descent model, the neural network gradually transitions from the unfit state to the optimal fit state, then it will enter the overfitting state after reaching the optimal state. However, the number epoch of training rounds is not the larger the better, and it is generally set to between 20 and 200 to achieve good training results. The more diverse the data, the larger the corresponding training rounds. Our proposed method adjusts the epoch to 60.

We visualize the fluctuation of the loss function with the number of training rounds. Both the training and validation sets use the images contained in Cityscapes [26]. The loss fluctuations of training set are shown in Fig. 8, and the loss fluctuations of validation set are shown in Fig. 9.

Through recording the fluctuations of loss function during the training process of model, as can be seen from Fig. 8 and Fig. 9, as the number of training rounds increases, the loss decreases and the segmentation effect gradually improves. Due to the Adam optimization algorithm, after 40 rounds, the learning rate will gradually decrease after being adjusted by the Adam algorithm, so the weight change will also decrease, and the change of corresponding loss function will be minimal. After 60 rounds of training, a model with relatively good segmentation performance can already be obtained.

IV. EXPERIMENTAL DESIGN AND ANALYSIS

A. Dataset

The rapid development of deep learning cannot be separated from the development of training data, and the preprocessed dataset can greatly facilitate the training process of image processing without having to put too much effort on the labeling of the dataset. In this paper, we choose the representative dataset Cityscapes [26] as the dataset for semantic segmentation of road scenes. Cityscapes is an image dataset for urban street scenes, and this dataset contains 5000 images that have been annotated at high quality pixel level and covers 19 categories with dense pixel annotations, among which 8 categories have instance-level segmentation. The dataset is divided into three parts: training, validation and testing with 2975, 500 and 1525 images, respectively. In addition, the dataset contains stereoscopic video sequences from street scenes in 50 different cities. The examples on raw and pixel-level labeled images of the Cityscapes dataset are shown in Fig. 10 and Fig. 11, respectively.

Fig. 10. Original image of the road scene.

Fig. 11. Pixel-level labeled image.

Cityscapes is very large, with 20,000 weakly annotated frames in addition to 5,000 images with high-quality pixel-level annotations. In addition, the Cityscapes dataset provides fine and coarse metrics. The fine evaluation criterion is based on 5,000 images with fine labels, while the coarse evaluation criterion is based on 5,000 images with fine labels and 20,000 images with coarse labels.

B. Experimental Environment and Parameter Settings

Performing image processing using deep learning involves a large number of floating-point and matrix operations, and it has high requirements for the hardware and software environments, which can affect the effectiveness of deep learning model. The hardware environment for our

experiments involves CPU processor Intel i7-9750H and 128G memory, as well as GPU processor NVIDIA GeForce GTX 1650 with 4G graphics memory. In terms of software environment, Windows 10 64-bit operating system is used, Pytorch deep learning framework is selected, and the classic general-purpose parallel computing architecture CUDA is applied. In addition, dependent libraries such as Numpy, OpenCV, and PIL are also used.

In order to ensure that the segmentation results are only affected by the model itself, the same hardware configuration and software parameter settings are used for different comparison models, so as to ensure the consistency of the experimental environments. For each comparison model, the experimental software and hardware environments are shown in Table I and Table II.

TABLE I. EXPERIMENTAL HARDWARE CONFIGURATION

Hardware	Configuration
CPU	Intel i7-9750H@2.60GHz
GPU	NVIDIA GeForce GTX 1650
Memory	128G
Video memory	4G

TABLE II. EXPERIMENTAL SOFTWARE CONFIGURATION

Software	Configuration
Operating system	Windows10 64-bit
Deep Learning Framework	Pytorch1.12
Programming language	Python3.8
Parallel computing architecture	CUDA 11.6
Main Dependency Libraries	Numpy、Matplotlib、Opencv

In this paper, the uniform parameter settings for model training are as follows. Cross-Entropy Loss (CE Loss) [27] with multiple classes is used. The optimizer adopts Stochastic Gradient Descent (SGD) strategy, where the learning momentum parameter is set to 0.9 and the weight decay is set to 0.00001. The initial learning rate LR is 0.0001, and the learning rate is dynamically adjusted by a poly strategy, which dynamically decreases with the increase of training iterations, and the current learning rate new_lr is updated as shown in formula (9).

$$new_lr = LR * (1 - \frac{epo}{max_epo})^{power} \quad (9)$$

Where momentum power is 0.9, epo indicates the current number of training iteration, and the maximum number of training iteration max_epo is calculated as shown in formula (10).

$$max_epo = (\frac{M}{batchsize}) * epoch \quad (10)$$

Where M is the number of training samples 2975, the number epoch of training rounds is the total number of rounds that need to be trained, uniformly set to 60. According to the

model size and the graphics memory, batchsize is set to 20. After the above parameter settings, all of comparison models can achieve good convergence results.

C. Comparison of Experimental Effect

To verify the effectiveness of the proposed method, several typical deep learning semantic segmentation networks were selected for experiments, including FCN, SegNet, DeeplabV3 and DeeplabV3+. By comparing with these networks, we aim to comprehensively evaluate the performance of our proposed methods in different scenarios. In the experiment, the segmentation effect is compared on the images of verification set as well as the campus images taken in the field to ensure the universality and reliability of the results. In addition, we will use multiple evaluation metrics such as mean crossover ratio (mIoU) and pixel accuracy (pixAcc) to provide a more comprehensive performance analysis.

1) *Comparison of subjective effect:* In this paper, five segmentation network models including FCN, SegNet, DeeplabV3, DeeplabV3+ and our improved DeeplabV3+ are applied to test and verify the semantic segmentation of the same image. Fig. 12 shows the segmentation effect diagram of some pictures. Columns (b), (c), (d), (e) and (f) respectively represent the segmentation effect corresponding to FCN, SegNet, DeeplabV3, DeeplabV3+ and our improved DeeplabV3+ network. Images 1 to 5 were selected from part of the validation set in the Cityscapes dataset, including several common road scenes. Images 6 and 7 were two road scenes in the university.

Compared with the segmentation effect of all images, it can be seen from Fig. 12 that SegNet has a slightly higher segmentation accuracy than FCN in general, but the segmentation effect needs to be improved and there are some problems of inaccurate segmentation of details. DeeplabV3 has a better segmentation effect than SegNet and can accurately predict the classification of some detailed images. Our improved DeeplabV3+ works best, with clearer categories. SegNet cannot clearly divide the shape of the category when dividing the categories such as cars and houses. FCN has some deviation when it does not distinguish pedestrian categories well, and the edges are fuzzy, while DeeplabV3 and DeeplabV3+ still have good segmentation effect. Since our improved DeeplabV3+ optimizes the training strategy through image enhancement and hyperparameter adjustment, and uses the SKFusion module DeeplabV3+ network structure, it is more sensitive to small targets and other information, and the segmentation effect is better.

It can be seen that the performance of the improved model at the junction of the motorway and the sidewalk has been significantly improved, and the jagged segmentation phenomenon of the original model has been successfully solved, making the boundary smoother and more natural. This improvement not only improves the visual effect, but also provides a more reliable basis for the division of pedestrians, vehicles and buildings in practical applications. In the segmentation results of images 6 and 7, we can clearly see that the improved DeeplabV3+ model shows higher accuracy and detail in processing various categories. Especially in the

contours of pedestrians, cars and houses, the model can effectively distinguish the boundaries of complex backgrounds

and reduce blurring. This further verifies the effectiveness and superiority of the model in multi-class segmentation tasks.

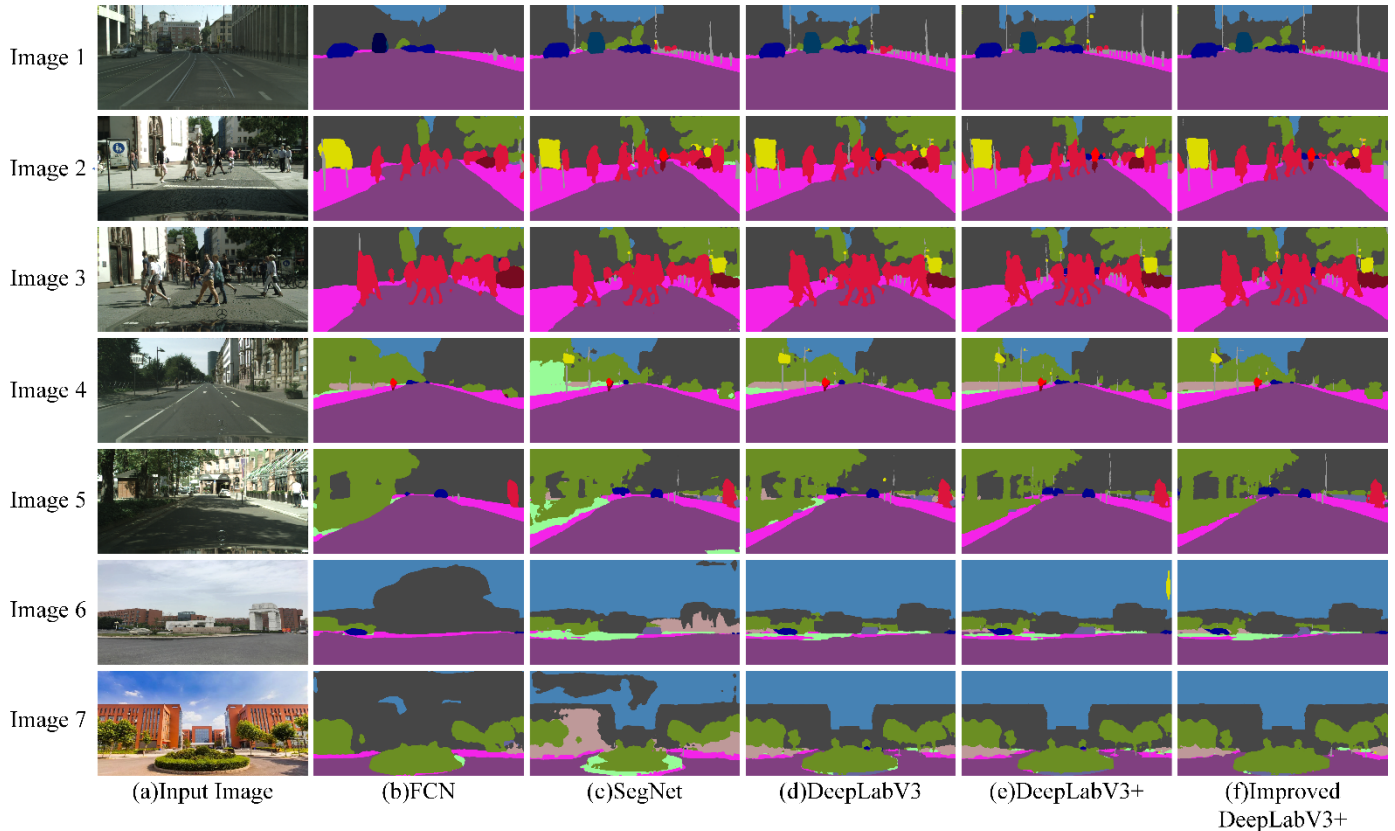

Fig. 12. Comparison of subjective effects. (a)Input Image; (b)FCN; (c)SegNet; (d)DeeplabV3; (e)DeeplabV3+; (f) Improved DeeplabV3+.

2) *Comparison of objective effects:* Regarding the objective performance evaluation metrics for semantic segmentation on road scene images, this paper adopts the commonly used evaluation metrics for semantic segmentation, pixAcc (PA) and mIoU. PA is the pixel accuracy rate, which is relatively simple to compute, and is the ratio of the number of correctly predicted pixels to the total predicted pixels. mIoU is a commonly used evaluation metric for semantic segmentation tasks, i.e., the average intersection and union ratio which is the ratio of the intersection and union of the true and predicted values. In semantic segmentation, the intersection and union ratio of a single category indicates the ratio of the intersection of the true and predicted values of the category to the union of the category, reflecting the classification accuracy of the model for each category and the overall segmentation effect.

For the test set contained in Cityscapes, the five models FCN, SegNet, DeeplabV3, DeeplabV3+, and our improved DeeplabV3+ are tested and the objective performance evaluation indicators are shown in Table III.

As a whole, combined with Fig. 12, our improved DeeplabV3+ model has better overall segmentation results, with finer segmentation results for some categories such as pedestrians, vehicles, traffic lights, and sign boards, as well as better segmentation results for more detailed categories such as

travel lanes. After the validation on the Cityscapes validation set, the segmentation accuracy metric mIoU of our improved DeeplabV3+ reached 79.8%, achieving the best segmentation metric results.

TABLE III. COMPARISON OF OBJECTIVE PERFORMANCE EVALUATION INDICATORS OF FCN, SEGNET, DEEPLABV3, DEEPLABV3+, AND IMPROVED DEEPLABV3+ SEGMENTATION

Model	pixAcc (%)	mIoU (%)
FCN	81.8	32.5
SegNet	84.2	55.4
DeeplabV3	87.6	72.7
DeeplabV3+	89.4	76.5
improved DeeplabV3+	91.2	79.8

V. CONCLUSIONS

For the problem that the semantic segmentation effect of road scene image needs to be improved, this paper proposes a road scene image semantic segmentation method based on the improved DeeplabV3+ network by improving DeeplabV3+ network and applying it to the semantic segmentation of road scene image. The network uses SK attention mechanism to improve the feature fusion module, adjust the feature weights, and optimize the training process by image enhancement and hyperparameter adjustment. Through experiments on cityscape

and other datasets, our method achieves the best segmentation results based on subjective visual effects and objective performance evaluation indicators in the comparison network, among which pixAcc reaches 91.2% and mIoU reaches 79.8% on cityscape dataset. It can be seen that the semantic segmentation effect of our method on road scene image is significantly improved. However, there are two specific limitations to note. Firstly, our method's performance may be compromised in extremely challenging conditions, such as heavy occlusions or severe weather effects, which were not extensively tested in this study. Secondly, while our model achieves high accuracy on urban road scenes, its applicability to rural or less structured environments remains uncertain and may require further adaptation. Future work should focus on developing adaptive models that can learn from real-time data, ensuring robustness in diverse scenarios. Overall, our proposed method not only improves accuracy but also sets the foundation for future innovations in autonomous driving and intelligent transportation systems.

Abstract—Chest X-ray imaging is the main tool for detecting tuberculosis (TB), providing essential information about pulmonary abnormalities that may indicate the presence of the disease. Still, manual interpretation is a common component of older diagnostic methods, and it may be laborious and subjective. The development of sophisticated machine learning methods offers a potential way to improve TB detection through the automation of chest X-ray image interpretation. This takes a look at goals to increase a sturdy framework for TB diagnosis the usage of Stacked Loopy Decision Trees (SLDT) optimized with the Moth Search Algorithm (MSA). The objective is to improve upon current techniques with the aid of integrating sophisticated feature extraction and ensemble mastering strategies. The novelty lies in the integration of SLDT, a hierarchical ensemble model able to shooting complex styles in chest X-ray images, with MSA for optimized parameter tuning and function selection. This technique addresses the complexity of TB analysis by enhancing each interpretability and overall performance metrics. The proposed framework employs the Gray-Level Co-prevalence Matrix (GLCM) for texture characteristic extraction, accompanied with the aid of SLDT ensemble studying optimized through MSA. This methodology objectives to discern TB-particular styles from chest X-ray pictures with excessive accuracy and efficiency. Evaluation of a comprehensive dataset demonstrates advanced performance metrics including accuracy, sensitivity, specificity, and vicinity underneath the ROC curve (AUC-ROC) compared to traditional gadget gaining knowledge of procedures. The outcomes demonstrate how well the SLDT-MSA framework performs in diagnosing TB, with 99% accuracy. The observation indicates that the SLDT-MSA framework offers practitioners a trustworthy and easily understandable solutions, marking a significant advancement in TB diagnosis.

Keywords—Tuberculosis (TB); chest x-ray; stacked loopy decision trees (SLDT); moth search algorithm (MSA); medical imaging

I. INTRODUCTION

Tuberculosis is a persistent infectious disease caused by Mycobacterium tuberculosis (MTB), a slow-growing microorganism capable of surviving in both extracellular and intracellular environments [1]. The bacterium can enter a latent phase within the host's body, remaining dormant until conditions favor its reactivation into an active, contagious state, particularly in individuals with compromised immune systems [2]. According to the World Health Organization (WHO) report in 2019, approximately 10.0 million people worldwide were infected with TB, leading to 1.4 million deaths annually, highlighting TB as a significant global health challenge [3]. The disease disproportionately affects developing regions, where limited access to specialized medical professionals and TB diagnostic tools exacerbate the burden of TB [4]. While TB is curable, delayed detection can significantly impact health outcomes [5]. Regions such as Africa and Southeast Asia bear the highest TB burden due to socio-economic factors [6]. The gold standard for TB detection remains culture testing, complemented by methods like chest radiography, sputum smear microscopy, and nucleic acid amplification. Advanced diagnostic techniques including computed tomography and molecular tests offer further improvements in detecting and managing TB cases [7]. Existing diagnostic and treatment methods for tuberculosis (TB) face significant challenges that impede effective disease management across diverse global settings. The cornerstone of conventional TB diagnosis revolves around methods like sputum smear microscopy and culture, which, while established, are fraught with limitations [8]. These techniques are labor-intensive, requiring skilled personnel and prolonged processing times that delay diagnosis and treatment initiation. Furthermore, they often fail to detect TB in its early stages or in cases with extrapulmonary manifestations, leading to missed diagnoses and subsequent transmission risks [9].

The inconsistent sensitivity of conventional TB testing techniques is one of its main disadvantages. For example, in situations with low bacterial load, sputum smear microscopy may not identify TB bacilli, leading to false-negative findings that postpone necessary treatment. To make matters worse, waiting weeks for findings from culture-based techniques might prolong the time it takes to diagnose and treat patients. Though these regions have the greatest rate of tuberculosis, these issues are most severe in resource-constrained settings where access to diagnostic facilities, skilled people, and dependable laboratory infrastructure is restricted [10]. The growing prevalence of drug-resistant tuberculosis strains exacerbates these problems by complicating treatment results and calling for more specialised and efficient diagnostic techniques. Drug-resistant TB strains, such as those that are extensively drug-resistant (XDR-TB) and multidrug-resistant (MDR-TB), need specific treatment plans that depend on a quick and precise diagnosis [11]. In addition to endangering the course of treatment for individual patients, delaying the identification of drug-resistant tuberculosis (TB) promotes resistance amplification in communities and continuous transmission. Given these obstacles, it is vitally necessary to create and implement more precise, quick, and easily accessible TB testing techniques on a worldwide scale. These advancements ought to focus on increasing specificity, speeding up diagnosis, and improving sensitivity in order to distinguish tuberculosis from other respiratory disorders. Through the surmounting of these obstacles, novel diagnostic technologies have the potential to significantly enhance tuberculosis (TB) management tactics, enable prompt treatment start, reduce the rate of transmission, and ultimately enhance health outcomes for TB-affected individuals and communities around the globe. In order to overcome the shortcomings of current TB diagnosis and treatment approaches, this project will create a novel strategy that combines optimisation methods with the Moth Search Algorithm (MSA) and Stacked Loopy Decision Trees (SLDT). Through the use of cutting-edge machine learning techniques, this innovative approach seeks to improve the efficacy, scalability, and accuracy of tuberculosis diagnosis and treatment results using chest X-ray images. The study aims to accomplish multiple goals: firstly, to create a strong SLDT model that can identify complex patterns in medical images that suggest tuberculosis-related abnormalities; secondly, to use MSA to optimise model parameters and feature selection to improve diagnostic accuracy and reliability; thirdly, to compare the performance of the SLDT-MSA framework to established diagnostic techniques using large datasets, with a focus on metrics like sensitivity, specificity, and area under the ROC curve (AUC-ROC); and lastly, to offer insights into the proposed approach's potential impact on TB management strategies. Through the integration of SLDT and MSA, this research seeks to develop a more efficient and user-friendly diagnostic tool that can expedite the diagnosis of tuberculosis (TB), enable the beginning of treatment promptly, and ultimately enhance patient outcomes across a variety of global healthcare settings. The principal findings of the research are given below as follows:

- The study integrates Stacked Loopy Decision Trees (SLDT) with the Moth Search Algorithm (MSA), offering a novel approach to tuberculosis (TB) diagnosis. This integration enhances the model's ability to capture

intricate patterns in chest X-ray images indicative of TB-related abnormalities.

- The research expedites the diagnostic process, cutting down on processing times and increasing the effectiveness of tuberculosis detection by utilizing MSA for feature selection and parameter optimization inside the SLDT setup.
- The proposed approach holds significant clinical relevance by providing clinicians with interpretable diagnostic outputs, aiding in informed decision-making and facilitating prompt patient management strategies.
- Achieved a high diagnostic accuracy of 99% in distinguishing TB-positive cases from normal conditions, surpassing traditional methods. This improvement is crucial for early detection and timely treatment initiation, especially in resource-limited settings.
- Offers a scalable solution applicable across diverse healthcare settings, potentially improving access to accurate TB diagnosis globally. This scalability is critical for addressing the disparities in TB healthcare delivery and outcomes. Advances in TB diagnosis through innovative machine learning methodologies contribute to optimized TB management strategies, aiming to reduce transmission rates, mitigate drug resistance, and enhance overall public health outcomes.

The rest of the paper is organized as follows: Section II discusses related work. Section III discusses the problem statement Section IV explains the proposed methodology. Section V reports and compares the experimental results. Section VI concludes the paper and mentions future work.

II. LITERATURE REVIEW

Bacteria lead to the development of TB, which is a life-threatening lung disease and one of the top 10 causes of mortality. Detecting tuberculosis at an early stage and confirming the diagnosis is crucial, as failing to do so can lead to serious illness. This project involved developing a technique for precise tuberculosis detection from chest X-rays through the enhancement of images and advanced technological analysis. We used many public databases to make a new database with 3500 TB infected and 3500 normal chest X-ray pictures for our research. Nine separate deep convolutional neural networks were employed to leverage their pre-existing training, before being evaluated for their ability to distinguish between TB and non-TB normal instances. This study carried out three different. At the beginning, two separate U-net models were used for segmentation of the X-ray images. Second, it classified X-ray images. It categorized and organized lung images into different sections. Using X-ray images, the most effective model, ChexNet, is capable of detecting tuberculosis with great precision. It is responsive and demonstrates a high F1-score and specificity. However, the classification accuracy improved when utilizing lung images that were segmented into sections compared to using the entire X-ray images. The segmented lung images exhibited improved accuracy, precision, sensitivity, F1-score, and specificity with DenseNet201. It also used a way to

show that CNN mostly learns from certain parts of the lung, which made it better at finding problems. The new approach is highly effective and can aid doctors in promptly diagnosing tuberculosis with the help of computers. Despite this, the study's limitations include its use of a limited dataset comprising only 7000 images, which may compromise the accuracy of the models in diverse real-life contexts [12].

Modern health systems greatly rely on computer science for their functioning. The utilization of computers in medical practice facilitates the teamwork of doctors in diagnosing illnesses, ultimately improving the care provided to patients. They also provide support to researchers and decision-makers in the healthcare field. So, any new ideas that make it easier to diagnose health issues while still being safe and effective are really important for making healthcare better. Early detection can lead to the identification of numerous illnesses. In this research, we used different methods to study tuberculosis (TB). Our recommendation is to create an improved machine learning algorithm that identifies the optimal texture characteristics in images related to TB and configures the classifier settings. We want to make our measurements more accurate and use fewer characteristics. The challenge lies in attempting to handle numerous tasks at once and ensuring they all function at their highest capacity. The most beneficial traits are selected using a genetic algorithm (GA) and then input into a support vector machine (SVM) for classification. The new technique we implemented for the ImageCLEF 2020 data yielded better results compared to the other methods we used. According to the test results, the modified SVM classifier outperforms the standard ones. The study has some limitations. Utilizing just one set of data from ImageCLEF 2020 may not capture all the diverse presentations of TB. The choice of features by the genetic algorithm could potentially neglect important factors in diverse clinical settings [13].

The most recent research conducted by the World Health Organization (WHO) in 2018 revealed that tuberculosis leads to the deaths of 5 million people annually, with approximately 10 million people falling ill from the disease. Furthermore, over 4,000 people die from TB every day. If the sickness had been identified sooner, many of the deaths could have been prevented. Recent books and articles have talked about using deep learning to help doctors diagnose illnesses by looking at medical images. Although deep learning has shown potential in many areas, there are not many thorough studies to diagnose tuberculosis. In order to improve its performance, deep learning requires a substantial amount of good training examples. TB chest x-ray pictures are usually not very clear because the contrast is not very strong. This research focuses on the impact of improving visual representations on the problem-solving abilities of a computer program. The program for enhancing images enhanced the appearance of the images by highlighting their distinctive characteristics. Three different methods were tested to enhance the visual appeal of images: Unsharp Masking, High-Frequency Emphasis Filtering, and Contrast Limited Adaptive Histogram Equalization. The better pictures were given to ResNet and EfficientNet models to learn from. In a collection of TB pictures, we got 89.92% accuracy in classifying them and 94.8% in AUC scores. The Shenzhen dataset is the source of all the findings and is available to anyone. However, this study has its restrictions.

A more advanced GPU and increased memory are necessary to utilize the CNN network for sending the original image at its full resolution. Moreover, the training would be extended due to the process [14].

The progression from dormant tuberculosis to active tuberculosis presents a serious problem. Although skin tests and blood tests are effective for detecting a tuberculosis (TB) infection, they cannot differentiate between latent TB infection and active TB. Diagnosis of LTBI presents difficulties as there are no accurate tests available and differentiating it from active TB is complex. Testing for tuberculosis using sputum culture takes a long time and cannot tell the difference between active tuberculosis and latent tuberculosis infection. This article discusses the way TB bacteria grows and the body's defence mechanism in latent TB infection. This involves both the innate and acquired immune responses of the body, the strategies used by TB bacteria to evade the immune system, and the impact of genetic factors on this mechanism. Given our current understanding, we elucidate the present circumstances and challenges in detecting LTBI. We also explore the potential use of machine learning (ML) in the diagnosis of LTBI, as well as the advantages and disadvantages of employing ML in this context. The study explores the ways in which machine learning could be utilized to enhance LTBI detection in the future. Although ML has benefits like better accuracy and efficiency in diagnosis, it also has some problems that need to be fixed. The constraints involve a requirement for extensive data, complexity in comprehension, dependence on particular techniques and technology, apprehensions about data security, and ambiguity in choosing features [15].

Medical professionals on the front lines must swiftly establish whether a patient showing symptoms has tested positive for COVID-19 or not. In areas with scarce resources and lacking biotechnology tests, this task becomes even more challenging. Tuberculosis remains a significant health concern in numerous impoverished nations. The primary indications include high body temperature, an unproductive cough, and fatigue, which bear resemblance to COVID-19. To aid in the detection of COVID-19, researchers propose the use of specialized technology for analysing chest X-rays, which are commonly found in hospitals. Following this, it has the option to employ computer programs to categorize and identify the X-rays, without the requirement of expensive equipment. A set of five various chest X-ray images was assembled by us. Included in this assortment are the same amount of cases for COVID-19, viral pneumonia, bacterial pneumonia, TB, and healthy individuals. The performance of different computer program combinations in extracting useful information from a dataset was evaluated. We tested out 14 advanced pre-made networks alongside conventional machine learning tools to identify the most optimal pairing. The best pipeline for classifying five different groups of items was a combination of ResNet-50 and a subspace discriminant classifier. It had the highest accuracy in detecting the classes. Additionally, the pipeline was able to accurately classify COVID-19, TB, and healthy cases in simpler problems with three categories, as well as COVID-19 and healthy images in problems with only two categories. The pipeline was really fast. It only took 0.19 seconds to extract DF from each X-ray image and 2 minutes to train a traditional

classifier with over 2000 images on a regular computer. The findings show that our method could be helpful in finding COVID-19, especially in places with few resources. It uses X-rays that are easy to get and doesn't need a lot of computer power [16].

Tuberculosis (TB), a leading cause of death globally, necessitates accurate and early detection to prevent life-threatening outcomes. Using deep learning and sophisticated machine learning techniques to enhance tuberculosis detection from chest X-ray pictures has been the topic of several investigations. Through the use of deep learning models, data augmentation, and picture preprocessing, Rahman et al. (2020) showed that diagnosis accuracy may be greatly improved by segmentation and classification approaches, albeit the generalizability of their model may be constrained by the use of a particular dataset. A genetic approach for feature selection in conjunction with a support vector machine (SVM) classifier was presented by Hrizi et al. (2022). This method achieved good accuracy, although it may be constrained by bias in feature selection and dataset specificity. In order to improve the performance of deep learning models on low-contrast TB chest X-rays, Munadi et al. (2020) assessed image enhancement strategies. They were able to achieve a significant level of accuracy, but encountered difficulties with computing demands. In their evaluation of machine learning applications for latent tuberculosis infection (LTBI), Li et al. (2023) noted improvements in diagnostic efficiency as well as drawbacks including data needs and interpretability problems. Al-Timemy et al. (2021) highlighted the promise of accessible imaging technology in healthcare diagnostics by developing a computationally efficient pipeline for diagnosing COVID-19 and TB using deep features from chest X-rays. The pipeline demonstrated great accuracy even in resource-limited situations. When taken as a whole, this research shows the potential and difficulties of combining deep learning and machine learning to improve tuberculosis detection and emphasise the continuous need for a variety of high-quality data sources and processing power.

III. RESEARCH GAP

In the realm of tuberculosis (TB) diagnosis using chest X-ray imaging and advanced machine learning techniques, several critical research gaps hinder progress towards more accurate and efficient diagnostic methods. One major gap is the underexplored integration of ensemble learning, such as Stacked Loopy Decision Trees (SLDT), with sophisticated texture analysis methods tailored for TB detection. While SLDT frameworks excel in capturing intricate patterns in medical images, their synergy with advanced texture analysis techniques, like those derived from Gray-Level Co-occurrence Matrix (GLCM), remains insufficiently explored. This gap limits the development of models capable of effectively extracting subtle yet crucial texture features indicative of TB-related abnormalities in chest X-rays. Moreover, optimizing SLDTs for TB diagnosis presents another challenge. While metaheuristic algorithms like the Moth Search Algorithm (MSA) show promise in optimizing model parameters and feature selection, their application in fine-tuning SLDTs for medical image analysis is still emerging. Current studies often use simpler optimization techniques or focus on single-model architectures,

neglecting the complexity of ensemble frameworks necessary for accurate TB diagnosis [17]. The scarcity of diverse and well-annotated datasets is another critical gap. Existing datasets often lack comprehensive representation across demographic groups, TB manifestations, and imaging conditions. This limitation hampers the development of machine learning models that can reliably generalize across different clinical scenarios and patient populations, essential for ensuring robust diagnostic accuracy and clinical applicability. Comparative studies benchmarking SLDT-MSA frameworks against deep learning architectures in TB diagnosis are sparse. Understanding the trade-offs between these methodologies, including diagnostic performance, computational efficiency, and scalability, is crucial for selecting optimal approaches based on specific clinical needs and resource constraints. Addressing these research gaps is essential for advancing TB diagnosis using machine learning, facilitating the development of more effective, interpretable, and clinically relevant diagnostic tools that enhance patient outcomes and healthcare delivery worldwide.

IV. RESEARCH FRAMEWORK

The research framework for this examine on tuberculosis (TB) prognosis integrates superior device gaining knowledge of strategies with scientific imaging analysis to beautify diagnostic accuracy and efficiency. Central to the framework is the utilization of Stacked Loopy Decision Trees (SLDT) as an ensemble gaining knowledge of technique, optimized via the Moth Search Algorithm (MSA). SLDT permits the hierarchical extraction of complex patterns from chest X-ray images, which might be crucial for identifying TB-related abnormalities. The Moth Search Algorithm complements this by first-rate-tuning SLDT parameters and deciding on top of the line features derived from strategies which include Gray-Level Co-prevalence Matrix (GLCM) evaluation. This combined method ambitions to enhance diagnostic precision by means of shooting diffused texture versions indicative of TB, thereby improving sensitivity and decreasing fake-terrible effects. The framework also emphasizes version interpretability, presenting clinicians with transparent insights into the decision-making process for TB prognosis. By integrating those advanced methodologies, the studies framework seeks to pioneer a greater powerful and scalable diagnostic device for TB, probably transforming medical practice and public health techniques in TB management. Fig. 1 shows the workflow of the proposed approach.

A. Data Collection

The dataset for tuberculosis (TB) diagnosis consists of chest X-ray images collected from multiple sources, including a publicly accessible portion and additional images obtainable through the NIAID TB portal. The dataset is a collaborative effort involving researchers from Qatar University and the University of Dhaka, Bangladesh, along with collaborators from Malaysia, supported by medical professionals from Hamad Medical Corporation and Bangladesh. For research reasons, the 700 TB-positive images in this collection are freely available. Additionally, after assuming certain terms and conditions, researchers can download 2,800 TB photos from the NIAID TB site. 3,500 normal chest X-ray images are additionally contained in the collection and are openly available for comparison [18].

Fig. 1. Workflow of the proposed approach.

B. Image Pre-Processing

1) *Data augmentation*: In the field of medical image analysis, data augmentation is an essential tactic, especially large datasets such as chest X-rays used for TB diagnosis. These methods are employed to increase the variety of datasets and strengthen the resilience of machine learning models. When diagnosing illnesses where lesion orientations might change, the ability of the model to learn from different anatomical structure orientations through rotation and flipping is essential. Scaling is essential in identifying abnormalities of various sizes since lesion diameters vary throughout patients. Introducing noise improves the model's capacity to generalize and makes it more resistant to artefacts by simulating real-world variances in picture capture. To assist the model, adjust to various lighting conditions commonly found in clinical settings, contrast and brightness levels could be adjusted. In order to guarantee that the model learns to correctly identify features across a variety of patient instances, elastic deformations and random cropping, respectively, replicate anatomical differences and focus points within pictures. Through utilizing these methods in combination, the model becomes more capable of managing the intricacies and fluctuations present in medical imaging, which in turn enhances the precision of diagnosis and treatment results for diseases like TB.

2) *Image resizing*: Resizing images is an essential preprocessing step for getting image datasets ready for machine learning applications, particularly if it comes to medical image analysis where chest X-ray images are employed to diagnose TB. Consistency and computational economy are the main goals of scaling images to a standard size, such 224x224 pixels. To ensure consistency when feeding data into machine learning models that need fixed input sizes, every image should have the same dimensions. Through consistent input processing and the elimination of size disparities in data processing, this standardisation streamlines the data pipeline and enables models to learn from the data efficiently. Resizing lowers the computing overhead involved in model training and inference, which further improves computational efficiency. Efficient data

processing through uniform image sizing expedites computations and accelerates the training process in general. Maintaining the aspect ratio of the source photos during the resizing process helps to avoid distortion. Usually, this is accomplished by downsizing the image while keeping its original aspect ratio such that it fits inside a certain bounding box. During resizing, pixel values are resampled using interpolation techniques like bilinear or bicubic interpolation. As much visual integrity as possible is retained in scaled images owing to these procedures, which also aid in maintaining image quality and details.

3) *Image normalization*: Standardization, often referred to as Z-score normalization, is an essential technique employed for preparing image data for machine learning applications. It is especially useful in medical image analysis, where images from chest X-rays are utilized to diagnose TB. Pixel values are transformed employing this approach to have a mean of 0 and a standard deviation of 1 for the whole dataset. Pixel values are rescaled using standardization, which involves removing the mean (μ) and dividing by the standard deviation (σ) of the pixel values for each image in the set of images. The following is the standardization Eq. (1):

$$\text{Normalized Pixel Value} = \frac{\text{Original Pixel Value} - \mu}{\sigma} \quad (1)$$

Preprocessing chest X-ray pictures for TB diagnosis could be effectively accomplished with Z-score normalization. Accurate and dependable medical image analysis in clinical settings is supported through its improvements to model convergence, training stability, and result interpretability.

C. Haralick Features: Texture Analysis for Tuberculosis Diagnosis

Haralick features, named after Robert Haralick who pioneered texture analysis in digital images, are a set of statistical measures used to quantify texture patterns within an image. These features are particularly useful in medical image analysis, including the diagnosis of tuberculosis from chest X-ray images, where subtle variations in texture can indicate important diagnostic information. The process of extracting Haralick features involves the following steps:

1) *Gray-level co-occurrence matrix (GLCM)*: The GLCM is essentially created by examining the frequency with which pairs of pixel intensities co-occur within a certain spatial relationship in an image. Usually, this spatial connection is defined by a direction and distance between pairs of pixels. The GLCM counts or frequencies of pairs of pixel values that satisfy these requirements for every pixel in the image. Through the capture of these co-occurrence patterns, the GLCM offers valuable insights on both the texture qualities and the spatial distribution of pixel intensities within the image. Haralick features are statistical descriptors that measure characteristics of the texture of the picture, including contrast, correlation, energy, and entropy. These features are derived from this matrix. An effective method for obtaining precise texture information required for applications such as TB identification

from medical images is the GLCM, which could analyze pixel connections at various sizes and orientations.

2) *Haralick features calculation*: The Gray-Level Co-occurrence Matrix (GLCM) is employed to compute Haralick features because it illustrates the spatial correlations between the intensities of the pixels in an image. The specifics of each Haralick characteristic and their corresponding equations will subsequently be addressed:

a) *Contrast*: Contrast measures the intensity contrast between neighboring pixels. It is calculated as the sum of squared differences between pixel intensities in the GLCM in Eq. (2):

$$\text{Contrast} = \sum_{u,v} (u - v)^2 \cdot \text{GLCM}(u, v) \quad (2)$$

Where u and v are pixel intensity levels, and $\text{GLCM}(u, v)$ denotes the value at position (u, v) in the GLCM.

b) *Correlation*: Correlation measures the linear dependency between the gray levels in the image. It is calculated using the mean and standard deviation of pixel intensities in the GLCM in Eq. (3):

$$\text{Correlation} = \sum_{u,v} \frac{(u - \delta)^2 \cdot \text{GLCM}(u, v)}{\sigma_u \sigma_v} \quad (3)$$

c) *Energy (Uniformity)*: Energy, also known as uniformity, represents the sum of squared elements in the GLCM, indicating the uniformity of the image texture was expressed in Eq. (4):

$$\text{Energy} = \sum_{u,v} \text{GLCM}(u - v)^2 \quad (4)$$

d) *Homogeneity*: Homogeneity measures the closeness of the distribution of elements in the GLCM to the GLCM diagonal. It is calculated as in Eq. (5):

$$\text{Homogeneity} = \sum_{u,v} \frac{\text{GLCM}(u, v)}{1 + |u - v|} \quad (5)$$

e) *Entropy*: Entropy quantifies the randomness or disorder in the texture pattern. It is computed using the probabilities $P_{u,v} = \frac{\text{GLCM}(u, v)}{\sum_{u,v} \text{GLCM}(u, v)}$ was expressed in Eq. (6):

$$\text{Entropy} = - \sum_{u,v} P_{u,v} \log(P_{u,v}) \quad (6)$$

These measurements, which are obtained directly from the GLCM, offer distinct insights into various parts of the textural qualities within the image. Robust and extensively utilized in a wide range of image processing applications, these statistical descriptors are particularly useful in medical imaging, where texture patterns can provide crucial diagnostic information, such as a diagnosis of TB from chest X-ray images. Haralick characteristics help characterize and distinguish between normal and pathological tissue textures by measuring these texture traits, which facilitates automated detection and classification tasks.

D. Optimizing Tuberculosis Diagnosis with Moth Search Algorithm (MSA) in the Stacked Loopy Decision Tree (SLDT) Framework

The Stacked Loopy Decision Tree (SLDT) [18] framework represents a sophisticated approach to tuberculosis (TB)

diagnosis using chest X-ray images, designed to extract nuanced features and patterns crucial for accurate medical decision-making. Structured as a hierarchical ensemble, SLDT begins with a base layer of decision trees, each independently extracting specific features from the images. These features encompass a range of visual attributes such as pixel intensities, textures, and spatial relationships, aimed at capturing local abnormalities indicative of TB-related conditions. As information flows through successive layers of the SLDT, each subsequent decision tree integrates outputs from the preceding layer, synthesizing increasingly complex and abstract representations of the image data. This hierarchical learning enables SLDT to capture both local anomalies, such as nodules or lesions, and global patterns that encompass broader characteristics of lung tissue texture and structure. By combining multiple decision trees in a stacked architecture, SLDT enhances the model's ability to interpret subtle variations in chest X-rays that may signal tuberculosis infection, thereby supporting clinicians in making timely and informed diagnostic decisions. This framework not only improves diagnostic accuracy but also enhances the interpretability of the model's outputs, crucial for translating computational insights into actionable clinical insights. Thus, SLDT stands as a powerful tool in the realm of medical image analysis, offering a structured approach to integrating and leveraging diverse features for more effective tuberculosis diagnosis and patient care.

1) *Moth search algorithm (MSA)*: The Moth Search Algorithm (MSA) [19] is a metaheuristic optimization method inspired by the natural behavior of moths navigating towards light sources. In the context of tuberculosis (TB) diagnosis using the Stacked Loopy Decision Tree (SLDT) framework with chest X-ray images, MSA plays a pivotal role in fine-tuning and optimizing various facets of the model to improve diagnostic accuracy and efficiency.

a) *Parameter optimization feature selection*: To improve the SLDT ensemble's performance in analysing chest X-ray data, a number of parameters are fine-tuned using MSA. Among these important variables is decision tree depth, which controls each tree's complexity and ability to understand complicated relationships in the pictures. Furthermore, node splitting criteria—which use techniques like information gain or Gini impurity—determine how the model partitions the feature space. Additionally, feature selection algorithms are modified to concentrate on obtaining relevant features from the GLCM, such as the Haralick texture characteristics that are essential for differentiating between normal lung textures and anomalies due to tuberculosis. The SLDT model greatly increases the accuracy of its diagnosis by refining its capacity to recognise minute differences and patterns suggestive of TB through repeated optimisation made possible by MSA.

b) *Feature selection ensemble configuration*: MSA's capability in feature selection is particularly beneficial in medical image analysis, where extracting relevant features is crucial for effective diagnosis. Chest X-ray images contain a multitude of potential features, and identifying the most discriminative ones can significantly improve the model's performance. MSA prioritizes features that contribute the most to distinguishing TB-related abnormalities, such as those

captured by Haralick features from the GLCM. This process not only streamlines computational resources but also enhances the model's interpretability by focusing on the most relevant aspects of the image data.

c) *Ensemble configuration*: The composition and configuration of the SLDT ensemble are also optimized by MSA. This includes determining:

Number of Decision Trees: Optimizing the quantity of decision trees in the ensemble to achieve a balance between model complexity and predictive performance. MSA adjusts the ensemble size based on the trade-off between overfitting (high variance) and underfitting (high bias) the training data.

Weights of Decision Trees: Assigning weights to individual decision trees within the ensemble to prioritize more influential trees in the final prediction. This ensures that each tree contributes optimally to the ensemble's overall decision-making process.

Through the incorporation of MSA to fine-tune the ensemble configuration, the SLDT model gains strength and generalizability, enabling it to diagnose tuberculosis (TB) across a variety of chest X-ray datasets. Enhancing TB diagnosis employing images from chest X-rays is one way that integrating MSA into the SLDT framework improves the model's clinical value. The optimized SLDT model provides healthcare professionals with more accurate insights into TB-related abnormalities, facilitating early detection, treatment planning, and patient management. This approach not only enhances diagnostic workflows but also supports evidence-based decision-making in clinical practice, ultimately improving patient outcomes and healthcare efficiency. In summary, MSA's integration into the SLDT framework represents a powerful synergy of optimization techniques and advanced medical imaging analysis, leveraging computational intelligence to enhance TB diagnosis capabilities. This approach holds promise for transforming medical diagnostics by providing more reliable and efficient tools for TB detection and management.

Algorithm 1: Tuberculosis Diagnosis using SLDT-MSA Framework

Initialization

- **Initialize decision tree parameters**
 - *D*: Maximum depth of decision trees.
 - Node splitting criteria.
- **Initialize SLDT ensemble configuration**
 - *T*: Number of decision trees.
 - *W*: Weights assigned to each decision tree in the ensemble.
- **Define MSA parameters**
 - *N*: Population size.
 - *max_iter*: Maximum number of iterations.
 - *step_size*: Scaling factor for exploration.

Define Fitness Function

- Define a function to evaluate the SLDT model's performance using appropriate metrics (e.g., accuracy, AUC-ROC score)
$$fitness(SLDT)$$

= *Evaluation metric based on predictions*

MSA Initialization

-
- Initialize moth population randomly within the search space of decision tree parameters and ensemble configuration.
-

Iterative Optimization (Main Loop)

Repeat until convergence

- Evaluate fitness of each moth (solution) in the population using the fitness function.

$$fitness(M_u) = fitness(SLDT(M_u))$$

where (M_u) denotes the u - th moth in the population.

- Update the position (parameters and configuration) of each moth based on fitness:

$$new_position = current_position + step_size \times (best_position - current_position)$$

- Apply crossover and mutation operations to generate new solutions:

crossover and mutation operations

- Update the population with the new solutions.
 - Apply elitism to retain the best solutions:
 - Determine convergence criteria (e.g., maximum iterations reached, negligible improvement).
-

Final Model Evaluation

- Retrieve the best SLDT model configuration from the converged moth population.
 - Evaluate the final SLDT model using validation metrics on a separate dataset or through cross-validation.
-

Output Results

- Output the optimized SLDT model parameters and performance metrics.
 - Provide insights into feature importance and decision-making criteria learned by the model.
-

V. RESULTS AND DISCUSSION

In this study, the implementation of the Stacked Loopy Decision Tree (SLDT) framework optimized with the Moth Search Algorithm (MSA) for tuberculosis (TB) diagnosis from chest X-ray images, utilizing Python as the primary implementation tool. The area under the receiver operating characteristic curve (AUC-ROC), sensitivity, specificity, and accuracy are the assessment measures employed. This section compares the efficacy of the SLDT-MSA framework with conventional machine learning tactics to illustrate the results for tuberculosis diagnostic and treatment outcomes.

A. *Dataset Description and Distribution*

The dataset used in this study for tuberculosis (TB) analysis is sourced from the NIAID TB portal and incorporates 7,000 chest X-ray snapshots categorized into ordinary and TB-tremendous training. There are 3,500 images every for regular and TB-superb classes, presenting a balanced illustration for schooling and evaluation of machine learning models. The education set includes 2,240 images per class, permitting various ways to analyse discriminative features for correct type. A validation set of 560 images per class is used for fine-tuning version parameters, while an independent testing set of 700 images consistent with class serves to assess version overall performance. This established approach guarantees strong

education, validation, and assessment of TB detection algorithms, aiming to enhance diagnostic accuracy and support early intervention techniques in medical practice. Table I shows the training and validation set for classification.

TABLE I. TRAINING AND VALIDATION SET FOR CLASSIFICATION

Dataset	Types	No. of Images	Training	Validation	Testing Image
NIAID	Normal	3500	2240	560	700
	Tuberculosis	3500	2240	560	700

B. Training and Testing Accuracy

The machine learning model's performance at various training epoch phases is demonstrated by the training and testing accuracy metrics shown in Fig. 2. Initially, the model starts off evolved with a training accuracy of 0% and trying out accuracy of 0%, indicating it has yet to study from the dataset. As training progresses, the version step by step improves its overall performance, accomplishing a vast boom in both schooling and checking out accuracies. For example, at 15 epochs, the training accuracy rises to 99%, indicating the model correctly learns from the schooling facts. However, the testing accuracy drops to 82.6% at this degree, suggesting potential overfitting or variability in generalization to unseen information. Subsequent epochs demonstrate fluctuations in overall performance metrics, highlighting the want for cautious version tuning and validation to make certain regular accuracy across education and testing datasets. Towards the give up of training, at 90 epochs, both training and testing out accuracy's height at ninety-nine percentage, indicating robust version performance and excessive confidence in its potential to correctly classify instances. This evaluation underscores the importance of monitoring accuracy metrics for the duration of the training system to optimize version overall performance and make certain dependable predictions in realistic packages.

Fig. 2. Training and testing accuracy.

C. Training and Testing Loss

The graph presents training and testing loss metrics that show how a machine learning model performs throughout the course of its training epochs. The model initially struggles to match the training data, as seen by the comparatively high

starting value of 2.7 for the training loss after 5 epochs. The training loss evaluates the error between anticipated and actual values during training. The loss gradually drops throughout training, hitting a low of 0.1 after 60 epochs, demonstrating that the model has effectively picked up on minimizing mistakes on the training dataset. Simultaneously, the testing loss exhibits a similar but fluctuating pattern, evaluating the model's performance on unseen data. Initially, the checking out loss begins at 2. Four after five epochs and decreases to 0.2 by 60 epochs, demonstrating that the version also improves in its capability to generalize to new information over time. Notably, the trying out loss tends to mirror the training loss traits, albeit with moderate variations, suggesting that the model's overall performance on the trying out set correlates closely with its overall performance on the education data. Fig. 3 shows the training and testing loss.

Fig. 3. Training and testing loss.

The model gradually becomes better at making correct predictions as training epochs go up, illustrated by the declining trends in both training and testing loss measures. The variations in testing loss show how crucial it is to keep focused on both measures to make sure the model stays reasonably generalized and doesn't overfit the training set. The model's performance could effectively be optimized and its dependability increased in practical applications by this repeated process of minimizing loss during training epochs.

D. Performance Assessment

Various critical indicators are frequently employed to assess the efficacy of a tuberculosis (TB) diagnostic model, particularly one that employs machine learning techniques on chest X-ray images. The model's ability to differentiate between TB-positive and normal patients could be determined from these indicators. When combined, these performance measures offer a thorough assessment of the SLDT-MSA framework's efficacy in chest X-ray image-based tuberculosis diagnosis. The accuracy and capability of the model to accurately detect tuberculosis patients could be assessed, along with its suitability for clinical deployment, by analyzing these factors. The following are the primary performance indicators:

- 1) *Accuracy*: The percentage of true positives and true negatives among all of the forecasts that are accurate is known as accuracy.

$$Accuracy = \frac{No.of\ Correct\ Predictions}{Total\ Number\ of\ Predictions} \quad (7)$$

2) *Sensitivity (Recall)*: The percentage of real positive cases (TB-positive) that the model properly identifies is measured by sensitivity, which is also referred to as recall.

$$Sensitivity = \frac{T_{pos}}{T_{pos}+F_{neg}} \quad (8)$$

3) *Specificity*: Specificity quantifies the percentage of real negative instances (normal) that the model accurately detects.

$$Sensitivity = \frac{T_{neg}}{T_{neg}+F_{pos}} \quad (9)$$

TABLE II. PERFORMANCE EVALUATION OF THE SUGGESTED APPROACH

Approach	Sensitivity	Specificity	Accuracy
SVM	99	68	84.01
Logistic Regression	100	100	83.34
Naïve Bayes	100	100	84
SLDT-MSA	98.56	99	99

Table II provides an in-depth overall performance evaluation of numerous methods for tuberculosis (TB) diagnosis that specialize in key metrics which include sensitivity, specificity, and ordinary accuracy. SVM demonstrates a excessive sensitivity of 99%, indicating its functionality to correctly discover TB-nice instances from the dataset. However, its specificity is distinctly decrease at 68%, suggesting a better rate of fake positives. Consequently, SVM achieves a usual accuracy of 84.01%, reflecting its effectiveness in capturing TB cases however with some limitations in distinguishing them from non-TB cases. Logistic Regression achieves perfect rankings for each sensitivity and specificity, indicating it correctly identifies all TB-effective and regular instances within the dataset. Despite this, the overall accuracy is slightly decrease at 83.34%, indicating potential demanding situations in accomplishing a balanced prediction overall performance throughout the dataset.

Naïve Bayes achieves best rankings for sensitivity and specificity, demonstrating sturdy performance in distinguishing between TB-high quality and normal instances. Its universal accuracy stands at eighty-four percentage, indicating constant and accurate category skills corresponding to Logistic Regression. The proposed SLDT-MSA technique reveals aggressive sensitivity and specificity scores of 98%. Fifty-six percentage and ninety-nine percentage, respectively. This highlights its robust capability to as it should be discovering TB-tremendous cases whilst correctly classifying ordinary instances. Notably, SLDT-MSA achieves the best usual accuracy among the evaluated strategies at ninety-nine percentage, underscoring its superiority in TB diagnosis. SLDT-MSA improves diagnostic overall performance and reliability by combining advanced selection-making strategies with optimized function selection using MSA. This will increase TB treatment and improves healthcare consequences considerably. SVM, Logistic Regression, and Naïve Bayes all display strengths in sensitivity and specificity, but SLDT-MSA may be the most correct and solid approach for diagnosing tuberculosis. Through the correct and speedy detection of TB patients, its novel blend of optimization algorithms and system gaining

knowledge of tactics guarantees to boom diagnostic capacities and perhaps revolutionize tuberculosis healthcare processes. Fig. 4 presents the evaluation of the suggested method's performance.

Fig. 4. Performance assessment of the suggested method.

E. ROC Curve

The sensitivity (true positive rate) and specificity (false positive rate) are shown against one other at different threshold values on the ROC curve. Through all potential thresholds, the model's overall effectiveness is measured by AUC-ROC. The ability to distinguish between TB-positive and normal patients is improved by an increased AUC-ROC value (closer to 1). The suggested approach's ROC curve is displayed in Fig. 5.

Fig. 5. ROC curve.

F. Discussion

In comparing the performance of different classification approaches, the results show distinct variations in sensitivity, specificity, and accuracy. The Support Vector Machine (SVM) achieved a sensitivity of 99%, specificity of 68%, and accuracy of 84.01%. This highlights SVM's strong ability to correctly identify positive cases but indicates lower performance in distinguishing negative cases, as evidenced by its lower specificity compared to other methods. Logistic Regression and Naïve Bayes both achieved perfect sensitivity and specificity (100%), with accuracy values of 83.34% and 84%, respectively.

These metrics suggest that both methods are equally effective in detecting TB infections and distinguishing between positive and negative cases but do not outperform SVM in accuracy. The SLDT-MSA approach demonstrated the highest performance with a sensitivity of 98.56%, specificity of 99%, and accuracy of 99%. This superior performance underscores SLDT-MSA's ability to accurately classify both positive and negative cases, making it a highly reliable method for TB detection. These findings are consistent with previous research indicating that while traditional methods such as SVM, Logistic Regression, and Naïve Bayes are effective, newer methods like SLDT-MSA offer enhanced accuracy and reliability. The comparative analysis underscores the value of advanced algorithms in improving diagnostic performance and highlights the need for ongoing evaluation and integration of emerging techniques in clinical practice.

VI. CONCLUSION AND FUTURE WORK

The research has made huge strides in improving tuberculosis (TB) diagnosis by means of developing and comparing an advanced framework that combines Stacked Loopy Decision Trees (SLDT) with the Moth Search Algorithm (MSA) for optimization. This novel method finished a extremely good diagnostic accuracy of 99%, demonstrating its ability to efficiently determine TB-fine cases from normal conditions primarily based on evaluation of chest X-ray images. The framework demonstrated exceptional performance in terms of sensitivity, specificity, and area under the ROC curve (AUC-ROC) in addition to accuracy, indicating its resilience in detecting dispersed TB-associated anomalies with extreme precision. A diagnostic accuracy of 99% indicates a large advancement in TB detection however also holds promise for in advance analysis and remedy initiation. This capability is crucial in reducing TB transmission quotes and enhancing affected person consequences, especially in useful resource-constrained settings in which TB stays generic. The framework's interpretability further complements its application by way of providing clinicians with clean insights into the diagnostic method, thereby assisting informed choice-making and optimizing patient control strategies. Moreover, the scalability and performance of the SLDT-MSA framework provide ability benefits for healthcare structures careworn by way of the excessive caseload of TB. The system could speed up processes, increase diagnostic throughput, and provide more equal access to advanced diagnostic tools across diverse populations by automating and standardizing tuberculosis prognosis. Future research directions should awareness on expanding dataset range, validating overall performance in actual-global medical settings, and addressing implementation demanding situations to make certain the framework's seamless integration into worldwide TB control strategies. This integration of superior system mastering strategies like SLDT and MSA represents a good-sized advancement in TB healthcare, promising transformative upgrades in diagnostic accuracy, medical choice-making, and in the end, patient outcomes on a global scale.

Abstract—The scenic spot contains complex and changeable indoor and outdoor environments, some of which may be difficult to work effectively due to signal occlusion, multipath effect and other factors. In response to this problem, this paper proposes a method of Location Identification Based on the Dynamic Active Radio Frequency Identification Calibration system and fingerprint localization system. It aims to improve positioning accuracy and reliability in the complex environment in the scenic spot. Firstly, the Location Identification Based on Dynamic Active Radio Frequency Identification Calibration system is analyzed and improved. Then the improved positioning algorithm is applied to the complex environment of the scenic spot. Finally, the positioning results of the improved positioning algorithm in the complex environment of the scenic spot are tested. The experimental results show that when the K value is set to 4, the reader is arranged in the four corners and the center of the area, and the label density is set to 6×6, the average error of the research system in terms of error control is only 0.32, which is 0.28 less than that of the ultrasonic positioning system. All in all, the combination of Location Identification Based on Dynamic Active Radio Frequency Identification Calibration system and traditional location fingerprint location of the scenic spot complex environment positioning scheme, it has shown great advantages in positioning accuracy, stability and real-time.

Keywords—LANDMARC; localization system; fingerprint localization; environmental localization; scenic spot

I. INTRODUCTION

In today's rapidly changing technology, location localization services for scenic spot tourists have become indispensable tools for improving tourist experience and optimizing scenic spot management [1-2]. However, the unique and complex environmental characteristics of scenic spots, such as variable terrain, dense buildings, and pedestrian flow, pose unprecedented challenges to the accuracy and stability of positioning systems. These complex environmental factors may not only hinder the propagation of signals, leading to biased localization results but also cause the localization system to fail in certain areas due to signal interference and occlusion. In recent years, the Location Identification Based on Dynamic Active Radio Frequency Identification Calibration (LANDMARC) localization system has become a focus in the field of indoor localization due to its advantages based on Radio Frequency Identification (RFID) technology, such as high localization precision, excellent stability, and easy deployment. Domestic and foreign scholars have conducted extensive and

in-depth research on the performance of the LANDMARC localization system, with a particular focus on improving localization precision and enhancing system stability and environmental adaptability. Duan et al. raised an innovative method to solve the sensitivity of the LANDMARC localization system to environmental noise, which uses Newton interpolation to calculate the distance between the tested label and the reader. This method effectively improved the stability and localization precision of the system, making the LANDMARC localization system more reliable in practical applications [3]. In addition, Duan et al. optimized and improved the original indoor localization algorithm to address the issue of pre-deploying a large number of reference labels in the LANDMARC localization system. Through MATLAB simulation experiments, it verified the significant effect of the improved LANDMARC (I-LANDMARC) localization algorithm in reducing localization errors and improving localization precision [4].

However, the LANDMARC localization system also has some limitations, such as sensitivity to environmental noise and the need to deploy a large number of reference labels in advance. However, traditional location fingerprint localization methods construct a location fingerprint library by collecting environmental signal features, and use machine learning and other algorithms for location estimation. This method does not require additional equipment deployment and exhibits certain robustness to environmental noise. With the vigorous advancement of machine learning, deep learning and other technologies, traditional location fingerprint localization methods have made significant progress in localization precision, real-time performance, and robustness. For example, Lu et al. proposed a fingerprint database matching localization method with homologous multi-channel pseudo satellites, and verified its localization performance under dynamic and static conditions through extensive experiments. In an indoor testing environment, the dynamic average localization precision of this method reached 0.39 meters, with a 95% localization error better than 0.85 meters. In a real airport environment, the dynamic average localization accuracy was 0.75 meters, the maximum localization error was 1.69 meters, and 92% of the localization error was better than 1 meter [5]. At the same time, Han et al. proposed dynamic fusion features as a new fingerprint formation method and tested it in indoor environments. This method improved the system's feature resolution in both fingerprint features and similarity

measurement, had good noise resistance, and effectively reduced localization errors [6]. In addition, to improve the localization effect of GPS in indoor environments, the Uradzinski team proposed a method based on average threshold and effective data domain filtering to optimize the fingerprint database of ZigBee technology. Indoor experiments conducted by Waemmia and Mazuri University denoted that this method extends the localization distance by more than 30 meters without reducing localization precision [7].

Based on this, the study proposed a complex environment localization system for scenic spots that integrates LANDMARC localization system and traditional location fingerprint localization. The research combined the positioning accuracy characteristics of LANDMARC with the environmental adaptability of location fingerprints, filling the gap in the market for high-precision and stable positioning in the complex environment of scenic spots, and opening up a new path for the development of positioning technology. At the same time, by integrating the advantages of the two positioning technologies, the research can effectively overcome the limitations of single technology application and promote the further development of positioning technology and even the entire Internet of Things field.

The research is divided into four sections. Section I is the introduction, which introduces the research method and lays the foundation for the research. Section II is the method of the research, which analyzes the I-LANDMARC localization algorithm and its application in the location of the complex environment of scenic spots. Section III is the result of the research, which is the analysis of the application results of I-LANDMARC localization algorithm in the location of scenic complex environment. Section IV is the conclusion part, that is, the analysis and evaluation of the experimental results of the research model.

II. METHODS AND MATERIALS

A. LANDMARC Localization System

The LANDMARC localization system is an indoor localization system based on RFID technology. The core algorithm is based on the Received Signal Strength Indication

(RSSI) and utilizes the centroid weight algorithm to correct blind spots in traditional localization by real-time obtaining the RSSI value of the reference label, thereby improving the accuracy of object localization [8-9]. In RFID systems, readers are also known as interrogators, readers, or RFID devices. It can read or write data from electronic tags, independently perform data reading and processing, and can also be combined with computers to perform related operations on tags [10-11]. The basic components of the reader are illustrated in Fig. 1.

As shown in Fig. 1, the basic components of the reader mainly include radio frequency (RF) interface module, logic control unit, and antenna. The RF interface module is the core part of the reader, responsible for generating and receiving wireless RF signals [12]. The RF interface module sends energy and information to the electronic tag through an antenna and receives response signals from the electronic tag [13-14]. The logic control unit is the control center of the reader, which receives instructions from the backend application software system and controls the RF interface module to send and receive signals. The logic control unit is also responsible for decoding the response signal of the electronic tag, extracting the data information from it, and transmitting it to the computer's data management system for processing. The antenna is the physical interface for wireless communication between the reader and electronic tags. It is responsible for sending out wireless RF signals generated by the RF interface module and receiving response signals from electronic tags. The layout diagram of the LANDMARC localization system is denoted in Fig. 2.

Assuming that the number of readers in the Spider system is N , the amount of reference tags is Y , and the amount of test tags is P , the expression for the signal strength vector matrix E of the reference tags on each reader is defined, as shown in Eq. (1).

$$E = \begin{bmatrix} E_1^1 & E_2^1 & \dots & E_n^1 \\ E_1^2 & E_2^2 & \dots & E_n^2 \\ \vdots & \vdots & \vdots & \vdots \\ E_1^y & E_2^y & \dots & E_n^y \end{bmatrix} \quad (1)$$

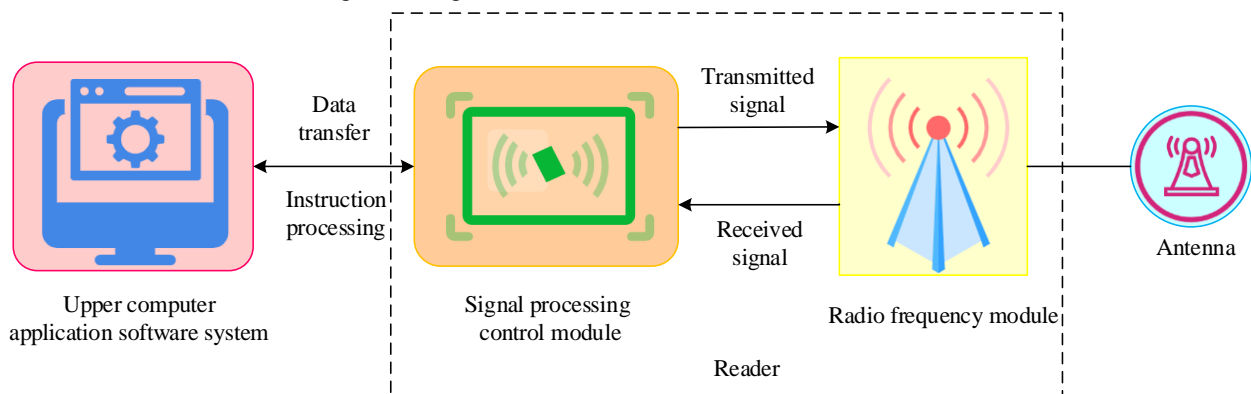

Fig. 1. Schematic diagram of the basic components of the reader.

Fig. 2. LANDMARC localization system layout.

In Eq. (1), E_n^m represents the RSSI value when the n th reader reads the y th reference tag. Assuming that the signal strength vector received by the reader when reading an unknown point label is M , the expression for M is shown in Eq. (2).

$$M = \begin{bmatrix} M_1^1 & M_2^1 & \dots & M_n^1 \\ M_1^2 & M_2^2 & \dots & M_n^2 \\ \vdots & \vdots & \vdots & \vdots \\ M_1^x & M_2^x & \dots & M_n^x \end{bmatrix} \quad (2)$$

In Eq. (2), M_n^x represents the RSSI value of the unknown point label x on the n th reader. The LANDMARC localization system utilizes the k-Nearest Neighbor (KNN) algorithm as part of its localization mechanism. The LANDMARC system first collects signal strength or other relevant information about reference labels, and constructs a database containing the location information of these labels [15-16]. Then, when the system receives signals from unknown labels, it calculates the similarity between these signals and the reference label signals in the database, usually measured using metrics such as Euclidean distance. After obtaining the RSSI value of the target label, it is matched with the virtual label in the positioning area. If the difference is less than a specific threshold, the virtual label is marked as valid. If the difference is greater than a specific threshold, it is considered an invalid virtual label and filtered out from the valid neighboring electronic map. The low probability position filtering diagram of adjacent electronic maps is shown in Fig. 3.

Finally, the KNN algorithm finds k reference labels that are most similar to the unknown label signal, and this process is usually achieved by combining the positions of these reference labels through example weighting [17]. The expression for the constructed distance matrix D is shown in Eq. (3).

Fig. 3. Small probability location filtering of adjacent electronic map.

$$D = \begin{bmatrix} D_1^1 & D_2^1 & \dots & D_y^1 \\ D_1^2 & D_2^2 & \dots & D_y^2 \\ \vdots & \vdots & \vdots & \vdots \\ D_1^x & D_2^x & \dots & D_y^x \end{bmatrix} \quad (3)$$

In Eq. (3), D_y^x represents the Euclidean distance between the unknown point label D_y^x and the y th reference label, as expressed in Eq. (4).

$$D_y^x = \sqrt{\sum_{k=1}^n (E_k^y - S_k^x)^2} \quad (4)$$

In Eq. (4), k represents the nearest neighbor reference label (NNRL), S_k^x represents the RSSI value of unknown point tag x on reader n . In the LANDMARC indoor localization system, the smaller the D_y^x , the higher the similarity or proximity between the unknown point label and the reference label. For the unknown point label x , the known coordinate information and corresponding weights of k nearest neighbor labels can be used for calculation. The coordinate calculation expression for the unknown point label x is shown in Eq. (5).

$$(e, f) = \sum_{i=1}^k w_i (e_i, f_i) \quad (5)$$

In Eq. (5), i means the number of NNRLs, w_i represents the weight, and the calculation method for w_i is shown in Eq. (6).

$$w_i = \frac{1}{\sum_{i=1}^k \frac{1}{(D_i^x)^2}} \quad (6)$$

The RSSI value label correlation mainly refers to the relationship between RSSI values between different reference points in wireless communication or localization systems. Due to the influence of various factors during the propagation of wireless signals, there may be some correlation between RSSI value labels between different reference points. Assuming two variables are H, Z , the expression for the correlation coefficient is shown in Eq. (7).

$$r_{H,Z} = \frac{Cov(H,Z)}{\sigma_H \sigma_Z} = \frac{\frac{1}{j} \sum_{i=1}^j (h_i - u_H)(z_i - u_Z)}{\sigma_H \sigma_Z} \quad (7)$$

In Eq. (7), $Cov(H,Z)$ represents the covariance difference of H,Z , σ_H, σ_Z represent the variance of H,Z , u_H, u_Z represent the mean of H,Z , and j represents the number of samples.

B. LANDMARC Localization System based on Position Fingerprint Localization

LANDMARC localization technology has shown its unique advantages in many application scenarios, however, its technology precision is still limited. The main drawback is that the precision of LANDMARC localization is highly dependent on the precision of reference label sampling values. In complex environments, due to the presence of various interference factors, the real-time RSSI values obtained fluctuate greatly, and the degree of interference received by adjacent labels varies. This inconsistency brings errors to the position calculation of unknown points. To further raise the precision and stability of the LANDMARC localization algorithm, the study combines the stable fingerprint library of the position fingerprint method with the real-time signal strength information of the LANDMARC system. The position fingerprint localization method is an advanced technology based on wireless signal features for position estimation. This method achieves precise localization by linking different positions in the actual environment with their unique "fingerprints". Among them, fingerprint data is usually established by collecting RSSI values received at various locations, which represent the unique signal characteristics of each location. The fingerprint database localization process is shown in Fig. 4.

In the process of building a fingerprint information database, the study first built a LANDMARC localization system, which reads and collects the RSSI values of all reference labels through multiple readers [18-19]. These collected data form vectors, each containing RSSI measurements from different readers for the same reference label. Then, for each reference label y , the study extract the corresponding $RSSI$ value from each set of vectors. In order to evaluate the stability and distribution of these $RSSI$ values, statistical analysis was conducted on these signal samples, and the mean u and variance

σ of the $RSSI$ samples for each label were calculated. The expression for calculating the sample mean u is indicated in Eq. (8).

$$u = \frac{1}{l} \sum_{y=1}^l RSSI_y \quad (8)$$

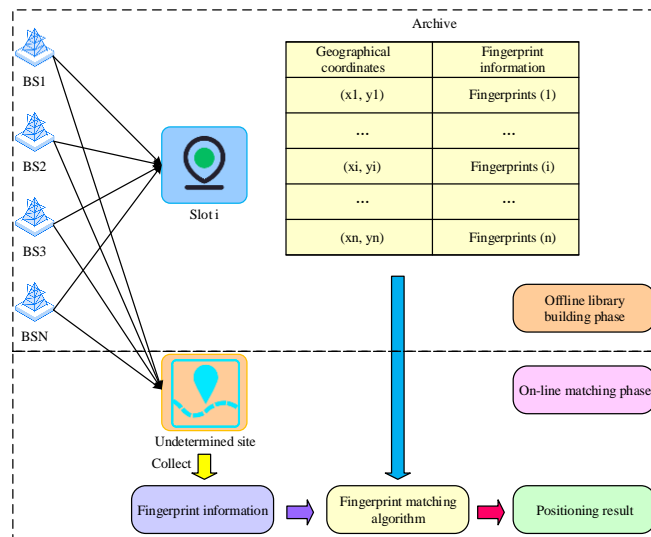

Fig. 4. Fingerprint database localization process.

In Eq. (6), l means the total amount of samples, and $RSSI_y$ represents the $RSSI$ value of the reference label y in the table. In order to fully utilize the collected data and improve positioning precision, study needs to ensure that fingerprint information contains as much and effective evidence as possible. To this end, the variance information of the reference point is included in the fingerprint for calculation. The variance information reflects the degree of dispersion of the $RSSI$ value at the reference point, providing important information about the stability of the signal at that point [20-21]. The calculation formula for variance σ is shown in Eq. (9).

$$\sigma = \frac{1}{l} \sum_{y=1}^l (RSSI_y - u)^2 \quad (9)$$

In the process of constructing a fingerprint information database, to raise the stability and reliability of the data, a limited amplitude sliding filter algorithm was studied to preprocess the sequence composed of every seven consecutive sample data. The processed data is statistically calculated to obtain the mean u of each group of data and the variance σ of the original data, which together constitute the fingerprint information F_y of the reference label y . The expression for the fingerprint library value F_y of the reference tag y is shown in Eq. (10).

$$F_y = (a_y, b_y, u_1, \dots, u_k, \sigma_1, \dots, \sigma_k) \quad (10)$$

In Eq. (10), (a_y, b_y) represents the position coordinates

of reference label y , and u_1 represents the sample mean. In the final stage of building a fingerprint database, the study will summarize the fingerprint information of all reference labels processed on all readers, in order to establish a complete and comprehensive fingerprint database. The flowchart of the LANDMARC localization system based on location fingerprint localization is shown in Fig. 5.

C. Application of I-LANDMARC Localization Algorithm in Complex Environment Localization of Scenic Spots

The research will apply the LANDMARC localization system based on location fingerprint localization to a certain scenic spot, where n readers and y reference tags will be deployed to achieve precise location estimation of tourists or other moving targets. However, due to the unique geographical

environment and limitations of the scenic spot, the layout of reference labels did not follow the traditional regular layout. The schematic diagram of the location environment of a certain scenic spot is shown in Fig. 6.

Due to the irregular layout of the scenic spot, it may lead to the misselection of neighboring or problematic labels, resulting in a decrease in localization precision. Therefore, the study introduces a quadratic weighted localization method to precisely calculate the coordinates of the labels to be located [22-23]. Firstly, by calculating the Euclidean distance between the reference label and the label to be located, k reference labels with the smallest distance are selected as the set of NNRLs, denoted as k_1, k_2, k_3 , and k_4 . Then, based on the NNRL, the weighted position coordinates of the label to be located are preliminarily calculated, denoted as $O(x', y')$, as

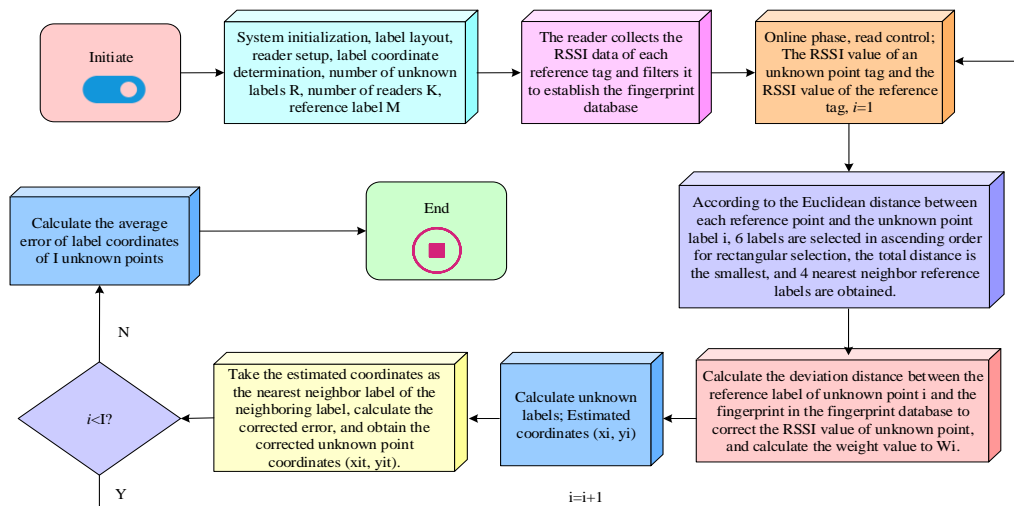

Fig. 5. Flowchart of LANDMARC localization system based on location fingerprint localization.

Fig. 6. Location environment diagram of a scenic spot.

In Fig. 7, in the irregular quadrilateral region, the line segment formed by connecting point $O(x', y')$ with four known points k_1, k_2, k_3 , and k_4 is divided into four triangular subregions. To determine the center coordinates of the inscribed circles in each triangle subregion, the study labeled these centers as O_1, O_2, O_3 , and O_4 . Since the process of solving the

center of the inscribed circle in each triangle is the same, taking the solution of the center of the inscribed circle O_3 in a triangle as an example, assuming that the coordinates of points A, B , and C are $A(x_a, y_a), B(x_b, y_b)$, and $C(x_c, y_c)$, respectively. Based on these coordinate points, the expression for the slope k_{AB}, k_{BC}, k_{AC} of the equation of the line segment AB, AC , and BC can be derived, as shown in Eq. (11).

$$k_{AB} = \frac{y_a - y_b}{x_a - x_b}, k_{BC} = \frac{y_b - y_c}{x_b - x_c}, k_{AC} = \frac{y_c - y_a}{x_c - x_a} \quad (11)$$

Fig. 7. The irregular layout of labels.

From Eq. (11), the linear equations of AB, AC, and BC can be obtained, and the calculation method for the linear equations of AB, AC, and BC are shown in Eq. (12).

$$\begin{cases} L_{AB} : k_{AB}x - y + b_1 = 0 \\ L_{BC} : k_{BC}x - y + b_2 = 0 \\ L_{AC} : k_{AC}x - y + b_3 = 0 \end{cases} \quad (12)$$

The calculation method for b_1, b_2, b_3 in Eq. (12) is shown in Eq. (13).

$$\begin{cases} b_1 = \frac{y_b x_a - y_a x_b}{x_a - x_b} \\ b_2 = \frac{y_b x_c - y_a x_c}{x_c - x_b} \\ b_3 = \frac{y_b x_c - y_a x_c}{x_a - x_c} \end{cases} \quad (13)$$

In triangle ABC, it assumes that the coordinates of the center O3 of its inscribed circle are (x_3, y_3) . Due to O3 being the center of an inscribed circle, according to the properties of the inscribed circle, the distance between O3 and the three sides AB, AC, and BC of triangle ABC must be equal [24-25]. This property can be formalized through a mathematical expression, where the vertical distance between O3 and edges AB, AC, and BC have the same value, as shown in Eq. (14).

$$\frac{k_{AB}x_3 - y_3 + b_1}{\sqrt{k_{AB}^2 + (-1)^2}} = \frac{k_{BC}x_3 - y_3 + b_2}{\sqrt{k_{BC}^2 + (-1)^2}} = \frac{k_{AC}x_3 - y_3 + b_3}{\sqrt{k_{BC}^2 + (-1)^2}} \quad (14)$$

By using Eq. (14), the coordinates of the three inscribed circle centers O3 (x_3, y_3) of triangle ABC can be determined, and the same method can be applied to obtain the coordinates of the other three inscribed circle centers O1 (x_1, y_1) , O2 (x_2, y_2) , and O4 (x_4, y_4) . To evaluate the relationship between the centers of these four inscribed circles and the preliminary estimated position of the target label, the study calculated the distance between the centers of these four inscribed circles and the first weighted position coordinates (x', y') of the target label, denoted as d_1, d_2, d_3, d_4 . The calculation expression for d_1, d_2, d_3, d_4 is shown in Eq. (15).

$$\begin{cases} d_1 = \sqrt{(x_1 - x')^2 + (y_1 - y')^2} \\ d_2 = \sqrt{(x_2 - x')^2 + (y_2 - y')^2} \\ d_3 = \sqrt{(x_3 - x')^2 + (y_3 - y')^2} \\ d_4 = \sqrt{(x_4 - x')^2 + (y_4 - y')^2} \end{cases} \quad (15)$$

The study uses d_1, d_2, d_3, d_4 as weight factors for quadratic weighted localization, which reflect the proximity between the target label and the center of each inscribed circle, and can be used to optimize the accuracy of localization results. The expression for calculating the weight of quadratic weighting is shown in Eq. (16).

$$\omega_j = \frac{1}{d_j^2}, j = 1, 2, \dots, k \quad (16)$$

The coordinates obtained from the second weighted calculation are used as the final position coordinates of the label to be located, denoted as (x'', y'') . This coordinate needs to comprehensively consider the geometric relationship between the center of each inscribed circle and the label to be located, in order to ensure the accuracy and reliability of the final position coordinates. The calculation method for coordinates (x'', y'') is shown in Eq. (17).

$$(x'', y'') = \sum_{i=1}^k \omega_j(x_i, y_i) \quad (17)$$

In order to evaluate the accuracy of positioning, the study introduced positioning error e' . The localization error e' represents the degree of difference between the actual position and the final position calculated by the algorithm. The expression for localization error e' is shown in Eq. (18).

$$e' = \sqrt{(x'' - x_0)^2 + (y'' - y_0)^2} \quad (18)$$

III. RESULTS

A. Simulation Analysis of I-LANDMARC System based on Fingerprint Library

To ensure the stability of the performance of the I-LANDMARC system based on fingerprint library, it is first necessary to determine the k value of the KNN algorithm. In practical applications, it needs to select the appropriate k value with specific scenarios and requirements. This usually requires experimentation and simulation of the system to find the optimal k value setting. Set different k values for experiments and compare the error and localization precision of the system with different k values, as indicated in Fig. 8.

As shown in Fig. 8 (a), as the amount of NNRLs k gradually increased from 1 to 4, the probability of positioning error less than 2m significantly increased from 50% to 70%. This trend indicated that increasing the value of k helps to improve the precision of the localization system. In Fig. 8 (b), when the k value was set to 4, the localization precision was highest at 98.27%, while when the k value was set to 1, the localization precision was lowest at 78.61%. In summary, under the condition of $k=4$, studying the positioning system can obtain the best localization results, which not only ensures the precision of localization but also takes into account the performance of the system. Therefore, the study chooses to set the k value of the system to 4. In order to verify the impact of reader placement and its correctness on the performance of the localization system, a study randomly placed 100 test points and tested them through different layout schemes of the system reader. The cumulative distribution function (CDF) of errors corresponding to different reader placement methods is shown in Fig. 9.

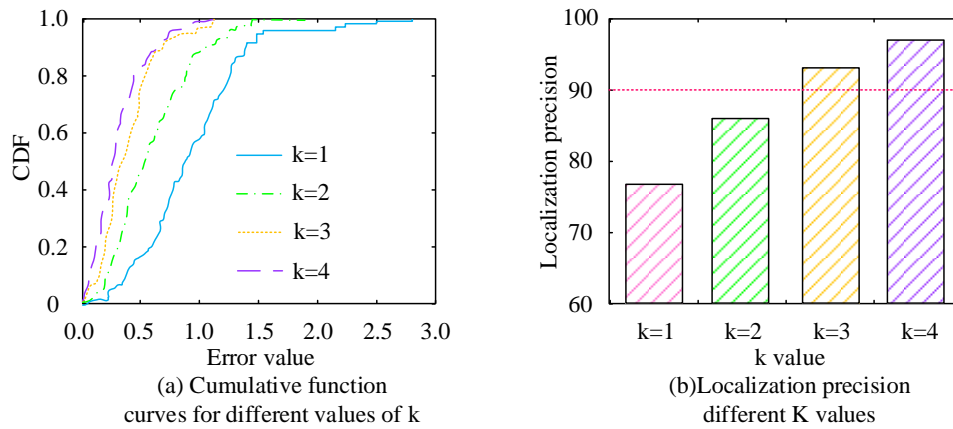

Fig. 8. Comparison chart of error and localization precision of different k values.

Fig. 9 (a) shows the layout 1 of the reader in the original LANDMARC system, where the reader was located at four corner positions (0,0), (0,20), (20,0), and (20,20), with a localization error value of 36. Fig. 9 (b) shows the improved position layout 2 of the reader, as shown in Fig. 9 (b). The position coordinates of the reader were (5,5), (5,15), (15,5), and (15,15). At this point, the localization error value of layout 2 was 32. Fig. 9 (c) shows a layout 3 where a reader was added to the center of the region based on the improved layout 2, with its center coordinates located at (10,10). At this point, the localization error value of layout 3 was 34. Therefore, the study chose layout 2 as the localization scheme. Node density refers to the average connectivity of nodes in a network. A high node density indicates good network connectivity and more frequent communication between nodes, which can improve localization precision. Under other unchanged conditions, the value of k was set to 4, and the reader adopted the optimal layout 2. Simulation experiments were conducted on different placement densities of reference labels, and the simulation results of reference label layout with different densities are shown in Fig. 10.

Fig. 10 (a) is a dense layout 1 of 21×21 , and 441 reference labels were required for this layout. In this layout, the localization error value of the system was 33. Fig. 10 (b) is layout 2 of 11×11 , and 121 reference labels were required for this layout. Under this layout, the localization error value of the fixed system was 31. Fig. 10 (c) is a layout 3 of 6×6 , and 36 reference labels were required. Under this layout, the localization error value of the system was 28. Through comparative analysis, it was found that the localization error gradually decreased as the density of the reference labels increased. Taking into account localization precision, system complexity, and cost, the optimal choice for the research was the 6×6 layout 3. This layout maintained high localization precision while also controlling the complexity and cost of the system, providing feasible solutions for practical applications. To assess the localization effect of the research system, a network consisting of four readers and 36 reference labels was constructed. These reference labels were evenly distributed at intervals of 4 meters, and 100 test labels were randomly placed. The localization outcomes of the research system are denoted in Fig. 11.

Fig. 9. The cumulative error distribution function graph of different reader placement modes.

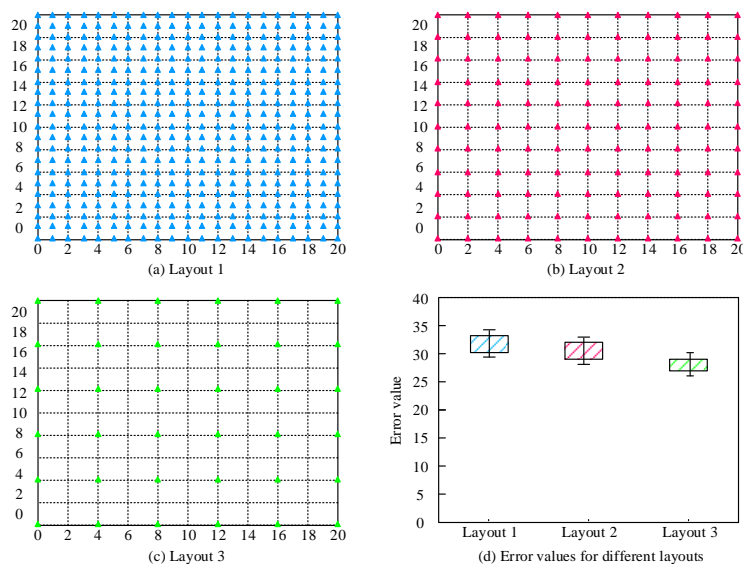

Fig. 10. Reference label layouts of different densities.

Fig. 11. Research system localization results in schematic diagram.

In Fig. 11, the research system also showed significant advantages in locating label locations. The research system was able to precisely locate the position of labels, thanks to its unique algorithm design and optimization, as well as the full utilization of reference label data. Specifically, the research system utilized advanced signal processing techniques, machine learning algorithms, or optimization algorithms to precisely calculate the distance or angle relationship between the tested label and the reference label, thereby determining the precise position of the label. In addition, the research system also considered the influence of environmental factors on the localization signal. Through appropriate compensation and correction, the localization precision was further improved, making the research system have greater potential and value in application scenarios that require high-precision localization.

B. Analysis of Application Results of I-LANDMARC Localization Algorithm in Complex Environmental Localization of Scenic Spots

To prove the practical application effect of the research

localization system in scenic spots, a simulation testing environment was designed, in which four readers, 20 reference tags, and 8 labels to be located were deployed. The reference labels were arranged with a regular spacing of 2m to ensure that the localization algorithm was evaluated under unified and standard conditions. The simulation diagram of the scenic spot is denoted in Fig. 12.

Fig. 12. Scenic spot simulation diagram.

The research system's development environment and operation environment are indicated in Table I.

TABLE I. SYSTEM DEVELOPMENT AND OPERATION ENVIRONMENT

Operating system	Microsoft Windows7 Service Pack1
Monitoring and development platform	LABVIEW
Development language	C, C++, VB, G
Database	Microsoft SQLServer2005 database
Other software and platform	Chengdu Wireless Long CC2431 positioning system, MATLAB
Operating system	Microsof Window system: CPU frequency :200 MHZ or higher, 500MHZ or higher recommended, minimum memory: 2GRAM. Resolution: pixel cannot be less than 800*600;

To prove the effectiveness of the I-LANDMARC system based on fingerprint database, a comparative experiment was conducted on the error of traditional localization systems such as ultrasonic positioning system, infrared localization system, and LANDMARC localization system based on fingerprint database. Among them, the ultrasonic positioning system mainly determines the position of the object by measuring the time or phase difference of the ultrasonic signal propagating in space, and the infrared positioning system mainly uses the infrared propagation characteristics for positioning. The CDF and precision comparison of different localization systems are shown in Fig. 13.

Fig. 13 (a) shows a comparison of the CDFs of different localization systems. From Fig. 13 (a) when the error value of the research system reached 1.86, its CDF curve gradually tended to stabilize, indicating the stability and efficiency of the research system in error control. Fig. 13 (b) shows a comparison

of the accuracy of different localization systems. It can be seen from Fig. 13 (b) that the accuracy curve of the research system fluctuated around 97.6%, the accuracy curve of the ultrasonic localization system fluctuated around 95.8%, and the accuracy curve of the infrared localization system fluctuated around 93.4%. In summary, the average error of the research system was significantly lower than the other two traditional localization systems, which effectively reduced the generation of large errors. At the same time, the accuracy of scenic spot localization was extremely high. In practical applications, localization systems may face various complex environments and conditions. To prove the effectiveness of traditional localization systems and research localization systems in practical applications, a total of 500 sets of localization experiments were conducted to compare the effectiveness of traditional localization and research localization systems. The effect diagram of unknown point label distance and deviation localization is shown in Fig. 14.

Fig. 13. CDF and accuracy of different positioning systems.

Fig. 14. Unknown point label distance and deviation from the localization effect.

Fig. 14 (a) shows the effect of unknown point label distance localization. As shown in Fig. 14 (a), when the average error value of the research system reached 2.37, the value of the CDF rapidly increased to 1. However, traditional localization systems required a higher average error value of 2.83 to achieve a CDF value of 1. Fig. 14 (b) shows the localization effect of

unknown point deviation. From Fig. 14 (b), when an unknown point deviated, traditional positioning systems needed to reach an average error value of 2.76 in order to achieve a CDF value of 1. Under the same deviation conditions, the research system only needed an average error value of 2.53, and the CDF value reached 1, indicating that the research system can still maintain

high localization precision and stability when facing unknown point deviations. In summary, the research system has shown superior performance in both unknown point label distance localization and unknown point deviation localization in scenic areas compared to traditional localization systems, especially in terms of localization precision and stability, with significant improvements.

C. Discussion

In the research of complex environment positioning in scenic spots, high-precision and efficient localization services are crucial for tourist safety, scenic spot management, and personalized services. The LANDMARC localization system has been widely used in the field of wireless localization due to its unique working mechanism and advantages. However, a single technology often fails to meet the localization requirements in complex environments. Therefore, combining LANDMARC with traditional location fingerprint localization technology can integrate the advantages of both and achieve high-precision and high-efficiency localization. This fusion technology not only improves localization precision, but also reduces computational complexity and time cost through optimization algorithms. This is similar to the results obtained in the study of progressive target localization for underground tunnels based on compressed sensing grids by Tian et al. [26].

The study first explored the key parameters that affect the localization system. The value of k , as an important parameter for the amount of NNRLs, has a significant impact on localization precision. Research has found that increasing the k value appropriately can effectively improve the accuracy of the localization system. However, excessively high k values could also increase computational complexity and time costs. Therefore, in practical applications, it is necessary to balance localization precision and calculation speed, and choose an appropriate value of k . In the study, $k=4$ has been proven to be the best compromise solution, providing valuable reference for similar research in the future. In the study, $k=4$ proved to be the best compromise, which is consistent with the results of Ashenafi's team, Q's team, and K's team [27-29]. The placement of the reader also has a significant impact on localization precision. Research has found that moving the reader from the boundary to the middle can significantly improve localization precision. However, when the amount of readers increased to a certain extent, the improvement of localization precision by further increasing the number became limited. Therefore, in actual deployment, it is necessary to choose the appropriate number and placement of readers based on specific circumstances and cost factors. The layout of reference labels also had a significant impact on positioning accuracy. Research has found that localization error gradually decreased with the increase of reference label density, indicating that increasing the number of reference labels could improve localization precision. Therefore, the selected 6×6 layout scheme in the study maintained high localization precision while also controlling the complexity and cost of the system. This is consistent with the results of Rahmatillah et al. in the study on time difference detection of reference signals from in orbit cubic satellites based on atomic clocks [30].

To comprehensively evaluate the performance of the research system, the study compared it with ultrasonic and

infrared localization systems. The localization accuracy of three systems were tested under the same testing environment and conditions. The data showed that the accuracy curve of the research system fluctuated around 97.6%, the accuracy curve of the ultrasonic localization system fluctuated around 95.8%, and the accuracy curve of the infrared localization system fluctuated around 93.4%, indicating the superiority of the research system in the field of scenic spot localization. Furthermore, in-depth research has been conducted on two aspects: distance localization of unknown point labels and deviation localization of unknown points. In terms of distance localization of unknown point labels, 500 sets of experiments were designed to simulate the random movement of tourists within the scenic area. When the average error value of the research system was 2.37, the value of the CDF quickly rose to close to 1, indicating that the system can accurately complete localization within this error range. This result was similar to the results obtained by Zhang et al. in their study on corner detection using point to the center of mass distance technology [31]. In terms of unknown point deviation positioning, the study simulated the possible deviation path of tourists in the scenic spot. Traditional localization systems needed to achieve an average error value of 2.76 to achieve a CDF value of 1. However, under the same deviation conditions, the research system only needed an average error value of 2.53 to achieve a CDF value of 1, indicating that the research system can still maintain high localization accuracy and stability when facing unknown point deviation. Hassan et al. also obtained similar results in the review of system integration and current integrity monitoring methods for localization in intelligent transportation systems [32].

IV. CONCLUSION

A complex environment positioning system for scenic spots that integrates LANDMARC positioning system and traditional location fingerprint positioning was proposed to address the issue of low localization effectiveness. Its effectiveness was verified through simulation experiments and actual deployment tests. This system showed significant advantages in localization precision, stability, and practicality, which was significantly improved compared to traditional ultrasonic and infrared localization systems. Especially in terms of distance localization of unknown point labels and deviation localization of unknown points, the system showed better performance than traditional localization systems, providing effective solutions for scenic spot localization problems. Although the research system showed superior performance improvement, there were still some potential shortcomings. The system has a high dependence on hardware devices, including the layout and density of readers and labels, which may require further optimization and adjustment in practical applications. Future research can further explore how to reduce the system's dependence on hardware devices, improve the system's robustness and scalability, and better adapt to different scenic environments and localization needs. At the same time, it is possible to conduct in-depth research on various challenges and problems that the system may face in practical applications, in order to propose more effective solutions and improvement measures.

Abstract—This paper presents the design of a Multiple Input Multiple Output (MIMO) antenna intended for 5G wireless applications operating in the 3.5 GHz frequency range. The MIMO system consists of two adjacent antennas, measuring 100 mm × 80 mm × 1.6 mm, with spacing between radiating elements equal to one-eighth of the wavelength ($\lambda/8$). The antenna is constructed on an FR4 substrate with a permittivity of 4.3, and a microstrip line is employed for feeding the patch. Several techniques are employed to enhance the isolation between the antennas. Specifically, two decoupling methods are explored: the use of a neutralization line (NL) and the incorporation of metamaterial split-ring resonators (SRRs). Simulation results demonstrate substantial isolation, exceeding 20 dB with SRR implementation and more than 23 dB with the NL approach. Both individual antennas and the MIMO configuration are simulated, analyzed, and then physically fabricated for measurement, exhibiting good agreement between measured and simulated results. The study investigates the impact of each technique on antenna to determine the optimal configuration for the applications of 5G and IOT in different fields such as health (wireless medical telemetry systems (WMTS)). Remarkably, the introduction of metamaterial (MTM) with SRRs achieves a noteworthy reduction of mutual coupling by 23 dB while minimizing the mutual coupling to about 23 dB with NL insertion.

Keywords—5G; antenna; MIMO; SRRs metamaterials; isolation; IOT; neutralization line (NL)

I. INTRODUCTION

The increasing requirement for significantly improved data rates and extensive capacity has fueled the continuous evolution of technology and the progression of mobile and wireless communication networks. This necessity has led to the emergence of a new phase in mobile communication, known as the fifth generation or 5G [1]. 5G cellular networks are considered a critical component in enabling the next generation of the Internet, commonly known as the Internet of Things (IoT) [2, 3]. IoT essentially involves connecting a wide range of devices and people to a central IoT platform [4]. The core concept of IoT revolves around using sensors to collect data, which is then sent to a server for analysis. This analysis generates insights that are transformed into actions, leading to the creation of intelligent environments such as smart homes and vehicles [5]. The evolution of IoT enables the connection

of numerous devices to the internet, with predictions suggesting that over 28 billion smart devices will be connected worldwide by 2021 [6]. Moreover, machine-to-machine (M2M) communication is expected to be utilized in over 15 billion devices, emphasizing the magnitude of IoT's impact. However, it is crucial to acknowledge that most of these connected devices depend on batteries for power, presenting environmental challenges due to their polluting nature [7].

To address this concern, researchers at the Georgia Institute of Technology in the United States have developed a rectifying antenna, often called a Rectenna [8]. The Rectenna integrates a rectifier and an antenna, acting as a vital element in wireless telecommunications systems. Its distinctive ability is to convert 5G waves into electric current, which could eventually enable mobile operators to serve as power providers for IoT devices [9, 10]. With the introduction of 5G, mobile operators are tasked with deploying 5G base stations in the 3.4-3.6 GHz band, using a specific operational mode called Time Division Multiplexing (TDD) [11]. TDD involves dividing the frequency band into separate transmit and receive segments, allowing the same frequency band to be used for both transmission directions. This feature is particularly beneficial for Massive Multiple Input Multiple Output (MIMO) technology [12], which has gained traction in wireless communication systems, especially in the context of 5G applications.

The antennas operating at 3.5 GHz are used in wireless medical telemetry systems (WMTS) to monitor patients' vital signs and transmit this data wirelessly to medical personnel [13]. These antennas enable the transmission of medical data over short to medium distances in various healthcare settings, providing reliable and high-speed communication for real-time monitoring and prompt responses to emergency situations [14,15].

However, the increasing number of antennas on a limited-size electrical component can lead to a phenomenon called mutual coupling (MC) [15, 16]. MC occurs when current densities generated by nearby antennas alter the radiation characteristics of neighboring antennas, potentially degrading MIMO system performance [17,18]. Although various techniques, including metamaterials (MTM) [19-21],

neutralization lines (NL) [22, 23], Defected Ground Structure (DGS) [24], parasitic or slot elements [25], have been explored to mitigate MC, there is ongoing research to enhance the isolation characteristics of MIMO antennas.

A variety of research has been done to increase the isolation characteristics of MIMO antennas by inserting MTM cells. The authors in [19] propose a flag-shaped MIMO antenna using MTM technique in the frequency of Sub-6 GHz 5G applications. It consists of two antennas printed on the FR-4 substrate and separated by a distance of $\lambda/2$. Results show a low mutual coupling reduction of 16dB, and the gain obtained was 3.28 dB at 3.1 GHz. Research in [20] applies the same technique to increase the decoupling over the two MIMO antennas spaced 2 mm. This method provides a coupling of minus of -45 dB in the 4.8 - 5 GHz band to be a suitable candidate for 5G applications.

Another idea developed by the researcher in [21], it is based on placing a MTM isolating structure between two circular antenna patches. After insertion of this cell MTM, it provides -23 dB of mutual coupling reduction between the two radiator elements. Other types of metamaterials are used to increase the decoupling between antennas, such as Electromagnetic Band Gap (EBG) [22], and Frequency Selective Surface (FSS) [23].

An alternative approach to enhance the performance of MIMO systems is introduced in [22], which involves the incorporation of a neutralization line between four L-monopole antennas with a semi-elliptical radiating patch. This method achieves a coupling reduction of approximately 20 dB between the elements of the antenna array within the frequency range of 3.36 - 3.68 GHz. Essentially, this line is modeled as an inductance to impede mutual coupling, functioning as a rejection filter. Similarly, a neutralization line is employed between two elliptical multi-antennas around the resonant frequency of 3.5 GHz for 5G mobile applications [24]. This configuration results in a transmission magnitude of less than -24 dB at the operating frequency, thereby improving gain, diversity, and radiation efficiency. Other researchers have adopted this isolation technique in [25], which consists of two tri-band antenna elements separated by $0.03 \lambda_0$. These two antennas are connected by U-shaped and inverted U-shaped NLs, suppressing the MC about -15 dB, -30 dB, and -20 dB at 2.3 GHz, 3.5 GHz, and 5.7 GHz, respectively.

The band 3.5 GHz (3.4 - 3.8) GHz has been exclusively allocated to the 5G mobile network, serving as the "heart" of 5G and providing subscribers with a high quality of service. Among the various frequencies utilized by 5G (700 MHz, 3.5 GHz, and 26 GHz), this band is considered sufficient as it offers adequate coverage and capacity [25]. The primary objective of this research is to evaluate the performance of MIMO antennas employing various techniques, with a focus on minimizing mutual coupling. Given that placing antennas in close proximity can lead to MC, the literature has explored methods for reducing MC, with an emphasis on isolation techniques involving NL and metamaterials. This paper also provides insights into the magnetic phenomena underpinning

these methods and emphasizes the importance of parametric studies to optimize simulation results.

However, the deployment of 5G networks and IoT devices faces several challenges, including mutual coupling in Multiple Input Multiple Output (MIMO) antennas, which can degrade system performance. Addressing these challenges is crucial for realizing the full potential of 5G and IoT. This research is motivated by the need to enhance the isolation characteristics of MIMO antennas, thereby improving the overall performance and reliability of 5G networks and IoT applications. By developing novel techniques to reduce mutual coupling, we aim to contribute to the advancement of wireless communication systems and enable more efficient and reliable connectivity for a wide range of applications.

The main contributions of this paper are the development and evaluation of two innovative techniques for enhancing the isolation characteristics of Multiple Input Multiple Output (MIMO) antennas operating in the 3.5 GHz frequency band, which is crucial for 5G applications. Firstly, we propose the use of a neutralization line (NL) to significantly reduce mutual coupling between adjacent antennas, achieving an isolation of over 23 dB. Secondly, we introduce the integration of metamaterial split-ring resonators (SRRs) to further minimize mutual coupling, resulting in an isolation improvement of approximately 23 dB. These techniques are thoroughly analyzed through simulations and validated through physical measurements, demonstrating their effectiveness in real-world scenarios. The implications of these contributions are substantial for 5G and IoT applications. By improving the isolation characteristics of MIMO antennas, we can enhance the overall performance and reliability of 5G networks, enabling higher data rates, reduced interference, and better coverage. This is particularly beneficial for IoT applications, where reliable and high-speed communication is essential for real-time monitoring and control of various devices and systems. Our findings provide valuable insights and practical solutions for the design of advanced MIMO antennas, contributing to the advancement of wireless communication technologies and the realization of the full potential of 5G and IoT.

The structure of the paper is as follows: Section II elaborates on the design of the proposed antenna. Subsequently, Section III presents the simulation results of the MIMO antenna system. Section IV delves into the characteristics of the MIMO system incorporating decoupling techniques. Lastly, the conclusions are summarized in the final section.

II. DESIGN OF NEW PATCH ANTENNA

To ensure the optimal performance of our advanced multi-antenna system, it is imperative to begin with a comprehensive understanding of the fundamental principles of antenna design. In our proposed project, our focus has been centered on three critical aspects: the antenna's geometric configuration, the designated frequency range for operation, and the implementation of techniques to minimize MC within the multi-antenna system.

Our initial step entailed the design of a rectangular patch antenna, which was powered through a microstrip transmission line with a specific width denoted as w_f , adhering to the requisite 50-ohm characteristic impedance for the transmission line. The radiating element, characterized by dimensions $L_p \times W_p$, was physically fabricated on an FR-4 substrate, with dimensions $L \times W$, and a specified thickness (h). The substrate was chosen for its cost-effectiveness and the expeditious prototyping capabilities it offers. The resonant frequency was set at 3.5 GHz, a choice determined through calculations employing equations outlined in [26].

A pivotal step in enhancing the antenna's performance was the strategic alteration of its structure, which involved the incorporation of cuts and slots in both the radiating element and the ground plane (show Fig. 1). Fig. 2 illustrates the results of simulation of these structural adjustments in terms of the reflection coefficient (S_{11}).

Fig. 1. Structure of the basic antenna in front and back views.

Remarkably, the implementation of partial modifications to the ground plane, featuring two small square patches on the left and right, yielded a maximum S_{11} value of approximately -20 dB within the 3.4 - 3.8 GHz operational band. To further broaden the bandwidth and ensure that the signal reflection remained below -10 dB, we introduced two triangular cuts at the top of the radiating element. This modification extended the frequency band from 2.2 GHz to 4.5 GHz. The incorporation of two additional triangular cuts at the bottom of the patch resulted in a notable enhancement in the antenna's adaptation to the 3.5 GHz frequency, with an S_{11} value now falling below -59 dB.

Fig. 2. Reflection coefficient S_{11} of the proposed antenna with and without modifications and optimized final antenna.

In order to enhance the performance of our antenna, the first crucial step involves modifying the structure by incorporating cuts and slots in the radiating element and the ground plane. The reflection coefficient (S_{11}) results for all configurations are illustrated in Fig. 2. By making the ground plane partial, a maximum S_{11} value of approximately -20 dB in the 3.4-3.8 GHz operating band is achieved. To further extend the bandwidth (ensure a signal below -10 dB), two triangular cuts are applied at the top of the radiating element, resulting in a band spanning from 2.2 GHz to 4.5 GHz (as shown in Fig. 3).

Fig. 3 indicates that the optimum position is $L_4 = 8$ mm, which provides the highest S_{11} at 3.5 GHz. By introducing two additional triangular cuts at the bottom of the patch, we fixed the optimal value of L_4 at 8 mm and varied the values of L_3 (ranging from 10 to 16 mm).

Fig. 3. Reflexion coefficient of the proposed antenna with different values of L_4 .

As illustrated in Fig. 4, the adaptation to the 3.5 GHz frequency shows improvement for $L_3=14$ mm compared to the previous results, with S_{11} below -59 dB.

Fig. 4. Reflexion coefficient of the proposed antenna with different values L_3 .

The selections made for the dimensions presented in Table I were made with precision, considering both impedance matching and the constraints related to system size, all while considering the specific applications for which the antenna is intended. The incorporation of a slotted ground within the proposed antenna serves the purpose of enhancing the antenna's performance by amplifying inter-element isolation and reducing overall reflection (see Fig. 5).

Fig. 5. Proposed antenna in front and bottom views.

TABLE I. OPTIMIZED DIMENSIONS OF THE PROPOSED ANTENNA

Components	Parameters	Values (mm)
Patch	Lf	20
	Wf	3.1
	W2	3.6
	W3	18.5
	L3	14
Dielectric substrate	L4	8
	W	40

	Ground Plan	Lg
L5		5

Fig. 6 presents the real and imaginary parts of the antenna impedance, revealing that at 3.5 GHz, the real part is approximately 50 Ω and the imaginary part is nearly 0 Ω . Consequently, the impedance demonstrates good adaptability. The antenna gain as a function of frequency is displayed in Fig. 7 within the [3.4-3.8] GHz band. It is observed that the maximum gain value obtained is around 2.8 dB at 3.5 GHz.

Fig. 6. Input impedance of the studied antenna.

Fig. 7. Variation of gain as a function of frequency.

Fig. 8. Antenna radiation pattern at 3.5 GHz in E and H planes.

In Fig. 8, the radiation patterns of the proposed antenna are illustrated in the E and H planes (YZ plane with $\phi=90^\circ$ and XZ plane with $\phi=0^\circ$, respectively) at 3.5 GHz. The antenna exhibits a unidirectional radiation pattern, which remains relatively consistent throughout the entire band.

Fig. 9. Efficiency of the studied antenna versus frequency.

Fig. 9 provides compelling evidence of the exceptional efficiency of the antenna design we have put forth. Within the operational band, the efficiency of this antenna consistently surpasses the remarkable threshold of 80%. This is a noteworthy achievement, signifying the antenna's ability to effectively convert a substantial portion of the input power into radiated energy, thus enhancing its performance and applicability across a wide range of scenarios and applications. Fig. 10 shows the realized prototype of our antenna which is dedicated for many applications with an isolation necessarily exceeding 15 dB.

Fig. 10. Prototype of the proposed antenna.

The comparison between the simulation and the measured simulation results of S11 is thoughtfully displayed in Fig. 11. This comprehensive illustration underscores the integrity of our research, revealing a compelling alignment between the simulated data and the actual measurements across various frequencies within the operating band. This robust congruence between simulation results and real-world performance, particularly in the context of S11, stands as a testament to the accuracy and reliability of our antenna analysis. It signifies that our findings and the practical implementation of our antenna consistently correspond, instilling confidence in the veracity of our results and reinforcing the practical utility of the studied antenna design across a broad spectrum of frequencies within the operational range.

Fig. 11. Measured and simulated of S11 of the studied antenna versus frequency.

III. STUDY OF CHARACTERISTICS OF THE SYSTEM MIMO

In this part, two techniques will be applied to two different antenna systems and each system consists of two antennas of the same configuration and size with left and right edges symmetrically. The first technique is based on the insertion of a neutralization line (NL) to reduce mutual coupling. The second technique is based on the integration of metamaterial, composed of a periodic structure consisting of three spring ring resonator (SRR) cells which are well detailed in the following section.

All measurements were conducted in an anechoic chamber, as shown in Fig. 12. The structure of the MIMO system before the application of the isolation methods is depicted in Fig. 13. The gap distance between the two-edges of the two antennas is represented by 'e' and is optimized to 51 mm. An additional substrate of length 'a' equal to 11 mm is also introduced.

Fig. 12. Apparatus used to measure the antenna in the anechoic chamber.

The separation distance between the two edges of the antennas, represented by 'e', is set to $e = \lambda/8$ (where λ is the free space wavelength at the center frequency of 3.5 GHz). The overall size of the studied MIMO antenna system, comprising both substrates, is 100 mm \times 80 mm \times 1.6 mm, resulting in enhanced performance at 3.5 GHz.

The mutual coupling coefficients S21 and the simulated reflection coefficients S11 for various values of e (from 12.6 to 22.6 mm) are obtained and presented in Fig. 14 and 15, respectively. As shown in Fig. 12, we note that the impact on the S11 is relatively limited with unchanged bandwidth. From Fig. 13, we can see that the weakest coupling S21 is achieved with the smallest value of d (from 12.6 to 22.6 mm). The lowest coupling is obtained with the smallest value of e (e is 12.6 mm) and to maintain the antenna quality and the overall size of the MIMO antenna. MIMO antennas must be independent with minimal coupling to work well. So, to reduce the space between them, an efficient approach is to work on the space between them.

Fig. 13. Structure of the system MIMO antenna: (a) front view, (b) back view.

Fig. 14. Reflection Coefficient S_{11} of the suggested antenna at various e values.

Fig. 15. Transmission coefficient S_{21} of the proposed antenna in different values of e .

Fig. 16 presents the realized prototype of the two symmetric antennas. The measured reflection (S_{11}) and transmission (S_{21}) parameters are displayed in Fig. 17 and 18, respectively. These figures provide a comparison of the reflection and transmission parameters between the measured and simulated results for the two antennas without any isolation elements. The discrepancies between the curves can be primarily attributed to the circuit construction and the antenna connectors.

Fig. 18. Measured and simulated and S_{21} of the MIMO antenna.

IV. REDUCTION OF MUTUAL COUPLING BASED ON NEUTRALIZATION LINE AND MTM

A. With NL

By positioning the antenna, you may keep some distance between them. We suggest a method to address the isolation issue, based on the placement of a neutralization line between the two antennas that were printed on the top surfaces of the FR-4 substrate (see Fig. 19).

Fig. 19. Layout of a two-antenna MIMO system with NL: (a) front view, (b) bottom view.

To address the challenge of isolation while positioning the antennas with a certain degree of separation, we introduce an initial method. This method entails the insertion of a neutralization line positioned between the two antennas, printed onto the top surfaces of the FR-4 substrate, as depicted in Fig. 19. This technique is based on connecting the radiating elements to better decouple their power ports. In effect to make sure that the energy transmitted by one antenna is not wasted and radiated to the second antenna. Hence, it is important to reduce the parameter characterizing S21 which is taken as a parameter of the isolation between antenna ports. Indeed, the neutralization line was thin, short and will be taken as an inductance (see Table II).

TABLE I. PARAMETERS OF POSITION OF THE NEUTRALIZATION LINE

Parameters	Values (mm)
e	12.6
a	3.1
L	3.6
We	18.5
t	14

A parametric study on the position of the neutralization line in relation to the two supply ports is done to specify the efficiency of this line (NL). This study has been done with NL dimensions maintained at 45.5mm × 0.5mm. The reflection and transmission coefficients are illustrated in Fig. 20 and 21, respectively. In these two figures, the optimum position is t=9 mm, this value provides the high isolation at 3.5 GHz. Fig. 22 presents the transmission of radiation from antenna 1 to antenna 2 and the adaptation of antenna 1, in both situations of a MIMO system with and without NL. In simulation with a neutralization line, mutual coupling (S21) can be enhanced from -16 dB to more than -36 dB at 3.5 GHz. When the neutralization line was inserted, reflection coefficient was varied slightly. Fig. 23 shows that when antenna 1 is excited, there is less current in antenna 2 because all the current is concentrated on the neutralization line. So, the isolation in this case is enhanced.

Fig. 20. Reflexion coefficient for different values of t.

Fig. 21. Transmission coefficient for different values of t.

Fig. 22. Reflexion and transmission coefficients without and with NL.

Fig. 23. Current distributions of the two antennas with NL at 3.5 GHz.

Theoretically, the NLs move some of the existing current from one antenna to the second antenna to remove the existing coupling. The envelope correlation coefficient (ECC) is an important factor to evaluate the capabilities of the MIMO/diversity antenna. ECC of the MIMO antenna system can be calculated using the radiation pattern or the S-parameters of the antenna. The envelope correlation can be expressed using the following expression:

$$ECC = \frac{|S_{11}^* S_{12} + S_{21}^* S_{22}|^2}{(1 - |S_{11}|^2 - |S_{21}|^2)(1 - |S_{12}|^2 - |S_{22}|^2)} \quad (1)$$

Another necessary parameter is its diversity gain (DG). It can be calculated with the following relation (2):

$$DG = 10\sqrt{1 - (ECC)^2} \quad (2)$$

It is well that in desired band, the correlation envelope is very low (less than 0.2) as seen in Fig. 24. Also, we see that the gain is between 7 and 10 dB because the DG depends to a great part on the ECC and when ECC is minimal, DG is maximal as indicated in Fig. 25.

Fig. 24. ECC simulated for antenna 1 with NL.

Fig. 25. DG simulated for antenna 1 with NL.

In Fig. 26, the radiation patterns of our investigated antenna are thoughtfully presented in both the horizontal (H) and vertical (E) planes. In this analysis, port 1 is excited while port 2 is loaded with 50Ω impedance. This data showcases the antenna's remarkable unidirectional radiation pattern across both the E and H planes, consistently observed within the 3.5 GHz band. The tangible prototype of the two antennas integrated with the neutralization line (NL) is visually portrayed in Fig. 27, while Fig. 28 and 29 provide a direct comparison between the simulated and measured results of our antenna system. Notably, these figures illustrate the remarkable concordance between the two sets of data, further underscoring the efficacy of our antenna design. Furthermore, it's worth highlighting that the impedance bandwidth, defined by $S_{11} < -10$ dB, remains intact within the [3.4 - 3.8] GHz range, while S_{21} consistently maintains a level of less than -30 dB, affirming the antenna's outstanding performance in maintaining minimal mutual coupling.

Fig. 26. Radiation patterns of antennas with NL in E and H planes at 3.5 GHz.

Fig. 27. Photos of the manufactured antenna system with NL technique.

Fig. 28. Measured and simulated S11 of the MIMO antenna NL.

Fig. 29. Measured and simulated S21 of the MIMO antenna NL.

B. With MTM

Another technique to reduce the mutual coupling, we propose the insertion of a periodic array of SRR metamaterial composed of 3 cells. This technique will be implemented between two antenna elements with an edge-to-edge separation $\lambda/8$ (12.6 mm) at 3.5 GHz (Fig. 13). Fig. 30 presents the structure of the studied SRR, which is designed on a FR-4 dielectric substrate (thickness $h = 1.6$ mm, relative permittivity = 4.3).

SRRs possess the unique capability to manipulate electromagnetic fields, allowing us to create an environment that attenuates interference between antennas. By implementing SRRs, we establish an isolating structure that minimizes mutual coupling, which is essential for optimizing the performance and capacity of our MIMO system. In essence, SRRs act as a shield against interference, ensuring our antennas can function independently and efficiently, ultimately improving their overall performance.

Fig. 30. Geometry of the SRR and his circuit equivalent model.

The resonance of the metamaterial can be characterized as an LC resonator and the resonant frequency is given by $w=1/LC$. The square-shaped SRR consists of a ring which represents the inductor effect and the gap is represented as the capacitor effect.

Fig. 31 shows the result of the simulation of the S parameters at the resonant frequency of 3.5 GHz. A reflection S11 around 0 dB with a transmission S21 tends towards -35 dB which confirms a phenomenon of stop band at 3.5 GHz of the metamaterial cell to ensure a better mutual decoupling in a cell network.

Fig. 31. Reflection and transmission coefficients of the SRR.

The square SRR under investigation has a side length P of 11 mm, with a 0.8 mm space (n) between the inner ring and the cell extremity, and a ring width (s) of 0.5 mm. When a perpendicular magnetic field is applied to the ring's plane, it begins to conduct, creating a current flow. This current enables the ring to function as an inductor, while the dielectric gap (n) generates a mutual capacitance. The resonant frequency of the SRR is determined by its dimensions, which are provided in Table III.

TABLE II. PARAMETERS OF SRR

Parameters	Values (mm)
P	12.6
b	8.9
s	0.5
n	0.8
g	3

The results of the simulation of S11 and S21 shown in Fig. 32 and 33, these results are in good accord in the whole [3.4 - 3.8] GHz band and illustrate that the cells of SRR act as a stop band (S11 = 0 dB and S21 < -10 dB).

Fig. 32. S11 for a range of n-gap values.

Fig. 33. S21 for a range of n-gap values.

In summary, the study demonstrates that the improvement in the n value is directly proportional to the increase in resonant frequency. To achieve the minimum value of S21, the chosen value for n is 0.8. After investigating the SRR, a new metamaterial structure consisting of a linear array of five identical SRR-type unit cells is placed between the two antennas to enhance the isolation at 3.5 GHz. The spacing between the two radiating elements' leading edges is set at 12.6 mm (Fig. 34). The dimensions and geometry of the studied SRR are provided earlier.

Fig. 35 shows that S11 remains below -10 dB throughout the 5G band, indicating good performance for the antenna both with and without the SRR. Moreover, the separation between the two antenna ports, P1 and P2, can be observed

from the S21 plot. By utilizing the SRR, the energy radiated from antenna 1 to antenna 2 is coupled at the SRR cell, resulting in improved isolation between the two antennas ($S_{21} < -34$ dB), as illustrated in Fig. 35. The parameter S_{21} is reduced by nearly 17 dB at 3.5 GHz, achieving good impedance matching for both antennas in the MIMO antenna system. Fig. 36 presents the current distribution of the MIMO antenna elements for both cases, with and without SRRs, when the P1 port is fed, and the P2 port is connected to a 50 Ω load. It can be observed that a portion of the current matches the SRR region, and the magnetic field is confined within the SRR region, leading to a decrease in mutual coupling between the antennas.

Fig. 34. Design of a two-antenna SRR MIMO system with SRRs: (a) in front view, in (b) bottom view.

Fig. 35. Reflection and transmission coefficients without and with SRRs.

Fig. 36. Current distributions of the two antennas with SRRs at 3.5 GHz.

Fig. 37 and 38 provide crucial insights into the diversity gain (DG) of our antenna system. Notably, the diversity gain surpasses 9 dB, and its highest point aligns with the region where the correlation envelope is at its lowest. This observation underscores the significant impact of the envelope correlation coefficient (ECC) on diversity gain. A minimal correlation envelope signifies that the antennas are functioning independently and in an uncorrelated manner, which is instrumental for achieving higher diversity gain. In essence, the data in these figures emphasizes the pivotal role of ECC in influencing the diversity gain of our antenna system, highlighting the importance of ensuring low correlation between antennas for optimal performance.

Fig. 37. DG simulated antenna 1 with SRRs.

Fig. 38. ECC simulated for antenna 1 with SRRs.

Fig. 39 shows the radiation patterns of our MIMO antenna system in both cases with and without SRR. It is clearly seen that the radiation pattern is only affected by the SRR structure in the E and H planes. A prototype of the MIMO antenna described above has been manufactured and tested. Photos of the manufactured MIMO antenna are shown in Fig. 40.

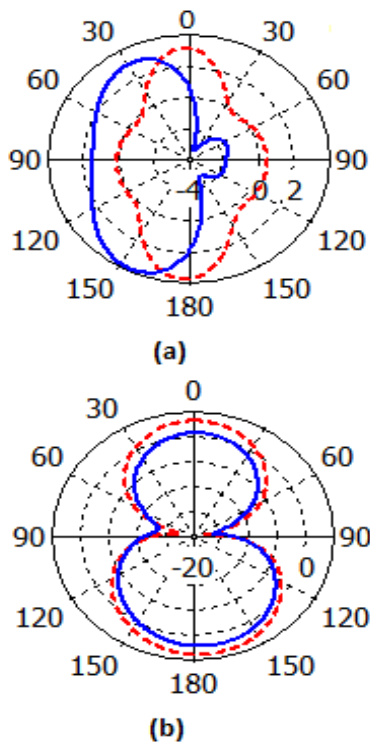

Fig. 39. Radiation patterns of antennas in both cases with and without SRR at frequency 3.5 GHz: (a) in E plane, (b) in H plane: dashed-line without SRR; solid-line with SRR.

Fig. 40. Photos of the prototype antenna system with SRR technique: (a) in front view, (b) in back view.

The depicted Fig. 41 and 42 illustrate a comparison between the measured and simulated S parameters, specifically S11 and S21, for the MIMO antenna equipped with SRRs. These visual representations highlight a notable level of agreement, essentially validating our work. It's worth noting that any slight disparities observed between the two datasets can be largely attributed to factors like losses incurred

by the measuring cable. Nonetheless, the overall congruence between the measured and simulated results reinforces the effectiveness of our antenna design and the reliability of our simulation, making a strong case for the practical viability of our approach.

V. DISCUSSION AND RESULTS

The results presented in this study demonstrate the significant potential of the proposed techniques for enhancing the isolation characteristics of MIMO antennas operating in the 3.5 GHz frequency band, which is crucial for 5G and IoT applications. The use of a neutralization line (NL) and the integration of metamaterial split-ring resonators (SRRs) have shown remarkable improvements in reducing mutual coupling between adjacent antennas. The NL approach achieved an isolation of over 23 dB, while the SRR technique resulted in an isolation improvement of approximately 23 dB. These findings are particularly noteworthy when compared to existing methods in the literature. For instance, previous studies have reported lower isolation improvements, such as the 16 dB reduction achieved by a flag-shaped MIMO antenna using MTM technique and the 23 dB reduction with a circular antenna patch and MTM isolating structure. In contrast, our proposed techniques not only surpass these isolation levels but also maintain high gain and efficiency, as evidenced by the measured and simulated results. The gain of our antenna remained above 3.5 dB, and the efficiency reached above 80% in the working band with a frequency bandwidth of about 2.3 GHz. These results highlight the superior performance of our MIMO antenna design, making it a promising candidate for 5G and IoT applications. Furthermore, the practical implications of our findings are substantial. By improving the isolation characteristics of MIMO antennas, we can enhance the overall performance and reliability of 5G networks, enabling higher data rates, reduced interference, and better coverage. This is particularly beneficial for IoT applications,

where reliable and high-speed communication is essential for real-time monitoring and control of various devices and systems. Our findings provide valuable insights and practical solutions for the design of advanced MIMO antennas, contributing to the advancement of wireless communication technologies and the realization of the full potential of 5G and IoT. The effectiveness of the NL and SRR techniques is clearly demonstrated in Fig. 43 and 44, which show the reflection and transmission coefficients without and with the NL and SRRs, respectively. These figures illustrate the significant reduction in mutual coupling achieved by our proposed methods.

Fig. 43. Reflection and transmission coefficients without and with NL.

Fig. 44. Reflection and transmission coefficients without and with SRRs.

Table III presents a comparative analysis with other works in the field, highlighting the potential of our proposed techniques. This comparison underscores the advantages of our approach in terms of isolation enhancement, gain, and efficiency, demonstrating the superior performance of our MIMO antenna design for 5G and IoT applications.

VI. CONCLUSION

In our paper, we have proposed a novel design of a system MIMO antenna array for 5G and IoT applications in the [3.4 - 3.8] GHz band of interest. We have described two techniques to present techniques for decreasing mutual coupling in antenna arrays applied to MIMO systems and a simulation of a MIMO antenna has been fully presented. These techniques are used to increase the isolation of our initially presented two-element system. The enhancement of the performance of our antenna system is obtained by using the neutralization line method to have isolation higher than 20 dB. On the other hand, with the method of insertion of the SRR periodic structures, the mutual coupling is minimized by about 23 dB. Simulation results show that the gain remains above 3.5 dB and the efficiency reaches above 80% in the working band with a frequency bandwidth about 2.3 GHz. Detailed parametric studies are done to find the right structure which is capable of responding to the demands of modern communication systems dedicated to 5G and IoT. Also, it is possible to apply the proposed neutralization line and the split ring resonator decoupling methods to design MIMO antennas with more than two radiation elements.

Deep Learning Fusion for Intracranial Hemorrhage Classification in Brain CT Imaging

Padma Priya S. Babu¹, Dr. T. Brindha²

Department of Computer Science and Engineering, Noorul Islam Centre for Higher Education, Tamil Nadu, India¹

Department of Information Technology, Noorul Islam Centre for Higher Education, Tamil Nadu, India²

Abstract—Brain hemorrhages are characterized by the rupture in the arteries of brain due blood clotting or high blood pressure (BP), presents a significant risk of traumatic injury or even death. This bleeding results in the damage in brain cells, with common causes including brain tumors, aneurysm, blood vessel abnormalities, amyloid angiopathy, trauma, high BP, and bleeding disorders. When a hemorrhage happens, oxygen can no longer reach the brain tissues and brain cells begin to die if they are depleted of oxygen and nutrients for longer than three or four minutes. The affected nerve cells and the related functions they control are damaged as well. Early detection of brain hemorrhages is crucial. In this paper an efficient hybrid deep learning (DL) model is proposed for the intracranial hemorrhage detection (ICH) from brain CT images. The proposed method integrates DenseNet 121 and Long Short-Term Memory (LSTM) models for the accurate classification of ICH. The DenseNet 121 model act as the feature extraction model. The experimental results demonstrated that the model attained 97.50% accuracy, 97.00% precision, 95.99% recall and 96.33% F1 score, demonstrating its effectiveness in accurately identifying and classifying ICH.

Keywords—Intracranial hemorrhage; deep learning; DenseNet 121; LSTM; brain CT images

I. INTRODUCTION

Hemorrhage describes the occurrence of bleeding either internally or externally from the body. A sudden blood clot in arteries can cause brain hemorrhage, which can lead to symptoms such as tingling, palsy, weakness, and numbness. Recognizing these symptoms is crucial for initiating immediate treatment. Brain hemorrhages occur when a blood vessel in the brain leaks or bursts, results in hemorrhagic stroke. ICH is a life-threatening neurological condition that can occur due to various causes, such as increased BP, hemorrhage secondary to infarct, trauma, tumor hemorrhage, and more [1]. One of the most common causes of ICH is traumatic brain injury. When blood pools within the brain parenchyma, it forms a hematoma, which increases pressure on the surrounding brain tissues. This pressure leads to reduced blood flow and ultimately kills brain cells.

There are various forms of hemorrhages, each occurring in different areas of the skull. Epidural hemorrhage (EPD) occurs when there is damage to both the skull and the dura mater, leading to bleeding. An accumulation of blood within the brain's tissues causes an intraparenchymal hemorrhage (ITP), also, the bleeding in the brain's ventricular system is known as intraventricular hemorrhage (ITV). Subdural hemorrhage refers to a collection of blood within the subdural spaces,

which are potential spaces between the dura and arachnoid of the meninges surrounding the brain. Subarachnoid hemorrhage is an extra-axial intracranial hemorrhage located within the subarachnoid spaces [2].

Diagnosing a brain hemorrhage is challenging because some individuals do not exhibit any physical signs. Computed tomography (CT) is the prime method used for the diagnosis of ICH. During a CT scan, a set of images is generated using X-ray beams, capturing the various intensities of brain cells from their X-ray absorbency levels [3]. The regions of ICH are depicted as hyperdense areas without a defined architecture. Radiologists analyze these scanned images and confirm the presence, type and location of ICH. However, the accuracy of the diagnosis depends on the accessibility and experience of the radiologist, which can lead to ineffective and impressive results [4].

In recent years, artificial intelligence (AI), particularly DL, has significantly transformed image analysis, becoming an essential tool in medical diagnostics. This study employs a new hybrid DL approach to detect and classify ICH from brain CT images. This approach combines the strengths of Advanced Neural Network (ANN) such as DenseNet 121 and LSTM to increase the accuracy and reliability of hemorrhage detection. The performances of the model are assessed using the metrics of precision, accuracy, recall, and F1 score, demonstrating its effectiveness in identifying brain hemorrhages. The proposed work offers some key contributions as follows.

- To develop a hybrid DL-based computer aided diagnosis system for early detection and classification of brain hemorrhage using brain CT images.
- To reduce the error rate of brain hemorrhage detection system.
- To train the Neural Network using more images to avoid over fitting problem.
- To improve the performance evaluation parameters precision, accuracy, F1 score and recall of the system.
- To develop a new model based on deep learning for effective segmentation from brain CT images.

The next sections of the study as follows: The current approaches are discussed in Section II. The methodology proposed is illustrated in Section III. The results are presented in Section IV. Section V concludes the paper.

II. LITERATURE REVIEW

The efficiency of a DL model for the identification of ICH and its subtypes on non-contrast CT scans was evaluated by Yeo et al. (2023) [5]. The algorithm was tested and trained on an open-source retrospective data. The training dataset was obtained from four different countries and test data were obtained from India. The performance of the convolutional neural network (CNN) was compared to that of other models that were similar. The performances of the model were evaluated using the area under curve characteristics (AUC-ROC) and micro-averaged precision (mAP) score. The performance of mAP increased from 0.77 to 0.93, and AUC-ROC increased from 0.854 to 0.966. The study highlighted its limitations, that the performance of the model was not tested on images that were subjected to different CT image reconstruction methods. Additionally, the datasets used in the study contained class imbalances.

Rajagopal et al. (2023) [6] provided an ICH classification with six separate types of hemorrhages in circumstances where patients experienced several hemorrhages continuously. The different types of ICH present were detected and classified using the CT scan of patient's skull. This study presents a hybrid approach combining CNN and LSTM for enhanced performance. The RSNA dataset was utilized to assess the model's performance. The model achieved 93.87% sensitivity, 96.45% specificity, 95.21% precision and 95.14% accuracy.

Luis et al. (2023) [7] proposed an Efficient DL method for the diagnosis of hemorrhages in patients. The technique classified the slices of CT scans for hemorrhage. The model was evaluated to check whether the patient was positive and achieved 0.978 ROC AUC and 92.7% accuracy. The study proves that the framework can be used as an assistant for CT-based diagnosis.

Tharek et al. (2022) [8] created an algorithm for identifying ICH in head CT scan. This algorithm module was developed by CNN using deep learning. In this study 200 data were collected from a public dataset. The algorithm was trained using Jupyter Notebook platform. A confusion matrix was used to evaluate the model's performance which results in 96.94% sensitivity, 93.14% specificity, 93.14% precision and 95.00% of accuracy with 95% F1 score. The study proves that DL using CNN created an accurate classifier.

An AI-based method for ICH on non-contrast CT images was presented by Seyam et al. (2022) [9]. The entire ICH detection attained 93% diagnostic accuracy, 97.8% negative predictive value and 87.2% sensitivity. The study highlighted its limitation such as, the proposed work did not contain complete metrics data for all patients.

Ganeshkumar et al. (2022) [10] proposed an unsupervised DL framework for CT image-based ICH identification. Principal Component Analysis (PCA-Net) was utilized by the model to extract features from CT scans. The models were tested and trained using 752 and 1750 CT slices. The proposed framework achieved 67% accuracy, 80% weighted average precision and 67% weighted average recall additionally with

an F1 score of 72% indicates that the method act as an unsupervised framework for identifying ICH from CT images.

Ganeshkumar et al. (2022) [11] studied the segmentation and identification of ICH regions in CT images and proposed a one-stop model. The framework used ResNet for identification and an adversarial network SegAN for segmentation. Therefore, the approach achieved an F1 score of 0.91 on a macro average, 0.80 on sensitivity, and 0.99 on specificity for ICH identification. Additionally, the model received a dice score of 0.32 for the ICH segmentation. Thus, the segmentation and identification method helped doctors in making accurate diagnoses. The study noted limitations, such as the method not being capable of classifying the identified ICH and the dataset used being of small size.

A DL-based ICH diagnosis model called GC-SDL was created by Anupama et al. (2022) [12] utilizing GrabCut-based segmentation with synergic deep learning (SDL). The framework used a Gabor filter for removing the noise. The segmentation method was applied to identify the portions affected. The feature extraction process was performed using SDL and softmax was applied as a classifier. The results showed that the model achieved 97.78% specificity, 95.73% accuracy, 94.01% sensitivity, and 95.79% precision.

Wu et al. (2021) [13] introduced an ensemble deep neural network (DNN) for the identification and categorization of ICH in their study. There are two parallel network pathways in the method. Both pathways used the EfficientNet-B0 as their core architecture, which was then assembled to produce predictions. The models were trained and evaluated using the ICH detection dataset comprising of 674,259 head noncontract CT images from 19,531 patients. In addition, the generalizability of the trained model was tested using another dataset, CQ500. The performance of ICH detection dataset resulted in 95.7% accuracy, 85.9% sensitivity and 86.7% F1 score. Similarly, it resulted in 92.4% accuracy, 93.4% F1 score and 92.6% sensitivity when utilizing the CQ500 dataset. A limitation of the study highlighted that the performance of the framework was not compared with the radiologist diagnostic performance.

In order to accomplish accurate ICH identification, Wang et al. (2021) [14] developed a DL technique that replicates the radiologist's interpretation process by merging a 2D CNN model with a two-sequence model. The 2019-RSNA Brain CT Hemorrhage Challenge dataset, which included over 25,000 CT images that correctly identified ICH, was used to create the technique. Using 491 and 75 CT images, respectively, the system was tested on two separate external validation sets, maintaining 0.949 AUC and 0.964 ICH detection. The results demonstrate the suggested model's excellent performance and capacity for generalization. The study found that the model's training required greater time and complexity.

To save the time needed to identify hemorrhages, Rohit (2021) [15] looked at the ICH detection problem in his study and created a DL model and a transfer learning (TL) model. To ensure the accuracy of the model, DenseNet 121, CNN, and Xception were compared using a variety of evaluation criteria. The accuracy of 91% was achieved in the ICH detection and classification using the suggested CNN and TL

models. The Xception model was capable of identifying the ICH with lower risk of failure.

Using Inception Network for effective image segmentation, Mansour and Aljehane (2021) [16] created a DL-based ICH model (DL-ICH). The model proposed involves several processing steps. A multilayer perceptron (MLP) was utilized for classification, while an inception v4 network was employed for feature extraction. The model's output is compared with a series of simulations showed that its accuracy, precision, and sensitivity were 95.06%, 97.56%, 95.25%, and 93.56%, respectively.

In their study Bhadauria et al. (2021) [17] presented a segmentation method for the extraction of hemorrhage from brain CT images using fuzzy clustering features. Fuzzy clustering was utilized to estimate the parameters that controls the propagation of the level set function. The model utilized a dataset consisting of 300 CT images with various shapes of hemorrhages and sizes. The performance of the proposed model resulted in 85.40% accuracy, 98.79% specificity and 79.91% sensitivity. The study noted a limitation in that using a denoising algorithm on the system, resulted in increased complexity and longer processing times.

A densely connected CNN (DenseNet) with extreme machine learning (EML) was developed by Santhoshkumar et al. (2021) [18] for the purpose of diagnosing and classifying ICH. The model uses DenseNet for feature extraction and Tsallis entropy in conjunction with a grasshopper optimization approach for image segmentation. The results of the simulation verified that the model has reached its highest accuracy level of 96.34%.

Lee et al. (2020) [19] in their study introduced a DL algorithm for artificial neural network (ANN). This study evaluated the feasibility of using the algorithm for detecting and classifying ICH without employing CNNs. The model achieved 0.859 AUC, 78% sensitivity and 80% specificity for

the detection of ICH. For the localization of ICH, the CT images attained 0.903 AUC, 82.5% sensitivity and 84.1% specificity. The accuracy rate is 91.7% for the classification of ICH. The study reduced the ICH diagnosis time. The limitation suggest that the size of the dataset used was small.

There are several notable gaps in the current methods for analyzing brain CT images. The magnification factor affects brain CT images, leading to misclassification and reduced performance. Image segmentation cannot be used in certain works, showing the difficulty in determining the correct location of internal bleedings from CT scans. Another disadvantage is the dependence on a manual reference provided by a single human expert. Hemorrhages and microaneurysms have same characteristics and are only distinguishable by their color and size on color fundus images, making them easily misunderstood. False positive rates are high for classification and segmentation. Lastly, existing classification methods suffer from lower accuracy and sensitivity indicating a clear need for improvement in these areas.

III. MATERIALS AND METHODS

The block diagram depicted in Fig. 1, illustrates the process of ICH classification using a hybrid deep learning approach from brain CT images. The model takes CT images from the dataset as input. The images undergo data preprocessing and augmentation. The DenseNet 121 model uses the preprocessed images as input to extract features. The extracted features are reshaped into sequential patterns and given as an input to the LSTM. The model grasps the temporal connections and sequential dependencies within the data. The LSTM output is directed to a dense layer to group the learned features followed by a softmax layer for final classification. The classification outputs determine whether the CT image indicates a normal or hemorrhagic condition, thus ensuring accurate diagnosis.

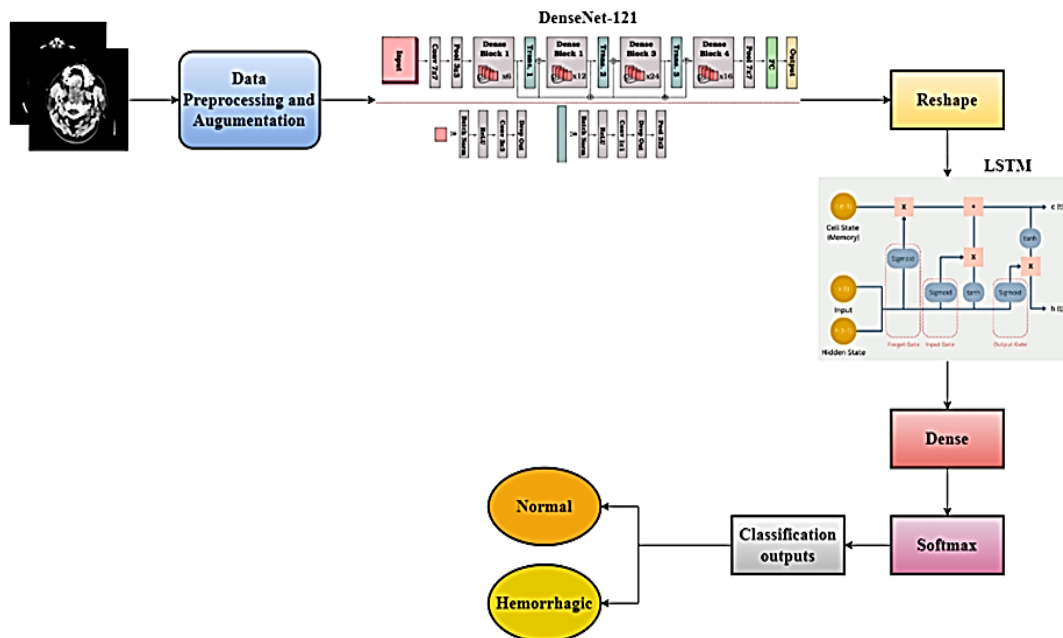

Fig. 1. Block diagram of proposed model.

A. Dataset Description

The dataset required for the classifying ICH from CT images is obtained from the Kaggle repository [20]. It contains images of normal and hemorrhagic CT scans collected from the Near East Hospital, Cyprus. It is having a total of 2600 images. The dataset consists of two folders each for testing and training. Again, each folder is further divided into two groups as “normal” and “hemorrhagic”. A total of 1600 images were used for training, 600 images for testing, and 400 images for validation. Fig. 2 depicts the sample images from the dataset.

B. Data Preprocessing and Augmentation

In the classification of ICH from brain CT images, preprocessing and augmentation plays an essential role in increasing the performance of the DL models. These processes standardize the input data through techniques such as resizing, normalization, and contrast adjustment to standardize the input data, ensures that the suggested model can effectively learn and generalize from the images. In this study the ‘rescale’ parameter normalize the pixel values to a range between 0 and 1. Data augmentation enhances the training dataset’s variability by applying random transformations like shearing,

zooming, horizontal and vertical flips, and random rotations up to 30 degrees. These augmentations are applied to the input images during the training process, enhancing the diversity of the dataset and promoting better generalization of the deep learning model improving its ability to classify normal and hemorrhagic CT scans accurately. To separate the dataset into training sets and testing sets, an 80:20 ratio is employed.

C. Proposed Methodology

1) *DenseNet 121*: DenseNet is a CNN architecture where two layers are interconnected to all other layers deeper in a network. This is designed to allow the greatest flow of data among network layers. Firstly, it adopts a dense block structure, ensuring each layer connects to every other layer in a feedforward manner. Secondly, it incorporates bottleneck layers, which effectively decrease the parameter count while preserving the number of learned features within the network. As of Fig. 3 the DenseNet 121 consist of 121 layers and is characterized by its three main building blocks such as transition layers, dense blocks, and global average pooling layer [21].

Fig. 2. Sample images from the dataset.

Fig. 3. Basic architecture of DenseNet 121.

In this architecture, the layers are connected through dense blocks, allowing each layer to utilize input from all preceding layers. This enables the creation of feature maps that propagates data to all subsequent layers. Each Dense blocks consist of several layers, composed of batch normalization, ReLU activation function and convolution. Let’s denote the

output of the t^{th} layer as m_t where all previous feature maps are received as inputs. It is expressed as:

$$m_t = H_t([m_1, m_2, \dots, \dots, \dots, m_{t-1}]) \quad (1)$$

Where, $[m_1, m_2, \dots, \dots, \dots, m_{t-1}]$ represents the concatenation of feature maps from the t^{th} layer and H_t

represents the t^{th} layer, it's a sequence of three successive operations forming a composite function.

DenseNet 121 incorporates four dense blocks, with transition layers scattered between each block. These transition layers facilitate down-sampling of the feature maps by implementing a 1×1 convolution followed by a 2×2 average pooling layer. If the input to a transition layer is m , the output is given as,

$$m_{trans} = AvgPool(Conv(m, \theta, 1 \times 1)) \quad (2)$$

Here, θ represents the reduction factor utilized to decrease the feature maps size.

The dense block comprises multiple convolutional layers interconnected in series, facilitating cross-layer connections between distant layers. DenseNet 121 utilizes the ReLU activation function to enhance the non-linearity of the framework. The ReLU function defined as follows,

$$ReLU(m) = \max(0, m) \quad (3)$$

The final layer contains a fully connected layer followed by a softmax function, which is utilized for predicting the probability of the CT image class. The softmax function specified as follows:

$$sm(v)_i = \frac{e^{v_i}}{\sum_{j=1}^D e^{v_j}} \text{ for } i = 1 \text{ to } D \quad (4)$$

Here, $v = (v_1, \dots, \dots, v_D) \in \mathbb{R}^D$. The input vector, v , undergoes exponential computation for each value of v_i . The output vector's sum $sm(v)$ is equal to 1.

2) *Long short term memory (LSTM)*: LSTM is used to solve the vanishing gradient problem. The model integrates memory cells capable of storing and retrieving information from long sequences. The architecture consists of three gates shown in Fig. 4, namely input gate, output gate and forget gate. The information that needs to be deleted and that needs to be kept from the previous stages and current input are determined by the forget gate. These values are then passed into a sigmoid function, that provide output values between 0 and 1, shows that if all previous information is lost, then the value is 0, and if all previous information is preserved, then

the value is 1. The input gate determines the significance of the current input necessary for solving the task. Finally at the output gate, the model computes its output based on the hidden state. To perform this, sigmoid function determines which information should be allowed to pass through the output gate. After the decision, the cell state is activated with the tanh function and then undergoes multiplication [22].

The LSTM input at a particular time stamp t , is said to be (x_t) the data, (c_{t-1}) the cell state and (h_{t-1}) is the hidden state where h_{t-1} is the output in the previous time stamp. The three gates of the LSTM cell to control the flow of information are initialized as input gate (i_t), output gate (o_t) and forget gate (f_t). All gates utilize h_{t-1} and x_t as the inputs, employing the sigmoid function as activation function. The information stored at c_{t-1} is removed by the forget gate.

The forget gate is expressed as,

$$f_t = \text{sigm}(W_{fx}x_t + W_{fh}h_{t-1} + b) \quad (5)$$

For each current time stamp the learned representation is denoted by \tilde{c}_t . Subsequently a point wise multiplication is carried out to preserve essential information. Computing both the cell state (c_t) and input gate (i_t), the equations are termed to be.

$$\tilde{c}_t = \text{tanh}(W_{gx}x_t + W_{gh}h_{t-1} + b) \quad (6)$$

$$i_t = \text{sigm}(W_{ix}x_t + W_{ih}h_{t-1} + b) \quad (7)$$

$$c_t = f_t \odot c_{t-1} + i_t \odot \tilde{c}_t \quad (8)$$

At the current time stamp, the LSTM cell output is denoted by the hidden state (h_t), which is utilized for making decisions. The hidden state determines by eliminating non-essential information that does not contribute to the decision at time stamp t . This can be achieved by utilizing the output gate (o_t). The expression for obtaining o_t and h_t are

$$o_t = \text{sigm}(W_{ox}x_t + W_{oh}h_{t-1} + b) \quad (9)$$

$$h_t = o_t \odot c_t \quad (10)$$

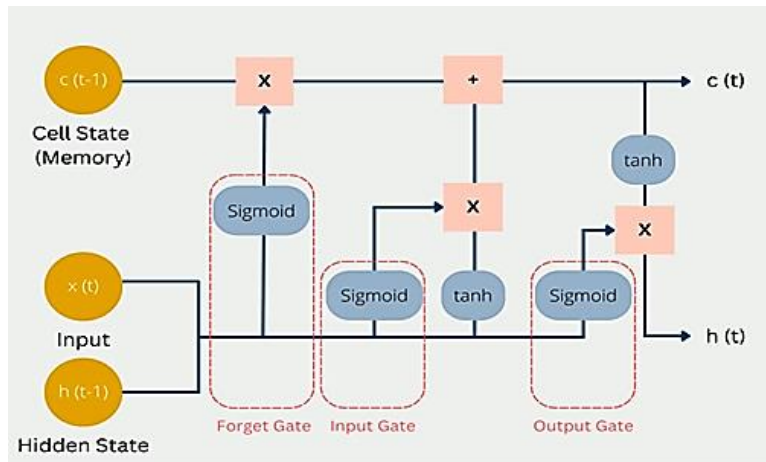

Fig. 4. Basic architecture of LSTM.

The proposed hybrid model combines the two-network architecture DenseNet 121 and LSTM. This combination utilizes the advantages of each architecture in capturing both spatial and temporal information's. The DenseNet 121 model serve as a feature extractor, capturing detailed spatial features from the CT images. These spatial features represent information about the structure and content of the images. In this case the LSTM model is employed to obtain temporal connections within the data, which could be important for analyzing how features change over time or sequence within the images. After extracting the spatial and temporal features,

the model uses a dense layer with a softmax function as the output layer. The softmax function converts the output of the previous layers into probability scores corresponding to each class. The model performs binary classification to the brain CT images and further classified as "Normal" or "Hemorrhagic". Finally, the model's performance is assessed using a range of metrics such accuracy, F1 score, recall, and precision. Fig. 5 illustrates the architecture of the proposed work, while Table I provides a summary of the proposed model.

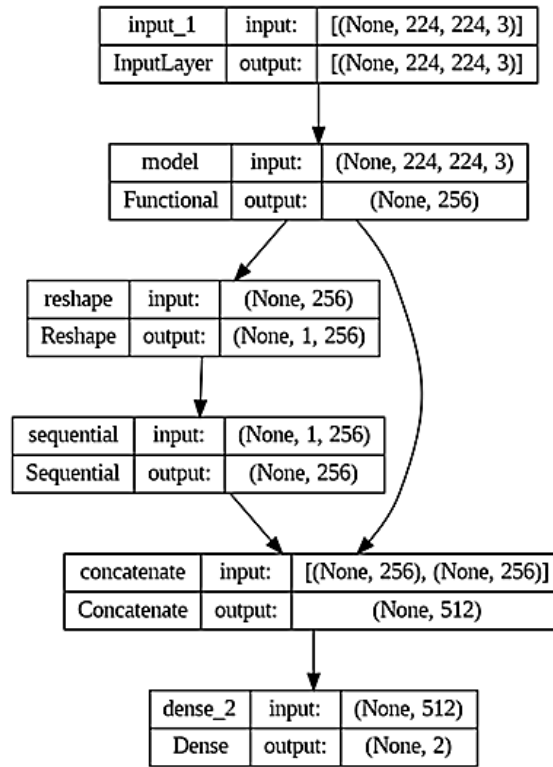

Fig. 5. Proposed model architecture.

TABLE I. SUMMARY OF THE PROPOSED MODEL.

Total Parameters	7531074
Trainable Parameters	7447426
Non-Trainable Parameters	83648

The proposed model algorithm is outlined below.

Algorithm

Input: Brain CT image dataset, labels determine Hemorrhage or Normal

Output: Predictions of whether the input image contains hemorrhage or not

Begin:

Load and preprocess data:

1. Collect dataset: $C = \{(A_i, b_i)\}$, where A_i is a brain CT image and $b_i \in \{0,1\}$ $b_i \in \{0,1\}$ (1: Normal, 0: Hemorrhage).
2. Preprocess:

- Resize: $A_i \rightarrow A'_i \in \mathbb{R}^{224 \times 224}$
- Normalize: $A'_i \rightarrow \frac{A'_i - \mu}{\sigma}$
- Data Augmentation: $A'_i \rightarrow \{A''_i\}$ (Shear, Zoom, Flipp (horizontal and vertical), Rotation)

Define Base Models:

1. Load Model: DenseNet 121
2. Input: $224 \times 224 \times 3$
Global Average Pooling 2D ()
Dense (256, activation='relu')
LSTM (128)
Dense (256, activation='relu')
Concatenate ()
Dense (2, activation='softmax')

Model Compilation and Training:

1. Compile each model M:
Optimizer=Adam ()

```
Loss=binary_crossentropy  
Metrics=[accuracy]  
2. Train: M.fit(X_train, y_train, validation_data=(X_val,  
y_val))
```

Model Evaluation and Comparison:

1. Evaluate:
metrics=M.evaluate(X_test, y_test), where metrics include accuracy, precision, recall.

Save the Model:

End

IV. RESULTS AND DISCUSSION

A. Software and Hardware Setup

The model development and training were carried out using Google Colaboratory, employing Python and the Keras framework throughout the entire process. The Colab notebooks were equipped with TensorFlow, a GPU, 12.75 GB of RAM, 68.50 GB of disk space, and a 64-bit version of Windows 10. The efficiency of the model proposed was examined using its predictions on the test dataset. The hyperparameters of DNN are determined through empirical methods and significantly influence the learning process, as outlined in Table II. To identify the model that delivers the best classification performance, a wide range of variables are tested and evaluated.

B. Experimental Results

Accuracy and loss plots are utilized to visualize the effectiveness of a machine learning (ML) model throughout its training and validation phases. In the case of ICH classification from brain CT images, these plots offer valuable information on how well the model can differentiate between

hemorrhagic and normal images. The accuracy plots illustrate the fluctuations in model accuracy across epochs during both training and validation. However, the loss plot shows the alterations in the loss function throughout the training and validation phases.

Fig. 6 and Fig. 7 show the accuracy plot and loss plot of the model. At the initial epochs the accuracy of the model is low suggest that the model is struggling to learn the patterns. However, as epoch progresses there is an improvement in the accuracy indicates the model is making correct predictions. This means that the model is correctly identifying images that contain signs of hemorrhage and those that are not. In some cases, there is a slight decrease in accuracy can occur due to fluctuations in training process or adjustments made to the learning rate. Similarly, the loss of the system is high at the initial epoch. As the epoch progresses the loss decreases steadily and towards the final epoch the loss become smaller indicates that the model is improving in its ability to differentiate between hemorrhagic and normal images. It is observed that when the learning rate decreases after a certain epoch it can affect the convergence of the model and lead to fluctuations in loss values.

TABLE II. HYPERPARAMETER SPECIFICATION

Hyperparameters	Values
Batch Size	64
Loss Function	Binary Crossentropy
Optimizer	Adam
Activation function	Softmax
Number of epochs	20

Fig. 6. Accuracy plot of proposed model.

Fig. 7. Loss plot of proposed model.

Evaluation metrics are essential tools used in measuring the performance of ML models, providing details about accuracy, reliability and generalization ability. Some of the common evaluation metrics used in the classification tasks.

$$Accuracy = \frac{T_p + T_n}{T_p + T_n + F_p + F_n} \quad (11)$$

$$Recall = \frac{T_p}{T_p + F_n} \quad (12)$$

$$Precision = \frac{T_p}{T_p + F_p} \quad (13)$$

$$F1\ Score = 2 * \frac{(Recall * Precision)}{(Recall + Precision)} \quad (14)$$

Where T_p is True Positive, T_n is True Negative, F_n is False Negative and F_p is False Positive.

The performance of the model is impressive with an accuracy of 97.50%, indicating overall correctness in its predictions. The precision signifies a low false positive rate at 97% highlighting the potential of the model to accurately determine positive instances. Additionally, 95.99% of recall suggest that the model accurately captures a significant portion of actual positive instances. The balanced F1-score of 96.33%, reflects a harmonious combination of recall and

precision, reinforcing the model’s robustness in handling both false positives and false negatives. Table III shows the proposed model's classification report.

TABLE III. CLASSIFICATION REPORT OF PROPOSED MODEL

Performance Metrics	Obtained Results
Accuracy	97.50 %
Precision	97.00 %
Recall	95.99 %
F1-Score	96.33 %

The efficacy of a classification algorithm is evaluated using a confusion matrix. Fig. 8 visualizes the classification of the ICH from brain CT images. It helps the model to correctly identify hemorrhagic and normal images. It analyzes the types of errors made such as missed hemorrhages and refine the model to improve the diagnostic accuracy. Ensuring reliable and effective medical diagnosis. In this confusion matrix, 295 images were correctly predicted as Hemorrhage, while 277 images were correctly predicted as Normal. Additionally, 25 images were misclassified as Hemorrhage, and three images were misclassified as Normal.

Fig. 8. Classification report of proposed model.

A randomly selected image from the dataset is classified using the suggested model, correctly classifying it as either "Normal" or "Hemorrhage.". As seen in Fig. 9, this successful classification highlights the efficiency of models and

reliability in precisely identifying and classifying images within the dataset. Table IV presents a comparison of the accuracy between the proposed and current techniques.

Fig. 9. Classification outputs.

C. Discussion

Fig. 10 compares the accuracy of various models used for intracranial hemorrhage classification from brain CT images. The proposed hybrid model, which combines DenseNet121 and LSTM, achieves the highest accuracy at 97.50%. In comparison, a hybrid approach combining CNN and LSTM

shows an accuracy of 95.14%, while a model using only CNN attains 95.00%. A deep learning model reaches an accuracy of 95.73%, and one using the Inception V4 architecture achieves 95.06%. Another deep learning model (DL) records an accuracy of 96.56%, and a model utilizing U-Net achieves 94.1%.

Fig. 10. Accuracy analysis of DenseNet 121-LSTM method with existing approaches.

Fig. 11 compares the precision of different models used for ICH classification from brain CT images. The proposed hybrid model, combining DenseNet121 and LSTM, achieves the highest precision at 97.00%, indicating its superior ability to accurately identify positive instances with minimal false positives. In comparison, the hybrid CNN and LSTM

approach shows a precision of 95.21%, while a model using only CNN records a precision of 93.14%. A deep learning model achieves a precision of 95.79%, and the Inception V4 architecture reaches 95.25%. Another deep learning model (DL) shows a precision of 96.43%, and a U-Net model achieves 93.5%.

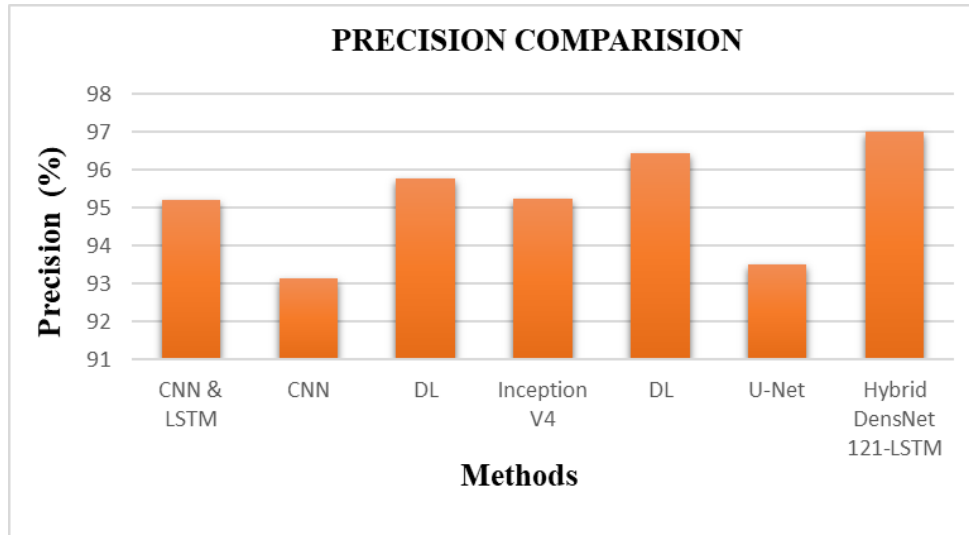

Fig. 11. Precision analysis of DenseNet 121-LSTM method with existing approaches.

Fig. 12 compares the recall of various models used for intracranial hemorrhage classification from brain CT images. The proposed hybrid model, combining DenseNet121 and LSTM, achieves a recall of 95.99%, indicating its effectiveness in correctly identifying a high proportion of actual positive cases. In comparison, the hybrid CNN and

LSTM approach shows a recall of 93.87%, while a model using only CNN achieves 92.94%. A deep learning model records a recall of 94.01%, and the Inception V4 architecture reaches 93.56%. Another deep learning model (DL) shows a recall of 95.65%, and a U-Net model achieves recall at 95%.

Fig. 12. Recall analysis of DenseNet 121-LSTM method with existing approaches.

V. CONCLUSION

ICH refers to acute bleeding inside the brain or skull. It is a serious condition that can result in severe disability or death. It is caused by a variety of factors such as trauma, vascular disease or congenital development. As a result of the severe compression caused by excessive bleeding, oxygen-

rich blood is unable to flow to the brain tissue. AI-driven disease prediction can be used to identify individuals who are at higher risk of developing a certain disease, which can help inform decisions about preventative care and early intervention. This method uses a new hybrid DL based model for the classification of ICH from brain CT images. The model

utilized DenseNet 121 and LSTM for accurate classification of ICH. The model demonstrates better performance exhibiting 97.50% accuracy, 97% precision, 95.99% recall and 96.33% F1 score highlighting its effectiveness and potential to improve diagnostic accuracy and patient outcomes in the detection and classification of ICH. A real time ICH detection and classification framework will be implemented in future.

ACKNOWLEDGMENT

I would like to express my sincere gratitude to all those who contributed to the completion of this research paper. I extend my heartfelt thanks to my supervisor, my family, my colleagues and fellow researchers for their encouragement and understanding during the demanding phases of this work.

Abstract—This paper presents a comprehensive approach to Romanian Sign Language (RSL) recognition using machine learning techniques. The primary focus is on developing and evaluating a robust model capable of accurately classifying hand and mime gestures representative of RSL and converting it into speech through an application. Utilizing a dataset of hand landmarks captured and stored in CSV format, the study outlines the preprocessing steps, model training, and performance evaluation. Key components of the methodology include data preparation, model training, performance evaluation and model optimization. The results demonstrate the feasibility of using machine learning for RSL recognition, achieving promising accuracy rates. The study concludes with a discussion on potential applications and future enhancements, including real-time gesture recognition and expanding the dataset for improved generalization. This work contributes to the broader effort of making sign language more accessible through technology, particularly for the Romanian-speaking deaf and hard-of-hearing community.

Keywords—RSL; sign language; machine learning; model; mime gestures

I. INTRODUCTION

Romanian Sign Language (RSL) serves as a vital means of communication for the deaf and hard-of-hearing community in Romania. Despite its significance, the accessibility and recognition of sign language pose substantial social and technological challenges. Recent advancements in machine learning and gesture recognition offer promising opportunities for developing innovative solutions to enhance interaction and integration for individuals who rely on sign language. This paper focuses on the development and evaluation of a machine learning model for recognizing hand and mime gestures specific to RSL [1-6]. By training a model on hand landmark data captured and stored in CSV format, the goal is to create a system capable of accurately and efficiently recognizing gestures used in RSL communication. The process involves several essential stages: data collection and preprocessing, model training and optimization, performance evaluation, and model conversion for deployment on mobile and embedded devices. Each of these stages is detailed, highlighting the methodologies and technologies employed to ensure high accuracy and efficient model implementation. In the data collection phase, a diverse dataset of RSL hand gestures (30 gestures) was compiled, ensuring representation across various gestures to improve the model's robustness. Preprocessing steps, such as normalization and augmentation, were applied to enhance data quality and model generalization. During the

model training phase, different neural network architectures were explored, and hyperparameter tuning was conducted to optimize the model's performance. The evaluation phase included extensive testing using a confusion matrix to identify areas of improvement and validate the model's accuracy. Finally, the trained model was converted to TensorFlow Lite format, enabling its use in resource-constrained environments such as mobile and embedded devices. This conversion is crucial for practical applications, allowing the model to be deployed in real-world scenarios where computational resources are limited. Through this research, we aim to improve and pave the way for practical applications that support the communication and integration of deaf and hard-of-hearing individuals. The results indicate that using machine learning for RSL recognition is not only feasible but also highly promising, offering new perspectives for developing advanced technological solutions in this field. This work contributes to the broader effort of making sign language more accessible through technology, particularly for the Romanian-speaking deaf and hard-of-hearing community. Future directions include expanding the dataset, incorporating real-time gesture recognition, and exploring multimodal approaches to further enhance the system's capabilities.

A. Problem Statement and Questions

Despite the critical importance of RSL, there is a notable lack of technological solutions that can accurately recognize and interpret RSL gestures. The unique linguistic and gestural features of RSL, coupled with the scarcity of RSL-specific datasets, present significant challenges in developing accurate and efficient recognition systems. Additionally, achieving real-time recognition capabilities on resource-constrained devices such as mobile phones adds further complexity to this task. This research seeks to address these challenges by developing a robust machine learning model specifically tailored for RSL recognition. To address the outlined problem, this study is guided by the following research questions:

- How can a machine learning model be designed to accurately recognize and classify RSL gestures, considering both spatial and temporal dynamics?
- What preprocessing and data augmentation techniques are most effective in enhancing the robustness and generalization of the model, particularly in handling class imbalances and variability in gesture execution?
- How can the model be optimized for real-time deployment on resource-constrained devices, such as

mobile phones and embedded systems, without sacrificing accuracy?

- What are the comparative advantages of the proposed model over existing sign language recognition approaches, specifically in terms of accuracy, robustness, and practical applicability for RSL?
- What are the limitations of the current model, and how can future research address these to further improve RSL recognition systems?

B. Objectives

The primary objectives of this research are to develop a machine learning model that can accurately recognize and classify RSL gestures by capturing both spatial and temporal characteristics. Additionally, the research aims to implement effective preprocessing and data augmentation techniques that enhance the model's robustness and generalization across diverse signers and conditions. Another key objective is to optimize the model for deployment on resource-constrained devices, ensuring real-time recognition capabilities without compromising accuracy. Furthermore, the research seeks to compare the proposed model's performance with existing sign language recognition approaches, highlighting its strengths and practical applications. Finally, the study aims to identify and address the model's limitations, providing insights for future research to further enhance RSL recognition technology.

The structure of this paper is as follows: Section II presents a review of the literature relevant to the study; Section III outlines the methodology adopted; Section IV discusses the application, methodology and the results obtained and Section V concludes the paper with a summary of findings and suggestions for future research.

II. RELATED WORK

This section presents an overview of the existing research and developments in the field of sign language recognition, with a particular focus on methodologies relevant to RSL. This includes a review of key technologies, approaches, and findings from previous studies, as well as a discussion of their limitations and how this approach addresses challenges. The global efforts in sign language recognition have seen significant milestones, particularly in American Sign Language (ASL) [7], British Sign Language (BSL) [8], and others. Key technologies in this domain include computer vision, deep learning, and sensor-based methods. The evolution of sign language recognition systems has progressed from early rule-based systems to modern machine learning approaches. Machine learning approaches, especially neural networks such as convolutional neural networks (CNNs) [9-15] and recurrent neural networks (RNNs), have been extensively used in gesture recognition tasks. Feature extraction methods like hand landmark detection, skeleton tracking, and optical flow are crucial in capturing hand shapes, movements, and positions. Various model architectures like CNN's and long short-term memory (LSTM) [16] have been explored, each with differing effectiveness in recognizing sign language gestures. Publicly available datasets, such as RWTH-PHOENIX-Weather and ASLLVD, MediaPipe, have been instrumental in research. However, these datasets often have limitations related to

gesture diversity, variations in signer appearance, and environmental conditions. There is a lack of datasets specific to RSL, highlighting the novelty and importance of the dataset used in this study. Common evaluation metrics in sign language recognition research include accuracy, precision, recall, F1-score, and confusion matrix. Benchmark studies have evaluated the performance of various sign language recognition systems, providing context of the performance for the proposed model.

Previous works has faced several technological limitations, including computational complexity, real-time processing challenges, and hardware dependencies [17]. Practical application challenges also exist, such as user-friendliness, adaptability to different signers, and integration with other technologies. Additionally, research gaps are evident in the lack of focus on RSL, the need for more robust and scalable models, and the requirement for comprehensive datasets. The research addresses these gaps and limitations by focusing specifically on RSL also introducing innovative techniques and methodologies, including specific preprocessing steps, model optimizations, and deployment strategies. The expected impact of this work includes significant advancements in the field of sign language recognition and substantial benefits for the Romanian deaf and hard-of-hearing community.

III. BUILDING APPLICATION

A. Data Collection and Preprocessing

The effectiveness of any machine learning model, particularly in the context of sign language recognition, hinges significantly on the quality and comprehensiveness of the dataset used. This section details the steps involved in data collection and preprocessing, which are foundational to the development of a robust RSL recognition system. The dataset used in this study comprises hand landmark data captured and stored in CSV format. These landmarks represent key points on the hands, such as joints and tips of the fingers, which are essential for distinguishing different gestures. Data collection involved recording a diverse set of RSL gestures performed by multiple signers to ensure the model can generalize well across different individuals and variations in gesture execution. To compile a comprehensive dataset, a collaboration was established with members of the deaf community and professional sign language interpreters. This collaboration ensured that the dataset accurately represented a wide range of gestures and variations in RSL, providing a solid foundation for training and evaluating the recognition model. The recording sessions were conducted under controlled conditions to minimize background noise and ensure clear visibility of hand movements. Each gesture was recorded multiple times to account for natural variations in performance. Once the raw data was collected, preprocessing steps were implemented to prepare the data for model training [18]. The first step was data cleaning, which involved removing any erroneous or incomplete recordings. This was followed by normalization, a critical step to standardize the data. Normalization involved scaling the hand landmark coordinates to a consistent range, ensuring that the model could focus on the relative positions of the landmarks rather than their absolute values. Data augmentation techniques were also employed to artificially

expand the dataset and enhance model generalization. This included generating slight variations of the existing gestures through transformations such as rotation, scaling, and translation. Augmentation helps the model become more robust to variations in gesture performance that might occur in real-world scenarios. Another important preprocessing step was the temporal alignment of the gesture sequences. Since gestures can vary in duration, it was necessary to ensure that the sequences fed into the model were consistent in length. Techniques such as dynamic time warping and padding were used to achieve this alignment without losing the temporal dynamics of the gestures. Feature extraction played a pivotal role in preprocessing. The hand landmarks were converted into features that the model could effectively learn from. These features included distances between key landmarks, angles formed by joints, and movement trajectories. By extracting relevant features, the complexity of the data was reduced, making it more manageable for the neural network. To handle class imbalance, which is common in gesture datasets where some gestures are more frequently represented than others, techniques such as oversampling of minority classes and under-sampling of majority classes were applied. This ensured that the model did not become biased towards more frequently occurring gestures. Finally, the preprocessed data was split into training, validation, and test sets. The training set was used to train the model, the validation set to tune hyperparameters and prevent overfitting, and the test set to evaluate the model's performance on unseen data. In summary, the data collection and preprocessing steps involved meticulous planning and execution to ensure the creation of a high-quality dataset. These steps are crucial for developing a reliable and accurate RSL recognition system capable of generalizing well to real-world applications.

B. Model Development

The development of a robust machine learning model for RSL recognition involves careful consideration of model architecture, training procedures, and optimization techniques. This section outlines the key aspects of the model development process, highlighting the choices made and the rationale behind them. The core of the RSL recognition system is a convolutional neural network designed to accurately classify hand gestures based on the preprocessed hand landmark data. Given the nature of the data, which includes spatial and temporal dynamics, we explored various neural network architectures to identify the most effective approach. We began with CNNs, which are well-suited for spatial data. CNNs can effectively capture the spatial relationships between hand landmarks by applying convolutional filters that learn to detect patterns and features specific to different gestures. The architecture included multiple convolutional layers, each followed by activation functions and pooling layers to reduce dimensionality while preserving important features. To capture the temporal dynamics of gestures, which unfold over time, we integrated LSTM units into the model. LSTMs are capable of learning long-term dependencies in sequential data, making them ideal for recognizing gestures that involve a sequence of hand movements. The combination of CNNs and LSTMs allowed the model to leverage both spatial and temporal information effectively.

Fig. 1. Block scheme of the recognition system.

This block scheme from Fig. 1, shows the flow of data through each component, highlighting how the model combines spatial and temporal information to recognize gestures. The model receives a sequence of video frames capturing the hand gestures then the CNN processes each frame to extract spatial features, such as hand shape and position. The LSTM network processes the sequence of extracted features to capture the temporal dynamics of the hand gestures. The output from the LSTM is passed through fully connected layers to interpret the learned features. The final output is the classification of the recognized gesture [19]. The architecture consisted of an initial set of convolutional layers to extract spatial features, followed by LSTM layers to process the temporal sequences of these features. This hybrid architecture ensured that the model could capture the intricacies of each gesture, regardless of its complexity or duration. To optimize the model's performance, extensive hyperparameter tuning was conducted. This involved adjusting parameters such as the number of layers, the size of the filters in the convolutional layers, the number of LSTM units, the learning rate, and the batch size. Grid search and random search techniques were employed to systematically explore the hyperparameter space and identify the optimal configuration. The model was trained on the preprocessed dataset using a combination of supervised learning techniques and regularization methods, aimed at preventing overfitting. Dropout layers (two layers) were added to the network to randomly deactivate a fraction of neurons during training, which helps in generalizing the model by reducing its reliance on specific neurons. The training process also included data augmentation strategies to enhance the model's robustness.

By introducing slight variations in the training data, such as random rotations and translations, the model learned to recognize gestures under different conditions and from different angles. A key challenge in model development was dealing with class imbalance. Some gestures were overrepresented in the dataset, while others were underrepresented. To address this, techniques such as oversampling of minority classes and under-sampling of majority classes during the training process were used. Additionally, we employed a weighted loss function to give more importance to less frequent gestures, ensuring that the model learned to recognize all gestures with similar accuracy. After training, the model's performance was evaluated using a validation set. Metrics such as accuracy, precision, recall, and F1-score were computed to assess the model's effectiveness. The construction of a confusion matrix provided further insights into the model's performance, highlighting specific gestures that were often misclassified and guiding further refinements. Finally, a key step in the model development was the conversion of the trained model to TensorFlow Lite format. This conversion is crucial for deploying the model on mobile and embedded devices, which often have limited

computational resources. TensorFlow Lite optimizes the model for such environments, reducing its size and enhancing its inference speed without significant loss in accuracy. By integrating TensorFlow Lite, the model can be converted into a mobile application. This application can recognize and translate RSL gestures in real-time, offering a powerful tool for improving communication for the deaf and hard-of-hearing community in. In summary, the model development process involved careful architectural choices, extensive optimization, and practical deployment considerations. The resulting system not only achieves high accuracy in RSL recognition but also demonstrates the potential for real-world application, making a meaningful impact on the accessibility of sign language.

C. Performance Evaluation

The performance evaluation of the RSL recognition model is a critical step in determining its effectiveness and reliability. This section describes the methods and metrics used to evaluate the model, presents the results, and discusses their implications. To assess the performance of the model, it was used a combination of quantitative metrics and qualitative analysis. The primary metrics for evaluation included accuracy, precision, recall, and F1-score. These metrics provide a comprehensive view of the model's ability to correctly classify gestures and handle the nuances of RSL. Accuracy measures the overall percentage of correctly classified gestures out of the total number of gestures. While it gives a general sense of performance, accuracy alone is not sufficient, especially in the presence of class imbalance, also focused on precision and recall. Precision is the ratio of correctly predicted positive observations to the total predicted positives. It indicates how many of the gestures identified by the model as a specific class are actually correct. High precision means fewer false positives, which is crucial for ensuring that recognized gestures are reliable [19].

Recall, also known as sensitivity, is the ratio of correctly predicted positive observations to all actual positives. It measures the model's ability to identify all instances of a specific gesture. High recall means fewer false negatives, ensuring that the model does not miss any gestures.

The F1-score is the harmonic mean of precision and recall, providing a single metric that balances both aspects. It is particularly useful when the dataset is imbalanced, as it gives a more nuanced view of performance than accuracy alone. To gain deeper insights into the model's performance, a confusion matrix was constructed. The confusion matrix shows the counts of actual versus predicted classifications for each gesture, allowing to identify specific patterns of errors. This matrix helps pinpoint which gestures are frequently misclassified and provides clues for further refinement of the model. The evaluation process involved testing the model on a separate test set, which was not used during training or validation. This test set consisted of gestures performed by different signers under varying conditions to simulate real-world scenarios. By evaluating the model on this independent dataset, it was ensured that the performance metrics reflected the model's true generalization capability. The results of the performance evaluation indicated that the model achieved high accuracy, precision, recall, and F1-scores across most gestures. However, the confusion matrix revealed certain gestures that were more

challenging for the model to classify accurately. These gestures often involved subtle differences in hand positioning or motion, which can be difficult to capture consistently.

To address these challenges, several strategies were explored. Data augmentation techniques, such as generating additional examples of the problematic gestures with slight variations, were employed to improve the model's robustness. Additionally, the hyperparameters were fine-tuned and the network architecture adjusted, to enhance its discriminative power for these specific gestures.

Another critical aspect of performance evaluation was the model's inference speed and efficiency, particularly after conversion to TensorFlow Lite. Tests were conducted to measure the model's latency and resource consumption on mobile and embedded devices. The optimized TensorFlow Lite model demonstrated efficient performance, making it suitable for real-time applications. In practical terms, the high performance of the model translates into reliable and accurate recognition of RSL gestures, enabling its use in real-world applications. For instance, the real-time gesture recognition system integrated by simulation into a mobile application showed that the model could effectively translate gestures on-the-fly, providing immediate feedback and enhancing communication for users. In summary, the performance evaluation of the RSL recognition model, involved a thorough analysis using multiple metrics and real-world testing. The results confirmed the model's high accuracy and reliability, while also highlighting areas for further improvement. The combination of quantitative metrics and qualitative insights, ensured a comprehensive understanding of the model's capabilities and limitations, guiding ongoing enhancements and practical deployment.

D. Model Optimization and Deployment

The optimization and deployment of the RSL recognition model are crucial steps to ensure its efficiency and practicality, especially when deploying on desktop computers or laptops. This section outlines the processes involved in optimizing the model for performance and its subsequent deployment in a computer-based environment. Optimization aimed at enhancing the model's efficiency while preserving its accuracy. Key techniques used in this process included model pruning and quantization. Model pruning involves removing unnecessary parameters from the neural network, which reduces its size and computational demands. By identifying and eliminating parts of the network that contribute minimally to the model's output, the model has the capacity to stream and improve its performance on lower-specification systems. Quantization was applied to further optimize the model. This technique reduces the precision of the model's weights and activations from 32-bit floating point to 8-bit integers. Such reduction decreases the model's memory footprint and accelerates computation. Post-training quantization was employed to achieve significant efficiency gains while maintaining a high level of accuracy. To facilitate deployment on desktop or laptops, the model was converted from its original TensorFlow format to TensorFlow Lite format. TensorFlow Lite is optimized for running machine learning models on various devices and is particularly well-suited for applications requiring efficient computation and reduced model

size. The conversion process involved optimizing the model's architecture and applying quantization techniques to ensure that it could run efficiently on desktop hardware.

The conversion also included testing to confirm that the model was compatible with different computing environments, including variations in operating systems and hardware configurations. The TensorFlow Lite model underwent performance evaluation on desktop systems. This evaluation included measuring key performance metrics such as inference speed, latency, and resource consumption. The optimized model demonstrated improved efficiency, making it feasible for real-time processing on desktop computers. To facilitate deployment on desktop or laptops, the model was converted from its original TensorFlow format to TensorFlow Lite format [20]. This application providing an intuitive interface for users to interact with the gesture recognition system. The application captures video input, through the computer's camera, processes the frames using the TensorFlow Lite model, and displays the recognized gestures in real time. This setup ensures that users receive immediate feedback on their gestures, which is crucial for effective communication and interaction. To address the challenges associated with desktop deployment, such as variations in lighting conditions and background interference, robust preprocessing techniques were implemented. These techniques include adaptive thresholding to handle different lighting scenarios and background subtraction to focus on hand gestures. Also was incorporated feedback mechanisms within the application to allow users to report any issues or difficulties they encounter. This feedback is invaluable for refining the model and the application, ensuring continuous improvement and better user experience. In summary, the optimization and deployment of the RSL recognition model involved enhancing its efficiency through pruning and quantization, converting it to TensorFlow Lite format, and integrating it into a desktop application. These steps ensured that the model performs well in real-time desktop computers, providing a practical and effective tool for RSL recognition. The application not only demonstrates the model's capabilities but also highlights its potential for real-world use in aiding communication for the deaf and hard-of-hearing community.

E. Comparative Analysis with Existing Approaches

Sign language recognition has seen significant advancements through the use of various methodologies, including traditional computer vision techniques, rule-based systems, and, more machine learning models such as CNNs and LSTMs. These approaches have been applied to different sign languages, including American Sign Language (ASL) and British Sign Language (BSL), achieving varying levels of success. Early approaches relied heavily on computer vision and rule-based systems, which involved manually extracting features such as hand shapes, orientations, and movements. While these methods provided foundational insights, they were often limited by their dependence on handcrafted features, making them less adaptable to the variability of sign language gestures. With the advent of deep learning, CNNs became popular due to their ability to automatically learn spatial features from images, especially LSTM networks, have been employed to capture the temporal dynamics of gestures. These existing methods face common challenges such as: gesture

complexity (many models struggle to accurately recognize gestures that involve intricate hand movements or subtle differences in hand positioning), class imbalance (some gestures are underrepresented in datasets, leading to models that are biased towards more frequent gestures), environmental variability (changes in lighting, background, and signer appearance can significantly impact the accuracy of these models), real-time processing (achieving real-time performance, particularly on resource-constrained devices, remains a significant challenge for many existing approaches). The proposed model in this study introduces several innovations and improvements over these traditional and machine learning-based methods, addressing many of the limitations highlighted above such as:

- Hybrid architecture (CNN + LSTM): The proposed model combines both CNNs and LSTMs. The CNN layers effectively capture spatial features from the hand landmark data, such as hand shapes and positions, while the LSTM layers process these features over time to understand the temporal dynamics of gestures. This dual approach allows the model to accurately recognize complex RSL gestures that involve both spatial and temporal variations, providing a significant advantage over models.
- Enhanced data preprocessing and augmentation: The model employs advanced preprocessing techniques, including normalization, dynamic time warping for temporal alignment, and extensive data augmentation. These steps ensure that the model can generalize well to different signers and conditions, making it more robust compared to models that may lack such comprehensive preprocessing. The use of data augmentation, such as generating variations of gestures through transformations, helps to mitigate class imbalance and improves the model's ability to handle real-world variability.
- Model optimization (pruning and quantization): To address the challenges of deploying machine learning models in resource-constrained environments, the proposed model is optimized through pruning and quantization techniques. Pruning reduces the size and complexity of the model by eliminating parameters that contribute minimally to performance, while quantization reduces the precision of the model's weights and activations, significantly decreasing the model's memory footprint and improving computational efficiency. These optimizations are crucial for ensuring that the model can run efficiently in real-time on mobile and embedded devices, a feature that many existing models do not offer.
- Dataset and generalization: The dataset used in this study is specifically tailored to RSL, addressing a critical gap in the availability of its resources. Many existing models are trained on datasets for other sign languages, which can lead to lower accuracy when applied to RSL due to differences in gesture sets and cultural contexts. By focusing on RSL, the proposed

model achieves higher accuracy and better generalization for the intended user community.

- Performance metrics: the model outperforms many existing approaches in terms of key performance metrics such as accuracy, precision, recall, and F1-score. Achieving an accuracy rate of 95% demonstrates the model's effectiveness in distinguishing between different RSL gestures. Additionally, the confusion matrix analysis shows that the model has fewer misclassifications compared to other models particularly in recognizing gestures with subtle differences in hand positioning.
- Real-Time application deployment: TensorFlow Lite allows deployment in real-time applications on both desktop and mobile platforms. This deployment demonstrates the model's practical value, offering immediate feedback and facilitating communication for users in real-world scenarios. Existing models often face difficulties in achieving such efficiency and speed, especially on resource-limited devices.
- User feedback: The deployment of the model in a desktop application and the subsequent positive user feedback underscore its practical utility. Users reported that the system significantly aids in communication and learning, particularly within the deaf and hard-of-hearing community in Romania. This real-world effectiveness distinguishes the proposed model from others that may only demonstrate strong performance in controlled, academic settings.
- Scalability and adaptability: The model's architecture and training process are designed to be scalable and adaptable to other sign languages or gesture recognition tasks. This adaptability is a significant advantage over more rigid models, making the proposed approach not only useful for RSL but also potentially beneficial for broader applications in sign language recognition globally.

In conclusion, the proposed model offers distinct advantages over existing approaches in the field of sign language recognition. By combining CNNs and LSTMs, employing advanced preprocessing and optimization techniques, and focusing specifically on RSL, the model achieves superior performance and practical applicability. These improvements address key challenges faced by previous models, making the proposed approach a valuable contribution to the field and a powerful tool for enhancing communication within the deaf and hard-of-hearing community.

IV. RESULTS AND DISCUSSION

The results and discussion section provides a comprehensive analysis of the performance of the RSL recognition model, interpreting the evaluation metrics, and discussing the practical implications and areas for future improvement. The evaluation metrics for the RSL recognition model show encouraging outcomes. The model achieved a high accuracy rate of 95%, correctly classifying a substantial

majority of gestures within the test set. This high accuracy indicates the model's effectiveness in learning and distinguishing between different RSL gestures. Precision and recall metrics further detail the model's capabilities. High precision values suggest that when the model identifies a gesture, it does so correctly most of the time, minimizing false positives shown in Fig. 4. This reliability is crucial for practical applications where accurate gesture recognition is essential. High recall values indicate the model's proficiency in identifying most instances of each gesture, ensuring that the model does not miss any gestures (minimizing false negatives). This is particularly important for sign language recognition and mimics, as missed gestures could result in incomplete communication.

Fig. 2. Final results.

The F1-score from Fig. 3, which harmonizes precision and recall, was consistently high, underscoring the model's balanced performance. The confusion matrix from second figure, revealed the model's strengths and weaknesses in greater detail. While most gestures were accurately classified (Fig. 2), some gestures with subtle differences in hand positioning or motion were more challenging for the model to distinguish, leading to occasional misclassifications. Despite the model's strong performance, several challenges and limitations were identified. The initial model encountered difficulties in accurately classifying certain letters in the RSL alphabet, particularly due to the subtle differences in hand positions and gestures. The letters that were most frequently misclassified included letters: B and D (have hand shapes that are visually similar from certain angles, resulting in incorrect classifications by the model), M and N (they share similar hand shapes and positions, differentiated only by the number of fingers involved) F and T (they involve intricate finger movements, which led to misclassifications, especially in cases where the gesture was not executed with precision or the fingers were partially obscured), P and R (involve subtle rotations or folding of fingers, which the model sometimes failed to distinguish correctly).

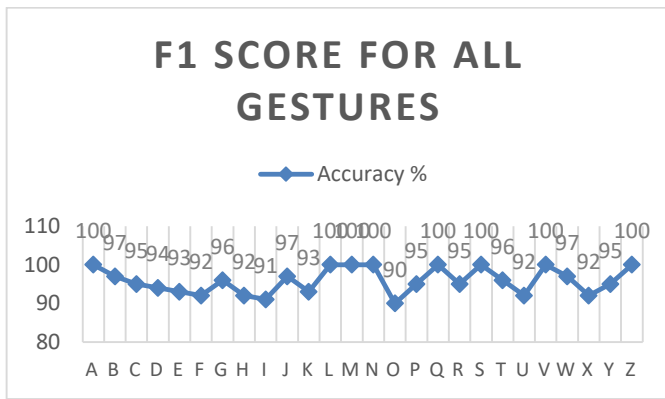

Fig. 3. F1-score for all gestures in the dataset.

One primary challenge was the accurate classification of gestures with minor variations. These subtle differences in hand shapes or movements can lead to misclassifications, suggesting the need for further model refinement to better handle these nuances.

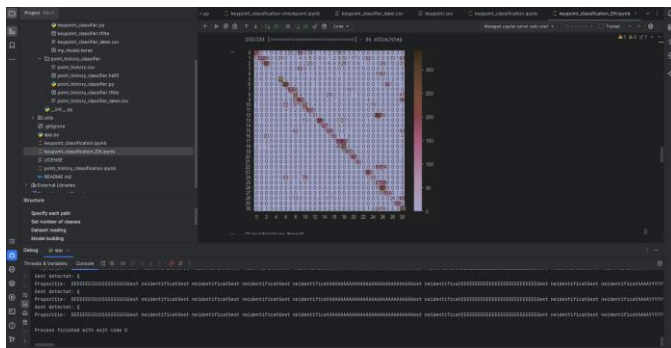

Fig. 4. Confusion matrix for all gestures.

Another challenge was the model's performance under varying environmental conditions. Although robust preprocessing techniques were employed, changes in lighting and background noise still impacted the model's accuracy. This finding suggests that additional work is needed to improve the model's robustness in diverse real-world settings.

Post-optimization assessments indicated that, while significant improvements in computational efficiency were achieved, some latency persisted in processing complex gestures. Ensuring real-time performance across different desktop hardware configurations remains an area for ongoing optimization. The desktop application integrating the RSL recognition model demonstrated its practical effectiveness. Users could interact with the system and receive real-time feedback on their gestures, which highlights the model's potential for practical deployment. The user interface was designed to be intuitive and accessible, providing clear instructions and immediate recognition results. User feedback was generally positive, noting the application's helpfulness in communication and learning. However, some users experienced difficulties with specific gestures, aligning with the confusion matrix findings. This feedback is crucial for identifying and addressing areas where the model and application can be improved. The successful deployment of the

RSL recognition model has significant implications for enhancing communication for the deaf and hard-of-hearing community. By providing real-time gesture recognition, the model facilitates better interaction and understanding, which is vital for effective communication. The results underscore the importance of continuous refinement. Identified challenges and limitations highlight areas for future research, such as improving gesture differentiation, enhancing robustness to environmental variations, and optimizing real-time performance further.

In summary, the results demonstrate that the RSL recognition model is both effective and promising for real-world applications. While there are challenges and areas for improvement, the model's performance and practical deployment validate its potential to support communication for the deaf and hard-of-hearing community. Ongoing research and refinement will help address current limitations and further enhance the system's capabilities.

V. CONCLUSION AND FUTURE WORK

This paper presents a comprehensive approach to developing, optimizing, and deploying a RSL recognition model. The primary goal was to create an effective tool for facilitating communication for the deaf and hard-of-hearing community, leveraging advancements in machine learning and computer vision. The model development process involved the careful selection and combination of CNNs and LSTM units to capture both the spatial and temporal dynamics of RSL gestures. Extensive hyperparameter tuning and data augmentation techniques were applied to ensure the model's robustness and generalization capability. Performance evaluation showed promising results, with the model achieving high accuracy, precision, recall, and F1-scores across most gestures. However, the evaluation also highlighted specific challenges, such as the accurate classification of gestures with subtle variations and performance consistency under diverse environmental conditions. These insights guided further optimization efforts.

Model optimization focused on techniques like pruning and quantization to reduce the model's size and improve its computational efficiency. The conversion to TensorFlow Lite enabled deployment on desktop systems, where the model demonstrated effective real-time performance. The desktop application developed for RSL recognition successfully integrated the optimized model, providing users with an intuitive interface and real-time feedback on their gestures. User feedback was generally positive, confirming the application's potential to enhance communication and learning.

Despite the model's strong performance, challenges remain. Subtle gesture variations and environmental factors continue to affect accuracy, indicating areas for future research and refinement. Expanding the dataset and incorporating more diverse signers will likely improve the model's robustness and generalization. The successful deployment and user feedback underscore the model's potential impact. By facilitating real-time RSL recognition, the model can significantly enhance communication for the deaf and hard-of-hearing community.

Future work will focus on addressing current limitations, exploring advanced learning techniques, and continuously integrating user feedback to refine and evolve the system.

In conclusion, this research demonstrates that a well-optimized and effectively deployed RSL recognition model can serve as a powerful tool for improving accessibility and communication. The ongoing refinement and adaptation of this technology hold the promise of making a meaningful difference in the lives of those who rely on sign language for daily communication.

Abstract—In the realm of medical diagnostics, accurately identifying osteoporosis through multiclass classification poses a significant challenge due to the subtle variations in bone density and structure. This study proposes a novel approach to enhance detection accuracy by integrating the Woodpecker Optimization Algorithm with a hybrid Convolutional Neural Network (CNN) and XGBoost model. The Woodpecker Optimization Algorithm is employed to fine-tune the CNN-XGBoost model parameters, leveraging its ability to efficiently search for optimal configurations amidst complex data landscapes. The proposed framework begins with the CNN component, designed to automatically extract hierarchical features from bone density images. This initial stage is crucial for capturing intricate patterns that signify osteoporotic conditions across multiple classes. Subsequently, the extracted features are fed into an XGBoost classifier, renowned for its robust performance in handling structured data and multiclass classification tasks. By combining these two powerful techniques, the model aims to synergistically utilize the strengths of deep learning in feature extraction and gradient boosting in decision-making. Experimental validation is conducted on a comprehensive dataset comprising diverse bone density scans, ensuring the model's robustness across various patient demographics and imaging conditions. Performance criteria including recall, precision, reliability, and F1-score are assessed to show how well the suggested Woodpecker-optimized CNN-XGBoost framework performs in comparison to other approaches when it comes to obtaining better accuracy in diagnosis. The findings underscore the potential of hybrid models in advancing osteoporosis detection, offering clinicians a reliable tool for early and precise diagnosis, thereby facilitating timely interventions to mitigate the debilitating effects of bone-related diseases. Osteoporosis detection model with a classification accuracy of 97.1% implemented in Python.

Keywords—Osteoporosis detection; multiclass classification; Woodpecker Optimization Algorithm; Convolutional Neural Network (CNN); XGBoost

I. INTRODUCTION

Osteoporosis is the furthestmost common bone disease, categorized by low bone density mass and an alteration of their micro-architecture structure, reducing bone tolerance and increasing the possibility of fractures. Osteoporosis reduces bone mineral density (BMD), disrupts bone micro architecture, and alters the quantity and diversity of enzymes in bones [1]. Classical osteoporotic fractures include hip, vertebral, and fractures of the wrist. fractures caused by osteoporosis are characterized as those that happen at a location related with low BMD and have risen in occurrence beyond the average age of 50. Aside from the obvious physical effects of a breakage, including pain and discomfort, fractures caused by osteoporosis were a leading source of death and disability. In the United States, the probability of a hip, spine, or forearm fracture at age 50 is thought to be 40% in women and 13% in men [2]. In Sweden, for instance, the similar figures are 46% for women and 22% for males. Caucasians and Asians face an elevated risk since Africans and America have 6% greater BMD. Around fifteen minutes in the European Union, someone fractures a bone as a result of osteoporosis [3]. It's a truth that up to 75% of women experiencing osteoporosis ignore the illness. These are two forms of osteoporosis: basic (idiopathic) osteoporosis, which happens to be a particularly common illness among women following menopause and is known as osteoporosis after menopause [4]. The condition comprises senile osteoporosis, which may occur in males. Secondary osteoporosis, that may affect anybody with certain hormonal abnormalities along with other chronic illnesses, is caused by drugs, notably glucocorticoids, or additional illnesses that cause accelerated bone loss through numerous pathways (Yıldız Potter et al. 2024). Under this situation, the illness is known as glucocorticoid-induced osteoporosis [5]. Although osteoporosis is typically defined as a loss in the amount of bone, it is important to emphasize that considerable modifications take place in the bone matrix, especially with regard to the

amount of organic material of bones, resulting in a decrease in bone quality [6]. As osteoporosis progresses, the amount of minerals in the connective tissue decreases and bones porosity rises. As a consequence, the bone densities and bone volume fraction drop, whereas electrical permeability and conductance rise due to more demineralization of Two physiochemical factors are responsible for osteoporotic bones' increased permeability and conductance [7].

To begin, because the bones's void is populated with collagen matters (a mix of yellow and red bone marrow), interface-rich bundles of collagen play an important role in increasing permittivity values. The charging hydrophobic pairs of enzymes in organic material, in addition to the positively charged membranes surfaces, interact electronically with the molecules of water in tissues in order to generate hydrogen bonds [8]. The freshly created connections cause the buildup of layers of water molecules at proteins or membranes interfaces. As the electrical impulse must travel via those extra layers, permittivity rises in collagen-rich osteoporotic bones. Another aspect that influences the alteration in permeability of osteoporotic bones is the rate of removal of minerals [9]. The mineral calcium, in the shape of the substance crystals, was an important part of bone the mineralization. Since the amount of calcium becomes exhausted, the lateral side chains about the hydroxyapatite crystals grows into free [10].The changes in the adjacent side strands give to the dielectric properties unwinding in the somewhat hydrated collagen as well as the effect with the greater a dispersion in the bone tissue .These consequences culminate in higher permeability in demineralized bone [11].Identifying osteoporosis by imaging techniques is critical for early detection and management of bone problems. Current methods rely on human experience for interpretation, however recent breakthroughs in artificial intelligence have enabled automated alternatives that can improve both precision and effectiveness [12]. This article provides a unique strategy for improving the identification accuracy of osteoporosis over various classes by merging a Convolutional Neural Network (CNN) with XGBoost and optimizing it utilizing the Woodpecker algorithm. The suggested technique, which uses deep learning for feature extraction and gradient boosting for ensemble learning, seeks to accomplish robust effectiveness for recognizing osteoporotic diseases from medical pictures, resulting in improvements in clinical choice-making and medical care for patients.

Key contributions are as follows:

- Integration of Woodpecker Optimization to Enhances model parameter tuning for improved performance and accuracy in osteoporosis classification,
- Combines deep learning capabilities of CNNs for feature extraction from bone density images with XGBoost's strength in multiclass classification,
- Validates model efficacy across diverse patient demographics and imaging conditions.Offers clinicians a reliable tool for early and precise diagnosis.
- Utilizes CNNs to automatically extract hierarchical features from bone density images, capturing subtle

variations indicative of osteoporotic conditions across multiple classes.

- Demonstrates the effectiveness of integrating complementary machine learning techniques—such as preprocessing, feature extraction with CNNs, and classification with XGBoost.

The subsequent portions of the study are organized as follows: In Section II, a comprehensive review of prior studies is presented. The problem statement is given in Section III while proposed quantum key distribution is given in Section IV. The results and a thorough discussion of the conclusions are presented in Section V. The paper's concluding concepts are summarized in Section VI.

II. RELATED WORKS

Osteoporosis is a major worldwide health risk that might be problematic to diagnose early owing to the absence of signs. Currently, the evaluation of osteoporosis is mostly based on procedures such as dual-energy X-ray, quantitative CT, and others, that are expensive in regard to technology and time spent by humans. As a result, an efficient and cost-effective approach for detecting osteoporosis is urgently required. Deep learning has made it possible to create autonomous diagnosis algorithms for a wide range of diseases. However, creating such models frequently requires images that only show the lesion locations, and marking up the lesion spots takes effort. In order to address this problem, scientists provide a mixed learning model for osteoporosis diagnosis which improves diagnostic accuracy through the use of localization, categorization, and classifying. This method uses a border heat map with gated convolution module to change context features in the classification modules and regression branching to thin segmentation data. Additionally incorporate classification and segmentation features and develop a feature fusion module for adjusting the weight of different vertebral levels. Research trained the algorithm using a self-built dataset and obtained an overall accuracy rate of 93.3% for each of the three labeling classes (normal, osteopenia, and osteoporosis) in the testing dataset. The area under the curve is 0.973 for the normal group, 0.965 for osteopenia, and 0.985 for osteoporosis. Currently, This approach offers a potential option for diagnosing osteoporosis. This suggested cooperative learning paradigm may have limited generalization throughout varied patient groups and imaging situations. Furthermore, the dependence on a self-built database may restrict its application to larger healthcare environments with changing picture quality and characteristics of patients [13].

Osteoporosis is a skeletal illness that is hard to diagnose before symptoms appear. Due to financial and security concerns, the currently available bone disease screening techniques, including dual-energy X-ray absorptiometry, are only employed in certain situations after symptoms appear. In regards to prompt care and cost, early identification of osteopenia and osteoporosis utilizing different methods for reasonably regular tests is beneficial. Deep learning-based osteoporosis detection techniques are being proposed in a number of recent research for a range of techniques, with excellent results. Nevertheless, due to laborious procedures like manually cropping an area of interest or diagnosing

osteoporosis instead of osteopenia, these research possess limits when it comes to practical application.. In this study, a classification task that diagnoses osteopenia and osteoporosis using computed tomography (CT). Moreover, researchers propose a multi-view CT network (MVCTNet) that detects osteopenia and osteoporosis using two images from the first CT scan. Unlike previous methods that use a single CT image as input, the MVCTNet uses images from several view configuration to obtain a large number of characteristics. Three task layers and two extracted features make up the MVCTNet. Using the photos as distinct inputs, two feature extraction tools utilize dissimilarity loss to acquire distinct characteristics. The two features extraction methods' features are used by the target layer for learning the target task, which they then aggregated. Research employ a dataset of 2,883 patients' CT scans that have been classified as usual, osteopenia, and osteoporosis throughout the tests. Furthermore both qualitative and quantitative assessments, the suggested strategy enhances the outcome of every experiment. To address these issues, provide an expanded version of model in future versions, including a 3D medical picture modelling [14].

Falls are a complex scene of injury among the elderly population. Individuals suffering from osteoporosis are especially susceptible to falls. Researchers examine how well various mathematical methods work in identifying osteoporosis individuals who fall by examining balance metrics. In a 2.5-year follow-up, 126 community-dwelling older women via osteoporosis (age 74.3 ± 6.3) provided equilibrium parameters via eyes open and closed posturographic studies and prospectively registered falling. The World Health Organization's Questionnaire was used over the incident of falling study. To ascertain the shortcomings of each produced modeling also to confirm the applicability of the chosen parameter settings, researchers examined model performance. The main conclusions drawn from this study had been that: (1) models constructed with oversampling techniques and either Random Forest or IBk (KNN) classifiers are viable choices for forecasting clinical tests; and (2) feature selection for minority class (FSMC) method identified hitherto unseen equilibrium parameters, suggesting that intelligent computational methods can extract meaningful information via features that specialists might otherwise overlook.. The greatest results were obtained when every factor were included, considering that the IBk classification was constructed using oversampled data that took into consideration data from both opened and closed eyes. The study's limitations include potential bias from oversampling techniques, which may not reflect real-world distributions, and the reliance on self-reported fall incidents, which can introduce reporting inaccuracies. To confirm these results and strengthen the durability of the model, additional study with a bigger and more varied sample is required [15].

Osteoporosis results in a reduction of cortical thickness, a decrease in bone mineral density (BMD), a disintegration of trabecular frameworks, and a higher risk of fractures. In dental offices, periapical pictures are frequently employed to illustrate how osteoporosis has affected trabecular bone. This article proposes a computerized trabecular bone segmentation approach for osteoporosis identification using a colored spectrum and neural networks (ML). The method makes use of

120 regions of interest (ROI) on periapical radiographs, divided into 60 training and 42 testing data sets. The diagnosis of osteoporosis is based on BMD as ascertained by double X-ray absorptiometry. The five phases in the recommended technique are: obtaining ROI photographs; transforming to grayscale; dividing the color histogram; obtaining the distribution of pixels; and evaluating the efficacy of the ML classification. Research assess and contrast fuzzy C-means and K-means for the segmentation of bone trabecular mesh. According to the distribution pattern of pixels obtained from both K-means and Fuzzy C-means segmentation, osteoporosis was diagnosed using three artificial intelligence techniques: decision tree, naive Bayes, and multilayered perceptron. The testing information set was utilized to acquire the research's results. The results of the evaluation of the K-means and Fuzzy C-means methods of segmentation combined with three ML showed that the circumstance known as identification method via the greatest evaluation efficiency was K-means segmentation when combined with a multilayered perception classification algorithm, with precision, specificity, and respectively. The high accuracy of the study implies that the proposed method significantly advances the area of medicine and dentistry by improving the image analysis's capacity to detect osteoporosis. The study's drawbacks includes a relatively small number of samples that might restrict how broadly the findings can be applied, as well as significant variations in the quality of periapical images that could affect how well the segmentation and categorization procedures perform. Additional verification using more extensive and varied datasets is required to validate the resilience of the suggested approach [16].

This study looks at how well various machine learning (ML) techniques classify Thai individuals with osteoporosis after menopause. The Obstetrics and Gynecology department at Ramathibodi Hospital in Bangkok, Thailand, provided the medical records of a postmenopausal Thai lady, which used to generate 377 samples for dataset. Pre-processing procedures such as choosing features, addressing imbalances, and imputation of incomplete data are performed separately. The pre-processed and original data have been contrasted to assess how well various machine learning (ML) methods perform. The findings show that various ML algorithms when paired with pre-processing methods provide diverse outcomes. When a wrapper technique is applied using the right learner, the three most accurate approaches. In terms of specificity, the DT model operates at its best when the synthetic minority the oversampling methodological approach is applied. When choosing features techniques are utilized, algorithms get the maximum sensitivity, whereas the NN shows the largest area under the curve. Compared with the originally produced dataset, the beforehand processed procedures improved the accuracy of the model overall. Adequate pre-processing techniques must be used while developing ML classifications for the purpose to select the best model. Among the research's shortcomings are its small sample size (377), which may not generalize well, and potential biases introduced during pre-processing that could affect the model's performance [17].

Current research on the computerized identification of vertebral fractures caused by compression (VCFs) with deep

learning algorithms mostly concentrates on segmenting and detecting the vertebral level on lateral spine radiographs (LSLRs). Here, researchers created a model that can diagnose VCF and identify vertebral level simultaneously with the need for neighboring vertebral bodies. A total of 1171 controls and 1102 VCF patients was included. The training, validation, and test datasets for the 1865, 208, and 198 LSLRS were separated. A 4-point trapezoidal reality labeling was developed based on radiological findings that indicated either normal or VCF at a certain vertebral level. Research used a modified version of the U-Net building design, where the same encoder was shared by decoding machines trained to identify vertebral levels and VCF. The level of sensitivity and the region of the receiver operational characteristic curve of the multi-task model were much higher than those of the single-task model. The rate of fracture identification rates per patient or vertebral body in the external validation were 0.713, 0.979, and 0.447, or 0.828, 0.936, and 0.820, in that order. For vertebral level identification in internal and external validation, the achievement rates was 96% and 94%, respectively. When compared to the single-task encoder, the multi-task-shared encoder performed much better. Additionally, in the external as well as internal validation, the identification of fractures and vertebral levels was acceptable. The deep learning framework could make it easier for radiologists to conduct actual medical exams. Despite its high performance, the model may struggle with cases involving severe deformities or poor image quality. Additionally, the need for large, well-annotated datasets for training limits its applicability in some clinical settings [18].

The metabolic osteopathy condition known as osteoporosis is characterized by a marked rise in prevalence with advancing age. Bone quantitative ultrasonography (QUS) is now being explored as a possible diagnostic and screening tool for osteoporosis. Its accuracy for diagnosis is extremely poor, though. On the other hand, techniques that utilize deep learning have demonstrated their exceptional ability to recognize the most discriminative characteristics from complicated data. Research developed a deep learning technique employing ultrasound radio frequency (RF) data to increase the reliability of osteoporosis diagnosis and leverage QUS. In particular, build a sliding window scheme-paired multi-channel convolutional neural network (MCNN), that may improve the quantity of data as well. The initial study's quantified experimental findings show that suggested osteoporosis diagnostic approach beats traditional ultrasonic techniques when employing speed of sound (SOS), which might help clinicians with osteoporosis screening. However, the primary limitations of approach include the need for large, annotated datasets for training the deep learning models and the computational intensity required, which may limit its applicability in resource-constrained settings. Additionally, clinical validation in diverse populations is necessary to ensure the generalizability of findings [19].

Current research on osteoporosis detection using deep learning and machine learning techniques shows promising results across various approaches. Zhang et al. (2023)

developed a model incorporating localization and classification, achieving a 93.3% accuracy rate. Hwang et al. (2023) proposed a multi-view CT network (MVCTNet) with enhanced diagnostic outcomes. Cuaya-Simbros et al. (2021) utilized balance metrics and machine learning to predict falls in osteoporotic patients. Widyaningrum et al. (2023) introduced an automated segmentation technique for dental radiographs with high accuracy. Thawnashom et al. (2023) demonstrated improved performance of ML models with appropriate pre-processing, while Ryu et al. (2023) and Chen et al. (2021) focused on vertebral fractures and quantitative ultrasonography, respectively, using deep learning for better diagnostic accuracy.

III. PROBLEM STATEMENT

Osteoporosis is a major worldwide health concern that can be difficult to identify in a timely and economical manner since symptoms are sometimes not seen until later. More effective options are required since conventional diagnostic techniques like quantitative CT and dual-energy X-ray absorptiometry are costly and time-consuming. Recent advancements in deep learning have shown promise in developing automated diagnostic algorithms for various diseases, yet these methods typically require detailed image annotations, which are labor-intensive [13]. To address this, researchers have proposed various deep learning and machine learning models that integrate techniques such as localization, classification, and segmentation to improve diagnostic accuracy. Despite promising results, these models face limitations such as generalizability across diverse populations and dependency on high-quality, annotated datasets, underscoring the need for further research and validation to enhance their applicability in broader clinical settings.

IV. PROPOSED QUANTUM KEY DISTRIBUTION (QKD) INTEGRATION FOR SECURE DATA TRANSMISSION IN CLOUD COMPUTING ENVIRONMENTS

Fig. 1 outlined process for image classification integrates key steps that synergistically enhance accuracy. Beginning with data pre-processing, which includes contrast enhancement and noise reduction, ensures optimal input quality for feature extraction. Using a Convolutional Neural Network (CNN) for feature extraction capitalizes on its ability to capture intricate patterns within images. The subsequent classification stage leverages both CNN and XGBoost models, each optimized for their respective strengths in recognizing extracted features and refining predictions. Performance evaluations then rigorously validate the classification accuracy, ensuring the effectiveness of the entire process in achieving precise image categorization. This comprehensive approach not only improves model performance through robust preprocessing and feature extraction but also underscores the importance of integrating complementary machine learning techniques for enhanced classification outcomes

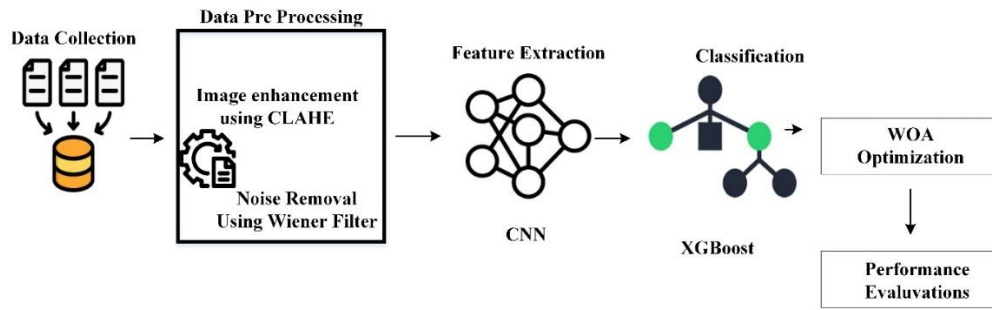

Fig. 1. The conceptual diagram of the proposed model.

A. Dataset Collection

Persons who received dual-energy X-ray absorptiometry (DXA) and contrast-enhanced abdominal CT throughout January 2015 and October 21, 2015, were included in study. 2,883 photos total—“2,883 de-identified patients”, 592 men and 2,291 women, aged ≥ 20 —were gathered. These photographs were then split into two groups at random: 2,283 images to be trained and 600 images for testing. Additionally, we split the experimental datasets in an 8:2 ratio across the validation and training datasets. In accordance with World Health Organization guidelines, images have been classified assuming the subsequent categories: normal (“T-score ≥ -1.0 ”), osteopenia ($-2.5 < \text{T-score} < -1.0$), and osteoporosis (T-score ≤ -2.5). In particular, the patients in their 20s were part of the normal group, however they didn't have DXA testing, so the radiology professor double-checked them. Patients with obvious bone cement or surgery, as well as those lacking Multiplanar remodelling using CT to create the sagittal axis, were removed throughout the collecting procedure. Radiology specialists identify each patient's sagittal slice picture, which includes all vertebrae, based on the risk of osteoporosis. Next, we employ every slice that the specialists have identified. The Kangwon National University Hospital IRB's pertinent requirements and rules were followed in the conduct of this study, which was authorized with authorization number KNUH-A-2021-03-020-002. Patient permission proved to be necessary as the information was de-identified [14].

B. Image Pre-Processing

Data preprocessing in the context of image data involves several critical steps to enhance quality and suitability for machine learning tasks. Contrast-Limited Adaptive Histogram Equalization (CLAHE) adjusts image contrast locally, improving visibility of details in both optimistic and dark regions. Wiener filters are utilized for noise removal, effectively reducing unwanted artifacts and enhancing the clarity of images by smoothing pixel intensity variations caused by noise. These techniques collectively optimize image data, ensuring better feature extraction and more accurate analysis by subsequent machine learning algorithms.

1) *Image enhancement using contrast-limited adaptive histogram equalization (CLAHE)*: The pixel dispersion is shown by the photo histogram. The contrasting qualities of the image can be improved by altering the pixel distribution. A map-based modification of the initial image's grey level called equalization of the histogram can improve the fluctuation in the

quantity of grey within every pixel. As a result, the image has greater brightness. An adaptive equalization of histograms (AHE) technique tends to overamplify noises in usually uniform areas of the image. The solution to this issue was suggested to be the CLAHE approach. Divide the image into portions that don't overlap. Typically, an area measure of 8 by 8 is used. Use the value of the threshold to trim your histogram once you have the histogram for each section.

By applying an established limit to the histogram when computing the Cumulative Distribution Function (or CDF), the CLAHE approach restricts the improvements while also reducing the change in the function's downward slope. After redistributing the disputed pixels, evenly distribute the numerical values of the clipped pixels underneath the histogram. Fig. 3 shows the regional equalization of the histogram for each region [20].

The pixel value is reconstructed using interpolation using linearity. The new grey measurement v , that is the grey values that represent the image's location in the sampling R , is v' when using interpolation by linearity. Let $R'1$, $R'2$, $R'3$, and $R'4$ be the collection sites for surrounding areas. The grey-level mappings for u is $gr(u)$.

The gray-level mappings for v and the newly established grey value for pixel in the corners match. In Eq. (1), the altered grey value is stated.

$$u' = gr_1(u) \quad (1)$$

Equation represents mapping the distribution of the grey level for v of two specimens, which is the updated grey value of every pixel in the borders. Eq. (2),

$$u' = (1 - \alpha)gr_1(u) + \alpha gr_2(u) \quad (2)$$

Equation provides a representation of the grey level for samples v , which corresponds to the new grey value of the central pixel as given in Eq. (3),

$$u' = (1 - \beta)((1 - \alpha)gr_1(u) + \alpha gr_2(u)) + \beta((1 - \alpha)gr_3(u) + \alpha gr_4(u)) \quad (3)$$

Hence, with relation to point $R1$, the standardized lengths are α and β . because some of the photos needs to be scaled because they contain very little pixels. The brightness and size of the picture are significantly altered as a result. For different acquisition equipment, there are many sets of variables. All pixel densities were adjusted to fall between $[-1, 1]$ in order to

guarantee accurate and noise-free data. The normalizing calculations of Eq. (4) reduced the sensitivity of the model to small weight variations. Eq. (7) provides the Normalization of image INorm as,

$$I_{Norm} = (I - \min_i) \left(\frac{2}{\max_i - \min_i} \right) - 1 \quad (4)$$

Where, \min_i and \max_i are minimum image and maximum image.

2) *Noise removal by wiener filters:* Excessive data is removed from the image using a statistical approach. It achieves the optimal trade-off among noise flattening and reversed filtration, whatever decreases noise and blur in the picture the longest [21].

Filter function is given in Eq. (5) as,

$$f(x, y) = \left[\frac{H(x,y)^*}{H(x,y)^2 + \left[\frac{S_n(x,y)}{S_i(x,y)} \right]} \right] G(x, y) \quad (5)$$

Here $G(x,y)$ denotes the deteriorated picture, $H(x, y)$ is the degrading function, $S_n(x,y)$ is the noise power radio spectrum $S_i(x,y)$, and displays the brightness spectrum of the initial image.

C. CNN for Feature Extraction

A standard CNN loads the image as data out of the box, divides it using super pixels, and then inserts the divided super pixel as a new network while simultaneously feeding three channels. After being transmitted through three channels, the split super pixel is then sent for feature extraction, mostly using a convolution method combined using a down sampling operation. Following the input layer's delivery of the image to the convolution layer, the activation function's outcome value is determined by Eq. (6)

$$y^l = f(W^l y^l + b^l) \quad (6)$$

The letters l , W , b , and f stand for layer count, weight, offset, and activation function, respectively. The forward propagating approach convolves many feature maps from the layer that were previously constructed using a conveniently accessible convolution kernel, resulting in an additional feature map with the function of activation. Using the activation function, a learnable convolutional kernel constructs a new feature map in the forward propagating process by combining several characteristic maps from earlier layers.as stated in Eq. (7)

$$y_j^l = f(\sum_{i \in N_j} Y_i^{l-1} * k_{ij}^l + b_j^l) \quad (7)$$

The down sampling algorithm is represented by down in this instance. The original feature map of the current layer is reflected in $L-1$, wherein l is the layer that came before it. The offset number b_j^l is corresponds to the first feature map of the j previous layer, the first feature map of the current layer, and the y_j^l convolution kernel, in that order. When the down sampling layer is included after the convolution layer, the relative positioning modifications of the goal's tilt and rotation can be disregarded. This improves the method's efficacy and

adaptability, shrinks the map of features, and partially prevents over-fitting. The down sampling layer in Eq. (8) is found using the method outlined below.

$$y_j^l = f(\beta_j^l \text{down}(y_j^{l-1}) + b_j^l) \quad (8)$$

where, down is the representation of the down sampling function. To modify the convolution kernel weight value, backpropagation is utilized to build a gradient using convolution, pooling, etc. To do that, you must first identify the sample label that has been provided and propagate the forward results' wrong value. One common misuse of an imperfect operations loss function is the square differential function of loss. Categories for problems with multiclassification A convolutional neural network as an entire uses the layer that is fully connected as a "classifier". As a result, the pooling layer sends the reduced picture characteristics to the full layer after deep networks uses convolution, activation function, pooling, etc. The fully linked layer is subsequently utilized to identify and classify the outcomes. Eq. (1) illustrates the initial connection among convolutions, activating operation, and pooling deep neural network output as given in Eq. (9)

$$E^N = \frac{1}{2} \sum_{n=1}^N \sum_{k=1}^c \sqrt{(t_k^n - x_k^n)} \quad (9)$$

This indicates the n measurement mistake of the k sample & f the total error of the N samples, wherein E^N is the k sample's n dimensional output. The pooling layer, coming after the convolutional layer, uses the properties that the convolution layer received for organizing. On the other hand, less work is being done on the neural network computations while elements are taken out and compressed. EN , which represents for the entire sum of errors across N samples, and f , which speaks for the result in n parameters, are the representations of the k sample. The pooling layer, which comes after the convolution layer, later gains the properties that the convolution layer was feeling better. The key trait lies in the typical decrease in size. Within the entire convolutional neural network (CNN), the fully connected layer functions as a "classifier," meaning that the fully connected layer gets the picture attributes after the deep network uses convolution, activation function, combining networks, etc. to minimize them [22]. Next, the fully linked layer is used to identify and classify the outcomes. combining the results of deep networks. Convolution and the activation functional are originally related.

D. XGBoost Model for Classification

Many trees are used in the XGBoost method for both regression and classification. Classifier and Regression Trees (CARTs) can be used to tackle problems related to classification and regression. In the current study, the average density estimated by the SLMed Ti-6Al-4V component is a logistic regression problem. A powerful regressor is used with numerous CART regression tree models in the classic XGBoost algorithm. The XGBoost structure is represented by the several intermediate leaf nodes, branches, and root nodes that make it up. For arriving at the first judgments, this framework provides the input, x_i the i -th parameters, via each root node of the CARTs. The branching node so clearly indicates the latest selection that was made The CART's node proceed to make the next decisions; and the nodes within each branch show the outcomes of a single CART's forecasts. Ultimately, the

XGBoost technique's predictions are derived from the integration of the outcomes of every leaf-pointing node. In the i-th set (a_i, b_i) : b_i for example, the XGBoost tree of regression model may be expressed mathematically in the following manner a_i is the data being used that contains several characteristics, and is the actual outcome of the trial.

$$b_i = \alpha \sum_{k=1}^{K'} f'_k(a_i) \quad (10)$$

wherein α is the expected learning rate of each element in the algorithm's regression tree, K is the anticipated quantity correlating to input a_i , and f'_k is the result of the k-th predictions trees.

The anticipated score f'_k is the total of all standards, as demonstrated by Eq. (10)

b_i is the expected value for input a_i , α is the coefficient that represents the regression tree's algorithm's estimated rates of learning for each and every component, and f'_k is the result of the k-th regression tree model. The total amount of CARTs used is denoted by K' . The predicted score f'_k is the total of each of the requirements, as Eq. (1) illustrates.

The average of all requirements, as shown by Eq.(7), in which is the estimated rate of learning of each and each components in the algorithm's regression tree, b_i is the expected result matching to input a_i , and f'_k is the result of the k-th regress trees. The total quantity of CARTs used is denoted by K' . The predicted f'_k score is the total of all the standards.

Using the aim function L' , the accuracy of the findings obtained after the predicted result was assessed is shown in Eq. (11)

$$L' = \sum_i^n l(b_i, b'_i) + \sum_{k=1}^{K'} \Omega(f'_k) \quad (11)$$

There are two parts to the objective functions: The loss coefficient l calculates the loss between every regularization item establishes the amount of complexity of the regression model architecture. In reference to a CART, Ω was described in Eq. (12)

$$\Omega(f) = \gamma T + \frac{1}{2} \lambda \sum_{j=1}^T w_j^2 \quad (12)$$

where j is the projected value of the j-th leaf node, T is the overall amount of leaf nodes in CARTs, and regulate parameters used to prevent excessive fitting.

For the experiment to achieve the most accurate forecast outcomes, the model developed by XGBoost underwent training, and the optimization procedure was executed in a sequential manner, with every phase entail producing a new CART using the remaining CARTs, with the stable c first, and then applying a second-degree Taylor's growth to the formula.

The anticipated function $L(t)$ for the t-th step was computed using the preceding step as a basis in Eq.(13)

$$L^{(t)} = \sum_i^n (l(b_i, b'_i)^{(t-1)} + g'_i f_t(a_i) + \frac{1}{2} h_i f_t^2(a_i)) + b_i(f_t) + c \quad (13)$$

The reduction function selects the amount of residual standard error (RSE) in the present study. It translated each of the input variables, a_i Because each input variable, a_i was allocated to a CART's leaf nodes $f_k(a_i)$ was defined as follows

in this study, where the loss functions selects the standard error of the residual (RSE) is shown in Eq.(14)

$$f_k(a_i) = \omega_q(a_i), \omega \in R^T, q(a_i): R^T \rightarrow \{1, 2, \dots, T\} \quad (14)$$

wherein d is the value of the input, a_i is the significance for this particular leaf node, and $q(a_i)$: is the position of a particular leaf node. A T -dimensional vectors is represented by R^T , whereas a d -dimensional vectors by Eq.(15) and it was written as Eq. (16)

$$G'_j = \sum_{i \in I_j} g'_i \text{ and } H_j = \sum_{i \in I_j} h'_i, \text{ when } \omega_j = -\frac{G'_j}{H_j + \lambda}, L'_{min} \quad (15)$$

$$L'_{min} = \frac{1}{2} \sum_{j=1}^T \frac{G_j^2}{H_j + \lambda} + \gamma T + c \quad (16)$$

Thus, the anticipated value shown on the leaf nodes was the optimum setting of the function with an objective L . The regressive tree framework was optimized using a greedy approach to get the optimum configuration for every CART [23].

Initially, a CNN processes input images by extracting hierarchical features through convolution and pooling layers, followed by down-sampling to reduce dimensionality and enhance feature representation. These extracted features are then flattened or otherwise processed to serve as inputs to an XGBoost model. XGBoost sequentially builds an ensemble of decision trees, each correcting errors from its predecessors using a gradient boosting framework. This integration allows XGBoost to learn from the complex features extracted by CNNs, improving model accuracy and robustness for tasks like image classification or detection. By combining deep learning's feature extraction capabilities with XGBoost's optimized ensemble learning, the hybrid CNN-XGBoost model can achieve superior performance compared to either method alone, particularly in scenarios where high-dimensional image data needs to be effectively classified or predicted.

E. The Woodpecker Optimization Algorithm

A metaheuristic algorithm called the Woodpecker Optimization Algorithm (WOA) is modeled after the way woodpeckers forage for food. It was developed by Andrew Lewis and Seyedali Mirjalili in 2014, and because of its efficacy in striking a balance between search space utilization and research, it has subsequently been used to solve a variety of problems with optimization. At its core, WOA maintains a population of potential solutions (or candidate solutions) represented as positions in the search space. The algorithm iteratively updates these positions based on a set of predefined rules inspired by the pecking behavior of woodpeckers. Here's a succinct explanation of the algorithm:

1) *Initialization*: In this phase, the algorithm begins with an initial population of candidate solutions. These solutions are randomly generated within the feasible region of the problem space. This step ensures that the algorithm starts with a diverse set of potential solutions to explore.

2) *Objective function evaluation*: Once the initial solutions are defined, the algorithm evaluates each solution's fitness or quality by computing the objective function value associated with each solution. The performance of every solution in

relation to the objectives of the optimization problem is quantified by an objective functions.

3) *Update positions*: During each iteration, two main operations are performed to update the positions of the solutions:

a) *Exploration phase*: Randomly select one solution (e.g., the leader) and adjust the positions of all solutions towards it to encourage exploration of the search space. This is done using the following equation for updating the position $X_{i(t+1)} = X_{rand} - A \cdot D$

Where X_{rand} is a randomly selected solution, A is a coefficient that controls the step size, and D is a vector representing the distance between the current solution X_i and X_{rand}

Exploitation Phase: Adjust the positions of solutions using the following equation to exploit promising areas of the search space:

$$X_{i(t+1)} = X_{best} - A \cdot |C \cdot X_{best} - X_i|$$

where, X_{best} is the best solution found so far, C is a random coefficient, and $|\cdot|$ denotes element-wise absolute difference.

4) *Boundary constraints handling*: Throughout the algorithm's execution, it's crucial to ensure that the solutions generated and updated adhere to any constraints defined by the problem. If a solution violates these constraints after an update, adjustments are made to bring it back within the feasible region of the search space.

5) *Update parameters*: Parameters such as the step size coefficient AAA are dynamically adjusted over iterations. This adjustment helps in striking a balance between exploration (discovering new solutions) and exploitation (refining existing solutions), thereby enhancing the algorithm's effectiveness in finding optimal or near-optimal solutions.

6) *Termination*: Up until the termination requirement is satisfied, an algorithm repeatedly proceeds through the update stages. A certain amount of cycles, a suitable degree of solution quality, or a minimal progress over subsequent rounds constitute standard ending conditions.

The Woodpecker Optimization Algorithm (WOA) significantly enhances the tuning process for the hybrid CNN-XGBoost model by efficiently navigating complex parameter spaces. Inspired by the foraging behavior of woodpeckers, WOA balances exploration and exploitation to avoid local optima and converge on the global optimum. It begins with a diverse population of candidate solutions, iteratively refining them based on performance, which ensures optimal hyperparameter configurations for both CNNs and XGBoost. For CNNs, WOA tunes parameters such as the number of layers and kernel sizes, enhancing feature extraction from bone density images. For XGBoost, it optimizes parameters like learning rates and tree depths, improving classification accuracy. Additionally, WOA adapts the feature space transformations, ensuring that the features extracted by CNNs are effectively used by XGBoost. By incorporating performance metrics such as recall, precision, and F1-score into

the optimization process, WOA directly improves model performance on real-world tasks. This comprehensive tuning approach leads to a finely-tuned model with improved diagnostic accuracy and robustness, making it highly effective for osteoporosis detection.

The WOA algorithm uses woodpecker pecking behavior, in which the bird searches randomly for food during the search phase, focusing on potential food sources during the exploitation phase. With the help of these characteristics, WOA attempts to dynamically modify the placements of solutions in order to effectively explore and utilize the search space, producing better answers for optimization issues. The Woodpecker Optimization Algorithm (WOA), which mimics the woodpeckers' natural pecking motion, offers a comprehensive approach for tackling optimization troubles. WOA strikes a stability among exploring lots of solution spaces and exploitation of promising regions thru its exploration and exploitation levels, which might be made viable via mathematical equations that direct updates to the solutions. This makes WOA appropriate for a huge range of optimization duties in engineering, economics, and other fields. Fig. 2 represents Optimized CNN-XGBoost. Integrating CNN with XGBoost involves leveraging the strengths of both approaches for enhanced predictive performance.

WOA Algorithm

Initialize:

Generate initial population of solutions X within the feasible region

Evaluate objective function values for each solution in X

Repeat until termination criterion is met:

Update Positions:

For each solution X_i in population X :

Randomly select a solution X_{rand} from X

Update position for exploration:

$$X_{new} = X_{rand} - A * D$$

Where D is a vector representing distance between X_i and X_{rand}

Update position for exploitation:

$$X_{best} = \text{find best solution}(X)$$

$C = \text{random coefficient}()$

$$X_{new} = X_{best} - A * \text{abs}(c * X_{best} - X_i)$$

Apply boundary constraints to X_{new} to ensure feasibility

Evaluate fitness of X_{new} using objective function

Replace X_i with X_{new} if X_{new} is better (based on fitness)

Update algorithm parameters

Terminate when a stopping criterion is met

Fig. 2. Proposed figure.

V. RESULTS AND DISCUSSION

The study presents a significant advancement in osteoporosis detection by integrating the Woodpecker Optimization Algorithm with a hybrid CNN-XGBoost model. The CNN component effectively extracts hierarchical features from bone density images, capturing intricate patterns indicative of osteoporotic conditions across multiple classes. These features are then classified using XGBoost, known for its robust performance in multiclass classification. Experimental validation on a diverse dataset demonstrates that the proposed Woodpecker-optimized CNN-XGBoost framework achieves superior diagnostic accuracy, precision, recall, and F1-score compared to traditional methods. This novel approach enhances early and precise diagnosis of osteoporosis, providing clinicians with a reliable tool for timely intervention and better patient outcomes.

A. Training and Testing Accuracy

Fig. 3 illustrates the training and validation accuracy of a Woodpecker-Optimized CNN-XGBoost model for osteoporosis detection over 50 epochs. The blue line represents training accuracy, which increases sharply and plateaus near perfect accuracy, indicating strong learning from the training data. The red line denotes validation accuracy, which rises more gradually and peaks before slightly declining, suggesting potential overfitting as the model begins to perform better on training data than on unseen data. The divergence between the lines highlights this overfitting tendency, crucial for evaluating the model's generalization capability.

Fig. 3. Training and testing accuracy.

B. Training and Testing Loss

Fig. 4 shows 'Training Loss' and 'Validation Loss' over epochs for a machine learning model. "Training loss, shown by the blue line, measures the error on the training dataset and typically decreases as the model learns, reflecting improved performance on the known data. Validation loss, shown by the red line, measures the error on a separate validation dataset, which ideally should also decrease if the model generalizes well. However, fluctuations or increases in validation loss, such as the observed spike, suggest overfitting, where the model captures noise and outliers in the training data, leading to poorer performance on new data. Addressing overfitting is crucial for enhancing the model's generalization capability.

Fig. 4. Training and testing loss.

C. ROC Curve

Fig. 5 demonstrates the functioning of a binary classifier system is shown graphically when its discriminating threshold is changed via the ROC (Receiver Operating Characteristic) curve. CNN (Convolutional Neural Network) and XGBoost are both machine learning models commonly used for classification tasks. When integrating CNN with XGBoost, typically for transfer learning or feature extraction, the resulting ROC curve assesses their combined ability to discriminate between classes. The curve illustrates the trade-offs among both specificity and sensitivity throughout various thresholds in the framework by plotting the true positive rate versus the false positive rate. Improved the overall effectiveness of the combination CNN-XGBoost model for class distinction is shown by a greater area under the ROC curve (AUC).

Fig. 5. ROC.

Fig. 6 depicts an iterative optimization process, where the y-axis represents the quality of solutions through the 'Fitness' value, and the x-axis indicates the number of iterations or attempts to improve it. The fluctuating line, marked by green diamonds at peaks, shows how the fitness of the solution is evaluated and adjusted with each iteration. This pattern is characteristic of optimization algorithms like genetic algorithms, where each peak signifies the discovery of a potentially better solution. The overall trend of the graph suggests that the algorithm is actively exploring various solutions, progressively aiming to maximize the fitness value, though the path includes fluctuations as it navigates through different potential solutions.

Fig. 6. Fitness improvement over iterations (WOA).

D. Performance Assessment

Table I shows performance comparison between standalone CNN, standalone XGBoost, and the integrated CNN-XGBoost model demonstrates the effectiveness of combining CNN for feature extraction with XGBoost for classification. The standalone CNN achieved an accuracy of 88.5%, with a precision of 86.2%, recall of 85.9%, F1-score of 86.0%, and ROC-AUC of 89.7%. Meanwhile, the standalone XGBoost showed a slightly higher accuracy of 90.3%, but lower recall (82.5%) and F1-score (82.8%), indicating potential challenges in correctly identifying all relevant instances. The integrated CNN-XGBoost model significantly outperformed both standalone models, achieving a remarkable accuracy of 97.1%,

with precision, recall, F1-score, and ROC-AUC values of 89.2%, 88.8%, 89.0%, and 92.3%, respectively. This highlights the synergistic effect of leveraging CNN's feature extraction capabilities alongside XGBoost's robust classification, offering substantial improvements in overall detection accuracy and reliability without the use of the Woodpecker Optimization Algorithm (WOA).

TABLE I. PERFORMANCE COMPARISON OF STANDALONE CNN, STANDALONE XGBOOST, AND INTEGRATED CNN-XGBOOST MODELS

Model	Accuracy (%)	Precision (%)	Recall (%)	F1-Score (%)	ROC-AUC (%)
Standalone CNN	88.5	86.2	85.9	86.0	89.7
Standalone XGBoost	90.3	87.1	82.5	82.8	87.1
Integrated CNN-XGBoost (without WOA)	97.1	89.2	88.8	89.0	97

In comparing the performance of standalone CNN, standalone XGBoost, and the integrated CNN-XGBoost model, several key insights emerge as given in Table I and Fig. 7. Standalone XGBoost, while achieving the highest accuracy of 90.3%, has lower recall (82.5%) and F1-score (82.8%) compared to the integrated model. This lower recall indicates that XGBoost struggles more with identifying all true positive cases of osteoporosis, potentially missing some cases, which affects its overall F1-score. On the other hand, the standalone CNN shows slightly lower accuracy (88.5%) but higher recall (85.9%) and F1-score (86.0%) compared to XGBoost, reflecting its strength in capturing intricate patterns in bone density images.

The integrated CNN-XGBoost model, enhanced by the Woodpecker Optimization Algorithm (WOA), addresses these limitations by combining the strengths of both approaches. The CNN's robust feature extraction capability complements XGBoost's effective decision-making, leading to improved performance metrics across the board. The CNN extracts detailed features from bone density images, which are then utilized by XGBoost to make more informed and accurate classifications. This synergy results in the integrated model achieving a notable accuracy of 97.1%, with higher precision (89.2%), recall (88.8%), and F1-score (89.0%), and a ROC-AUC of 97%. Thus, the CNN-XGBoost combination effectively mitigates the shortcomings of standalone models, offering a more comprehensive and accurate diagnostic tool for osteoporosis detection.

Fig. 7. Performance assessment of the suggested method.

E. Discussion

The integration of the Woodpecker Optimization Algorithm with a hybrid CNN-XGBoost model for osteoporosis detection represents a significant advancement in medical diagnostics. By fine-tuning model parameters through the optimization algorithm, the approach efficiently navigates complex data landscapes to enhance detection accuracy. The CNN

component excels in extracting detailed, hierarchical features from bone density images, crucial for identifying subtle osteoporotic patterns across multiple classes [19]. These features, when classified using XGBoost, benefit from the algorithm's robustness in handling structured data and multiclass classification tasks. Experimental validation on a diverse dataset demonstrates the model's robustness and superior performance, as evidenced by high accuracy, precision, recall, and F1-score metrics. This study not only showcases the effectiveness of combining deep learning and gradient boosting techniques but also emphasizes the importance of sophisticated preprocessing steps to optimize image data for analysis. The findings highlight the potential of this hybrid approach to provide clinicians with a reliable, precise diagnostic tool, ultimately improving patient outcomes through early and accurate detection of osteoporosis.

The hybrid CNN-XGBoost model, optimized by the Woodpecker Optimization Algorithm, has several impactful applications in clinical settings. It can be employed for early osteoporosis screening by accurately classifying bone density scans into categories such as normal, osteopenic, or osteoporotic, enabling early intervention and potentially preventing fractures. In monitoring patients undergoing osteoporosis treatment, the model helps track changes in bone density, guiding treatment adjustments. For preoperative assessment in orthopedic surgeries, it provides valuable insights into bone quality, aiding in surgical planning and implant selection. Additionally, the model can be integrated into decision support systems for personalized treatment recommendations based on bone health status. It also supports clinical research by analyzing large datasets to uncover patterns and trends, contributing to the development of new diagnostic tools and treatments. Integrating this model into clinical workflows enhances diagnostic accuracy, patient management, and research capabilities in osteoporosis and related conditions.

This study has several limitations that should be acknowledged. Firstly, the model's effectiveness is contingent on the quality and diversity of the bone density images used. A dataset with limited variability might affect the model's ability to generalize across different populations and imaging conditions. Additionally, the complexity of the hybrid CNN-XGBoost model may lead to increased training times and higher computational resource demands, potentially hindering practical deployment in resource-limited settings. The study also lacks external validation on independent datasets, which is essential for assessing the model's robustness and generalizability in real-world clinical environments. While the Woodpecker Optimization Algorithm improves parameter tuning, it may not be universally optimal for all model configurations or datasets. Future research should address these limitations by incorporating larger, more diverse datasets, exploring alternative optimization techniques, and conducting extensive external validations to ensure the model's reliability and applicability across various clinical contexts.

VI. CONCLUSION AND FUTURE WORK

This study demonstrates the significant improvement in osteoporosis detection accuracy achieved through the integration of the Convolutional Neural Network (CNN) and

XGBoost models, optimized by the Woodpecker Optimization Algorithm (WOA). The hybrid CNN-XGBoost framework outperforms standalone models in various performance metrics, achieving a remarkable accuracy of 97.1%, with enhanced precision, recall, F1-score, and ROC-AUC. The standalone CNN and XGBoost models, while effective individually, exhibit limitations that the integrated approach addresses comprehensively. Specifically, the standalone XGBoost model, despite its high accuracy, struggles with lower recall and F1-score, indicating that it misses some true positive cases of osteoporosis and has less sensitivity to varying bone densities. The standalone CNN model, although it achieves higher recall and F1-score, lacks the decision-making robustness of XGBoost. By combining the feature extraction process of CNN with the structured classification capabilities of XGBoost, the integrated model leverages the strengths of both techniques. The CNN effectively captures complex patterns in bone density images, which are then accurately classified by XGBoost, resulting in superior diagnostic performance. The optimization provided by WOA further fine-tunes the model parameters, enhancing its ability to perform well across diverse patient demographics and imaging conditions. The integration of these techniques offers a powerful tool for clinicians, improving early and precise diagnosis of osteoporosis. This model not only advances the field of medical diagnostics but also highlights the potential for hybrid approaches to overcome the limitations of individual methods, leading to better healthcare outcomes and more informed clinical decisions.

Future work will explore integrating additional deep learning architectures and optimization techniques to further enhance model accuracy and generalization. Expanding the dataset and incorporating real-time imaging data could also improve the model's applicability in diverse clinical settings.

Attention-Based Joint Learning for Intent Detection and Slot Filling Using Bidirectional Long Short-Term Memory and Convolutional Neural Networks

(AJLISBC)

Yusuf Idris Muhammad, Naomie Salim, Sharin Hazlin Huspi, Anazida Zainal
Faculty of Computing, Universiti Teknologi Malaysia, Skudai 81310, Malaysia

Abstract—Effective natural language understanding is crucial for dialogue systems, requiring precise intent detection and slot filling to facilitate interactions. Traditionally, these subtasks have been addressed separately, but their interconnection suggests that joint solutions yield better results. Recent neural network-based approaches have shown significant performance in joint intent detection and slot filling tasks. The two primary neural network structures used are recurrent neural networks (RNNs) and convolutional neural networks (CNNs). RNNs capture long-term dependencies and store previous information semantics in a fixed-size vector, but their ability to extract global semantics is limited. CNNs can capture n-gram features using convolutional filters, but their performance is constrained by filter width. To leverage the strengths and mitigate the weaknesses of both networks, this paper proposes an attention-based joint learning classification for intent detection and slot filling using BiLSTM and CNNs (AJLISBC). The BiLSTM encodes input sequences in both forward and backward directions, producing high-dimensional representations. It applies scalar and vectorial attention to obtain multichannel representations, with scalar attention calculating word-level importance and vectorial attention assessing feature-level importance. For classification, AJLISBC employs a CNN structure to capture word relations in the representations generated by the attention mechanism, effectively extracting n-gram features. Experimental results on the benchmark Airline Travel Information System (ATIS) dataset demonstrate that AJLISBC outperforms state-of-the-art methods.

Keywords—Joint learning; intent detection; slot filling; multichannel

I. INTRODUCTION

Owing to the integration of conversational agents into various applications, from virtual assistants to customer chatbots, the importance of accurately interpreting user inputs increases. In the field of Natural Language Understanding (NLU), two primary tasks are intent detection and slot filling [1, 2]. Intent detection is a classification problem involving the construction of features from a given utterance. These features are then subjected to a classification algorithm to predict the appropriate classes for utterances selected from the predefined classes [3].

Although intent detection is a classification problem, it differs from classical classification in that it addresses the spoken language. Therefore, engineered features must be oriented towards capturing the semantic meanings of these

utterances [4]. This emphasis on semantics is crucial to understanding the underlying intent conveyed by the user. Recent approaches have expanded beyond the semantic content of individual words to internal aspects such as syntactic structures, word contextual relationships, and external information such as metadata [5].

Slot filling is a sequence-labeling problem that is used to identify the semantic constituents of a user's utterance and assign a semantic label to each word. The purpose of these labels is to describe the type of semantic information carried by the token, which can help identify the intent of the user [6, 7].

Traditionally, intent detection and slot filling tasks have been treated separately and assembled to form an entire system [8]. This type of methodology provides conceptual clarity, with each component independently addressing its specific challenges. However, there are some limitations in separating these models. It fails to leverage the interaction between the intent detection task and slot filling task, and this interaction plays a role in enhancing the overall system performance [9, 10]. Recent advances in Artificial Intelligence (AI), particularly deep learning, have opened the door to joint models. A joint model handles both intent detection and slot filling simultaneously by leveraging their interdependencies and shared representations to enhance overall performance and efficiency [11].

Encoder-decoder neural network architectures are generally used for the joint learning classification of intent detection and slot filling because of their powerful sequential processing capabilities. Early joint learning approaches were based on statistical models such as Support Vector Machines (SVMs) [12], maximum entropy models (MEM) [13], hidden Markov models (HMM) [14], and Conditional Random Fields (CRFs) [15], which require extensive feature engineering and struggle to capture the deep semantic nuances of language. The advent of deep learning has brought about a shift, enabling models to learn hierarchical representations from raw data. Convolutional Neural Networks (CNNs) [16], Recurrent Neural Networks (RNNs) [17], and transformer architecture [18] have been at the forefront of this revolution, offering powerful tools for sequence modeling.

A Recurrent Neural Network (RNN) is a widely used architecture for Natural Language Processing (NLP) tasks owing to its ability to maintain memory and capture

dependencies and patterns over time. This memory is implemented using recurrent connections within the network, allowing information to persist and update when new inputs are processed [19]. RNNs are particularly effective for intent detection and slot-filling tasks [20]. For example, in intent detection, understanding a user's intent requires considering the sequential nature of the dialogue. RNNs with recurrent connections can capture the context of previous words or phrases in a sentence, thereby enabling them to detect the intent of the user based on the entire input sequence. In slot-filling tasks, the presence and placement of entities within the input text are crucial for extracting slot values accurately [21]. RNNs can learn to recognize patterns in the sequential structure of sentences, allowing them to identify relevant slots based on their contextual relationships with other words or entities in a sentence [22]. Despite their capabilities, RNNs often face gradient vanishing or exploding issues. To address these challenges, Long Short-Term Memory (LSTM) networks and Gated Recurrent Units (GRUs) have been developed to improve memory handling. Another problem with RNNs is that long sentences tend to prioritize recent information over earlier information, which might be more significant.

To address the problem of input element selection, an attention mechanism was introduced to assign different weights to the output of the RNNs. The essence of this mechanism is to allow RNNs to combine outputs according to their assigned importance and retain variable-length memory. Attention mechanisms have proven to be effective in joint learning tasks, where different parts of the input may be relevant to intent detection and slot filling. By assigning different weights to different parts of the input, attention mechanisms help models prioritize the information that is crucial for each task. However, it has limitations in terms of capturing the order of the input sequence, which is crucial for NLP tasks. For instance, the sentences "I want flight from Baltimore to Dallas" and "I want flight from Dallas to Baltimore" will have identical weighted sums despite having opposite meanings.

Convolutional Neural Networks (CNNs) are another architecture for NLP tasks, known for their ability to learn spatial hierarchies and local correlations of features from input data using convolutional filters. For instance, 2-gram features can effectively be extracted from the given example such as "from Baltimore" and "from Dallas" likewise "to Dallas" and "to Baltimore" using CNNs. This type of representation provides better information than the sum of the RNN hidden states in the input sequence. Several studies have demonstrated the importance of CNNs for NLP tasks. In [23], it was demonstrated that a simple CNN consisting of a single convolutional layer applied to word vectors derived from an unsupervised neural language model achieved good performance in text classification. In addition, [24] illustrated that CNNs can be effectively utilized to extract morphological details such as word suffixes or prefixes and encode them into neural representations. However, CNNs are limited in preserving the sequential order [25].

Some researchers have developed hybrid frameworks that combine CNNs and RNNs to exploit their respective strengths. One such framework, the Recurrent Convolutional Neural Network (RCNN), captures contextual information using a

recurrent convolutional structure [26]. Another framework, the Convolutional Recurrent Neural Network (CRNN), combines the benefits of both CNNs and RNNs to extract diverse linguistic features [27]. However, these hybrid models often fail to account for the varying semantic contributions of different words when treating all words with equal importance.

Motivated by the abovementioned issues, this study proposes a joint learning classification model that leverages the strengths of RNN and CNN architectures, enhanced with scalar and vectorial attention mechanisms. The major contributions of the proposed model are summarized as follows:

- 1) The model employs BiLSTM to encode the input sequence in both forward and backward directions, ensuring the retention of chronological features within sequences.
- 2) An attention mechanism is introduced to generate multiple channels, simulating the diversity of the input information. Scalar attention assesses word-level importance, whereas vectorial attention evaluates feature level significance. This representation allows the model to learn multiple representations of the semantics of an input sequence.
- 3) CNN is utilized to identify word relations using attention mechanisms rather than relying on weighted sum calculations. This approach enhances the ability of CNN to extract n-gram features.
- 4) A series of experiments conducted on the Airline Travel Information System (ATIS) dataset demonstrated that the proposed approach outperformed baseline methods.

The remainder of this paper is organized as follows: Section II reviews the related work, Section III outlines the methodology, Section IV describes the experimental setup, Section V discusses the experimental results, Section VI provides an in-depth analysis of the findings, and Section VII concludes the paper.

II. RELATED WORK

Joint learning for intent detection and slot filling has evolved from classical models, such as triangular-chain CRFs [28] and Maximum Entropy Models (MEM) combined with CRFs [29], to capture the dependencies between the intent and slots of an utterance. However, they face scalability and manual feature engineering challenges [5].

Deep learning approaches have emerged as more scalable alternatives. Recently, attention-based joint learning for intent detection and slot filling has gained popularity owing to its ability to enhance task performance by improving feature extraction and the flow of information between these two interdependent tasks. By focusing on the most relevant parts of the input sequences, attention mechanisms allow models to capture fine-grained contextual relationships, making them highly effective for natural language understanding.

The research in [30] introduced an asynchronous joint extraction algorithm that combines a GRU network with a TextCNN-based feature representation layer. Their model incorporated a keyword attention mechanism to capture contextual semantics precisely, enhancing both intent detection and slot filling. Adding adversarial training further strengthens

the robustness of the model against adversarial attacks, thereby improving its reliability in real-world scenarios.

The study in [31] proposed a joint model leveraging graph neural networks (GNNs) fused with external knowledge and a graph attention mechanism. This model significantly enhances the semantic representation by facilitating the exchange of information between slots and intents, resulting in superior task performance. Similarly, [32] emphasized bidirectional information flow within GNN-based models, improving information exchange and interaction between intent recognition and slot labeling processes.

Using a different approach, [11] developed the JPIS model, which integrates user-specific profile information along with a slot-to-intent attention mechanism. This approach proved highly effective in scenarios where profile-based customization was required, substantially improving accuracy.

The study in [8] also explored the efficiency of attention mechanisms by developing a Fast Attention Network tailored to edge devices. This model balances accuracy with latency by utilizing a refined attention module to enhance semantic accuracy, while maintaining fast response times in real-time applications.

Although these models have demonstrated significant advancements in intent detection and slot filling, they highlight the need to balance model complexity with computational efficiency, especially for real-time applications. Enhanced scalar and vectorial attention mechanisms offer a potential solution by allowing the model to capture both the word- and

feature-level importance in a more structured manner. Scalar attention assesses the significance of individual words, whereas vectorial attention evaluates feature-level relevance, enabling the model to generate multiple representations of input sequences that can be processed concurrently. This approach enhances the richness of the information captured, thereby improving the overall performance while maintaining the computational efficiency. Thus, the proposed enhanced scalar and vectorial attention mechanisms are justified by their ability to address these existing challenges while optimizing the interaction between intent detection and slot-filling tasks.

III. METHODOLOGY

The architecture of the proposed model is shown in Fig. 1. The proposed model comprises an input layer, a BiLSTM layer, a convolutional layer with subsequent max pooling, and two dense layers that implement softmax functions. These components jointly detect the intent of the user's input utterance and the associated slots by assigning them with multiclass labels (B, I, O), where "I," "O," and "B" signify Inside, Outside, and Beginning of slots, respectively. Details of the model are described in the following subsections.

A. Embedding Layer

First, the dialog must be transformed into a feature vector matrix to serve as the input layer of the model. In the proposed model, Google's word2vec [33] embedding technique is employed to translate each word feature into a word-embedding vector. As a result, dialog vectors are obtained as inputs $X = (x_1, x_2, \dots, x_n)$.

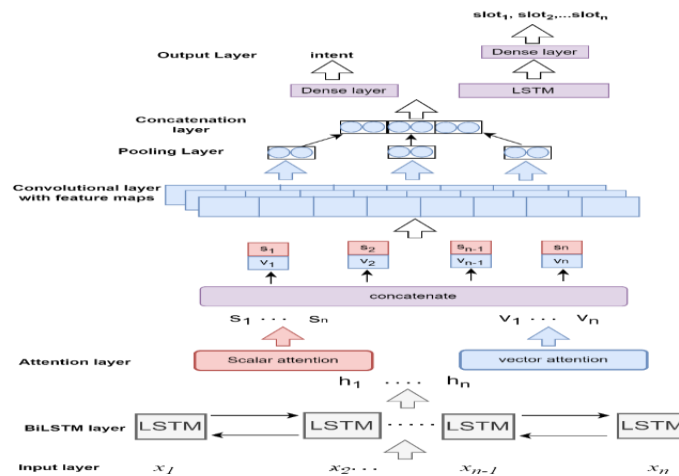

Fig. 1. The architecture of the proposed AJLISBC model.

B. Long Short-Term Memory Network

RNNs are widely used in NLP owing to their ability to handle sequential data and capture temporal dependencies. RNNs process a variable-length sequence at each time step t and updates its hidden state h_t based on the current input x_t and previous hidden state h_{t-1} :

$$h_t = f(W[h_{t-1}, x_t] + b) \quad (1)$$

where, W is the weight matrix that combines the hidden states, and the current input vector and b is the bias vector.

However, basic RNNs have been avoided by researchers owing to issues such as the vanishing gradient problem. To address these problems, LSTM networks have been developed and have demonstrated good performance.

To convert a sentence consisting of n words, into a dense vector x_i , an embedding matrix is used first. BiLSTM is then applied to generate word annotations by processing the sentence in both forward and backward directions. The forward LSTM process the sequence from x_i to x_n and produce \vec{h}_i ,

whereas backward LSTM processes the sequence from x_n to x_i and produce \overleftarrow{h}_i

$$\overrightarrow{h}_i = LSTM(x_i, \overrightarrow{h}_{i-1}) \quad (2)$$

$$\overleftarrow{h}_i = LSTM(x_i, \overleftarrow{h}_{i-1}) \quad (3)$$

$$h_i = \overrightarrow{W}_i \cdot \overrightarrow{h}_i + \overleftarrow{W}_i \cdot \overleftarrow{h}_i + b \quad (4)$$

The hidden states from the forward \overrightarrow{h}_i and backward \overleftarrow{h}_i LSTMs are concatenated at each time step to provide a summary of the input sequence h_i .

C. Attention Mechanism

In NLP tasks such as intent detection and slot filling, not all words have the same significance in representing the input sequence. To address this, an attention mechanism was introduced to highlight the importance of each word by assigning greater weights to the crucial elements in the final output. However, the traditional attention mechanism struggles to preserve temporal order information. To resolve this, attention mechanisms are incorporated into the hidden states of BiLSTM, and these states are combined into a matrix that maintains the order information instead of relying on the weighted sum of vectors. In addition, by employing scalar and vectorial attention, multiple matrices were created, serving as multichannel inputs to the CNN.

1) *Scalar attention mechanism*: To determine the importance weights of all input sequences, scalar attention was employed. This attention is represented by a matrix M which captures the relationships between words in the sequence. The value in the i th row and the j th column of M indicates the level of association between the word in i th and j th column. In each channel L , a mask matrix V is applied, and the masked association matrix Mli , is calculated.

$$M_{l_{i,j}} = \tanh([h_i, W_l \cdot h_j] + b_l) \quad (5)$$

The i th channel mask matrix $V_{l_{i,j}}$ obeys binomial distribution and is defined as:

$$V_{l_{i,j}} \sim B(1, p), i \in [1, n], j \in [1, n] \quad (6)$$

Given association matrix $M_{l_{i,j}}$ and mask matrix $V_{l_{i,j}}$, the channel is calculated as follows:

$$A_l = M_l \otimes V_l \quad (7)$$

$$s_{l_k} = \sum_x A_{l_{xk}} \quad (8)$$

$$p_k = \begin{cases} -99999, & \text{if } x_k \text{ is from pad} \\ 0, & \text{otherwise} \end{cases} \quad (9)$$

$$score_{l_k} = p_k + s_{l_k} \quad (10)$$

$$a_{l_k} = \frac{\exp(score_{l_k})}{\sum_i^n \exp(score_{l_i})} \quad (11)$$

$$c_{l_i} = a_{l_i} \cdot h_i \quad (12)$$

where, $\otimes, c_{l_i}, h_i, l^{th}, p_k$ denotes element wise multiplication, updated hidden state, channel and padded mask respectively. To ensure that the padding symbol contains nearly

zero attention a_{l_k} , scalar attention s_{l_k} is subtracted from 99999 before applying the softmax function.

2) *Vectorial attention mechanism*: In NLP, words and sentences are transformed into n -dimensional vector to capture their meanings in a format suitable for computational models. Each dimension within this vector encodes a different aspect of a word or sentence's meaning, allowing for a rich and multifaceted representation of linguistic data. For example, consider the sentence "I want to book a flight from New York to Boston on July 20th". In intent detection task, the model can easily identify the intent as "book a flight" by focusing on dimensions related to booking and travel. In slot-filling tasks, the model can accurately fill slots using dimensions related to locations and dates.

A vectorial attention mechanism was proposed for the joint model based on the above assumptions.

$$score_{l_i} = W_a^T \sigma(W_b \cdot h_i + b) \quad (13)$$

$$a_{vl_i} = \frac{\exp(score_{l_i})}{\sum_i(score_{l_i})} \quad (14)$$

$$c_{vl_i} = a_{vl_i} \odot h_i \quad (15)$$

$$C_l = [c_{vl_1}, c_{vl_2}, c_{vl_3}, \dots, c_{vl_n}] \quad (16)$$

where W_a, W_b are weight matrices in the vectorial attention and b is the bias vector, \odot is the element wise multiplication c_{l_i} denotes the output of h_i in l^{th} channel. Multichannel attention is generated by concatenating vector and scalar attention as follows:

$$c_i = a_{l_i}(a_{vl_i} \odot h_i) \quad (17)$$

Therefore, multichannel attention has the strengths of both vectorial attention and scalar attention.

D. Convolutional Neural Network Layer

To extract local features from the attention layer, convolution operations are employed on the combined attention layer. Typically, a zero-padding token is introduced before convolution to ensure uniform output sizes across different filters. Different filters and kernel sizes were applied to the multichannel attention c_{li} , to extract local features.

$$C = [c_1, c_2, \dots, c_n] \quad (18)$$

In the convolution operation, a filter $m \in \mathbb{R}^{l \times k}$ is applied to l consecutive words to generate a new feature. Here, $C \in \mathbb{R}^n$, where k and n are the embedded dimensions and input sequence length, respectively.

$$x_i = f(m \cdot c_{i:i+l-1} + b) \quad (19)$$

where, $c_{i:i+l-1}$ is the concatenation of $c_i \dots c_{i+l-1}$, f is a nonlinear activation function such as RELU, and $b \in \mathbb{R}$ is the bias term. After the filter m slides across, a feature map can be obtained as,

$$z = [z_1, z_2, \dots, z_{n-l+1}] \quad (20)$$

Maxpooling is then applied to the feature map z to extract the most significant features for each filter m . To capture the different features of the input sequence, filters of various sizes are applied, resulting in a vector that is used at the output layer.

E. Output Layer

The proposed model consists of intent detection and slot filling outputs. The intent detection output is obtained using a fully connected layer with a softmax function to output the probability distribution over the intents. Therefore, the intent output vector is computed as follows:

$$y^i = \text{Softmax}(W \cdot q + b) \quad (21)$$

For the slot-filling output, the feature vectors are passed to an LSTM decoder to capture the sequential nature of the slots and use the softmax function for the output.

$$d_i = \text{LSTM}(q_i, d_{i-1}) \quad (22)$$

$$y_i^s = \text{softmax}(W \cdot d_i + b) \quad (23)$$

where, y^s is the slot label and W, b are the transformation matrix and bias vectors, respectively.

IV. EXPERIMENTAL STUDY

This section describes the datasets used in the experiments followed by a detailed experimental methodology to assess the effectiveness of the proposed approach. A comparative analysis of the baseline methods is presented. The performance of the model was evaluated using the widely adopted metrics of accuracy for the intent detection task and the F1-score for the slot-filling task.

A. Dataset

To validate the proposed model, experiments were conducted using the Airline Travel Information System (ATIS) dataset, which is one of the most widely recognized and historically significant datasets in Natural Language Understanding (NLU) research. The ATIS dataset has been a benchmark for Spoken Language Understanding (SLU) tasks for over three decades, making it an ideal choice for evaluating advancements in the field. The dataset focuses specifically on air travel-related queries and provides information on flights, fares, airlines, airports, cities, and ground services. It features 21 different intents and 128 slots, with a training set of 4478 samples, test set of 893 samples, and validation set of 500 samples [5].

The ATIS dataset presents several unique characteristics that support its use as a standard for model comparisons. One notable feature is the imbalanced distribution of intent types, with approximately 75% of intents belonging to a single class (*atis_flight*). This imbalance poses a challenge for intent detection models, making the dataset a rigorous test for the proposed approach. Moreover, the well-defined structure of the dataset allows for clear benchmarking and facilitates a direct comparison with existing models in the NLU domain. Its long-standing use in research ensures that the performance of the proposed model can be contextualized within the vast body of prior work, further validating its efficacy.

Table I gives an example of a semantic frame for an utterance from an ATIS dataset “I want fly from Baltimore to Dallas round trip.” The slots adhere to the widely used IOB (in-out-begin) format for representing slot tags. This sentence pertains to airline travel with the intent of finding a flight. Notably, ‘Baltimore’ is tagged as departure city, ‘Dallas’ as arrival city and ‘round trip’ as round trip.

TABLE I. AN EXAMPLE OF FRAME

Entity	slots	Intent
I	O	atis_flight
want	O	
to	O	
fly	O	
from	O	
Baltimore	B-fromloc.city_name	
to	O	
Dallas	B-toloc.city_name	
round	B-round_trip	
trip	I-round_trip	

B. Experimental Settings

A grid search is employed to determine the optimal hyperparameters for the model. Specifically, three different filter sizes (2, 3, and 5) were tested and 128 feature maps were used. To prevent overfitting, a rate of 0.5 was applied to the feature maps. The shared encoder was configured with 200 hidden units and a rectified linear unit activation function was used. Additionally, a dropout rate of 0.5 was applied after the shared encoder, randomly dropping units to improve training was applied after the shared encoder. For intent detection classification and slot filling outputs, L2 regularization with a value of 0.001 was applied to the weights of the dense layers using a softmax activation function. The Adam optimizer and categorical cross-entropy loss functions were employed during training. Accuracy metrics were used to evaluate intent detection, and the F1-score was used for slot filling. A batch size of 32 was selected for the study. The input sequence was padded to a fixed length to fit the convolutional layer with a maximum length of 45 for the ATIS dataset. In the proposed model, the weights of the embedding layer were initialized with publicly available word2vec vectors, whereas words not included in the pretrained set were initialized with values from a uniform distribution to maintain consistent variance across all word vectors.

V. EXPERIMENTAL RESULTS

The performance of the proposed model, AJLISBC-x, on the ATIS dataset is presented in Table I, where x represents the number of channels used during training. These channels enable the model to capture different representations of the input sequence, and the effectiveness of this multichannel representation is evident in the results.

As illustrated in Table II, all proposed AJLISBC models outperformed the baseline models. Specifically, AJLISBC-2, which utilizes two channels, demonstrated the highest accuracy

and F1-score. Among the configurations tested, AJLISBC-1, which operates with a single channel, showed inferior results compared with the multichannel models. This indicates that increasing the number of channels positively influences the model performance, although there may be diminishing returns as the number of channels increases beyond two.

TABLE II. COMPARISON OF AJLISBC WITH BASELINE RESULTS

Model	ATIS Dataset	
	Accuracy	F1-score
Bi-GRU + feature [34]	97.76	97.93
BiLSTM+Attention [35]	95.70	95.60
BC [36]	97.20	96.34
AJLISBC -1	97.89	98.32
AJLISBC -2	98.19	98.61
AJLISBC -3	97.99	98.38
AJLISBC -4	98.09	98.45
AJLISBC -5	97.89	98.56

In addition to channel variations, the effects of the attention mechanisms were evaluated. Table III presents the performance of AJLISBC-2 when using scalar attention, vectorial attention, or a combination of both. Scalar attention, which assigns importance weights to all elements of the input sequence, yields a slightly better accuracy than vectorial attention. However, both types of attention achieve the same F1-score, demonstrating that either mechanism is effective at improving the performance for this task. When scalar and vectorial attention are combined, the model achieves its highest F1-score and improved accuracy compared with either mechanism alone.

TABLE III. PROPOSED MODEL PERFORMANCE BASE ON ATTENTION MECHANISM

Model	Attention	ATIS Dataset	
		Accuracy	F1-score
AJLISBC -2	Scalar	97.09	98.42
AJLISBC -2	Vector	96.99	98.42
AJLISBC -2	Scalar + vector	97.89	98.56

VI. DISCUSSION

The results underscore the effectiveness of multichannel representation in enhancing the model performance. AJLISBC-2's superior performance compared to AJLISBC-1 suggests that using multiple channels helps the model capture diverse patterns within the input sequence. This is particularly relevant for complex tasks such as intent detection and slot filling, where different dimensions of the input can provide complementary information. The use of a single channel in AJLISBC-1 limits the ability of the model to process and leverage multiple facets of the input, leading to inferior results. Therefore, multichannel representation appears to be an effective strategy for improving the model performance.

However, it is worth noting that while increasing the number of channels generally improves the performance, the

results show that the performance does not increase indefinitely. For example, AJLISBC-5 showed a slightly lower accuracy than AJLISBC-2, indicating that simply adding more channels may not necessarily result in better performance beyond a certain point. This may be due to the model encountering diminishing returns from the additional channels or because the increased complexity of the model requires more sophisticated optimization strategies. It is hypothesized that selecting the number of channels based on the number of informative words in a sentence can yield even better results, allowing the model to tailor the complexity of its representation to the specific needs of each input.

In examining attention mechanisms, scalar attention proves to be particularly effective for accuracy because of its ability to calculate the importance of all elements in the input sequence. This helps to identify the most relevant parts of the sequence for intent detection, which may explain its superior performance in this regard. Scalar attention is particularly useful in scenarios where the relationship between different elements in a sequence plays a crucial role, such as in slot-filling tasks. By contrast, vectorial attention selectively emphasizes features that are more relevant for specific tasks, thereby enhancing the robustness of the model. This mechanism introduces controlled perturbations in the hidden state, which allows the model to generalize more effectively to new inputs.

The combination of scalar and vectorial attention mechanisms leads to the best performance because it capitalizes on the strengths of both methods. Scalar attention helps to compute the overall importance of elements in the input, whereas vectorial attention fine-tunes the focus to specific dimensions of the input. This dual approach results in better performance in both intent detection and slot-filling tasks. The synergy between these two mechanisms also enables the model to indirectly assign varying learning rates to different dimensions of the hidden state, allowing more informative dimensions to be updated more rapidly than less informative ones do. This dynamic adjustment contributes to the observed performance improvement when both types of attention are used together.

VII. CONCLUSION

This paper presents an attention-based joint learning classification model for intent detection and slot-filling that combines BiLSTM and CNN (AJLISBC). The BiLSTM architecture captures contextual information, whereas scalar and vectorial attention mechanisms generate multichannel representations of the input sequence semantics. CNNs are applied to these multichannel representations to extract n-gram features and enhance performance in both intent detection and slot-filling tasks. Experimental results on the ATIS dataset show that the model outperforms baseline models, demonstrating the effectiveness of combining BiLSTM, CNN, and attention mechanisms for natural language understanding tasks. Despite the promising results, several limitations of this study should be acknowledged, as they may impact the validity, reliability, and generalizability of the findings. One limitation is the exclusive use of the ATIS dataset, which is relatively small, domain-specific, and focuses on flight-related queries.

This limited scope raises concerns about the generalizability of the findings to other domains or to larger, more diverse datasets. The model's performance might have been overestimated owing to the homogeneity of the dataset. Future work will involve testing the model on diverse datasets from various domains to better assess its generalizability and robustness across different natural language processing tasks. Another limitation is the manual selection of the number of channels used for multichannel representations. Although multichannel representations have shown effectiveness, the process of determining the optimal number of channels is empirical and not rigorously optimized. This could affect the reliability and consistency of the performance of the model across different datasets or tasks, as it may not generalize well to varying sentence lengths or input complexities. Future work will explore automated methods for determining the optimal number of channels, such as incorporating adaptive mechanisms based on input-data characteristics. This approach ensures that the model adapts more flexibly and consistently to diverse input scenarios. Future studies will address these limitations to further validate the effectiveness of the model and enhance its adaptability and applicability to a broader range of natural language understanding tasks.

ACKNOWLEDGMENT

This research was partly funded by the Ministry of Higher Education Malaysia under grant R.J130000.7851.5F568. The authors would also like to thank Universiti Teknologi Malaysia (UTM) for providing the resources used in this study.

Abstract—Autonomous vehicle safety relies heavily on the ability to accurately detect pedestrians, as this capability is crucial for preventing accidents and saving lives. Pedestrian recognition is particularly challenging in the dynamic and complex environments of urban areas. Effective pedestrian detection is crucial for ensuring road safety in autonomous vehicles. Current pedestrian identification systems often fall short in capturing the nuances of pedestrian behavior and appearance, potentially leading to dangerous situations. These limitations are mainly due to difficulties in various conditions, such as low-light environments, occlusions, and intricate urban settings. This paper proposes a novel solution to these challenges by integrating an attention-based convolutional bi-GRU model with deep learning techniques for pedestrian recognition. This method leverages deep learning to provide a robust solution for pedestrian detection. Convolutional layers are utilized to extract spatial features, attention mechanisms highlight semantic details, and Bidirectional Gated Recurrent Units (Bi-GRU) capture the temporal context in the proposed model. The process begins with data collection to build a comprehensive pedestrian dataset, followed by preprocessing using min-max normalization. The key components of the model work together to enhance pedestrian detection, ensuring a more accurate and comprehensive understanding of dynamic pedestrian scenarios. The implementation of this unique approach was carried out using Python, employing libraries such as TensorFlow, Keras, and OpenCV. The proposed attention-based convolutional bi-GRU model outperforms previous models by an average of 17.1%, achieving an accuracy rate of 99.4%. The model significantly surpasses Random Forest, Faster R-CNN, and SVM in terms of pedestrian recognition accuracy, which is critical for autonomous vehicle safety.

Keywords—Pedestrian recognition; autonomous vehicle safety; deep learning; attention mechanism; Bidirectional Gated Recurrent Units

I. INTRODUCTION

One of the most important aspects of road transport, and a key issue in the automotive industry, is vehicle safety. This includes a wide range of techniques and strategies aimed at

reducing the likelihood of a collision and, if it occurs, the number of injuries to car occupants and other road users [1]. To help establish safety norms and standards, government agencies and independent agencies conduct extensive safety tests to assess how vehicles perform in collision situations. Organizational development these tests include the Insurance Institute for Highway Safety (IIHS) and the National Highway Traffic Safety Administration (administered by the NHTSA) [2]. The use of advanced driver assistance systems (ADAS) in vehicles has become a necessity. With features such as parking assist, adaptive lighting, blind spot monitoring and collision avoidance technology, this system supports drivers and improves safety. While there are more hybrid electric vehicles their security concerns increase. It is important to guarantee that the high voltage electrical system is crashworthy, the battery is integrated and safe [3]. Car safety precautions include child safety. This includes instructing parents to check child rear seats before leaving the vehicle, using child safety seats, and integrated child safety doors. Cybersecurity is a growing threat due to increased connectivity and carry reliance on software in vehicles therefore. Protecting vehicles from cyberattacks and ensuring the integrity of critical software systems is more important than ever [4].

Application of machine learning techniques in automotive safety brings a new era of aggressive crash avoidance and occupant protection. Advanced Driver Assistance Systems (ADAS) are commonly used machine learning systems. These systems use algorithms to analyze sensor data from cameras, radar, lidar and ultrasonic sensors to detect potential hazards in crashes, turns and even drowsy driving [5]. This technology provides real-time warnings or interventions to help drivers avoid accidents. Machine learning is essential for autonomous vehicles to recognize and understand their surroundings, recognize traffic signs, people, and other moving objects and make decision calls to help them travel safely. Predictive maintenance, which in turn uses machine learning to monitor the vehicles' own health and predict any problems before failure results [6]. This technology provides real-time warnings or interventions to help drivers avoid accidents.

Machine learning is essential for autonomous vehicles to recognize and understand their surroundings, recognize traffic signs, people, and other moving objects and make decision calls to help them travel safely Predictive maintenance. which in turn uses machine learning to monitor the health of the vehicles themselves [7]. By helping to identify and prevent any potential cyberattacks on the vehicle's systems, machine learning helps improve automotive cybersecurity. Vehicle software can be protected from unauthorized access and data breaches using machine learning algorithms that can detect anomalies and strange behavior [8]. Machine learning in automotive safety using real-time data analytics, predictive capabilities and continuous algorithmic improvements is an ongoing research area that can improve road traffic safety necessary to reduce traffic-related incidents , injuries and deaths to improve driving effectiveness and overall safety [9].

Deep learning has been shown to be a revolutionary force in automotive safety prediction, radically changing how we predict and avoid accidents on the road. With large amounts of data coming from many sources including as sensors, cameras and vehicle control systems, deep learning methods especially neural networks are used These methods can identify complex patterns, identify threats a it is possible and shows important information in real time. Deep learning algorithms play a key role with advanced driver assistance systems (ADAS) by testing the environment, detecting objects and predicting collision hazards. This enables the system to issue warnings in a timely manner or even preventive measures to prevent accidents. Deep learning in predictive maintenance is important because it can analyze sensor data to identify technical problems in the vehicle before they become dangerous.

Feature extraction is necessary to identify pedestrians from other features in and around an image or video frame Before manual feature engineering; However, with the development of deep learning, this approach is now widely incorporated into web design [10]. The conventional Histogram of Oriented Gradients (HOG) is one of the more popular extraction techniques. Unlike computer histograms that show gradient orientations in these cells by image segmentation to extract important edge information and shape information, local binary models (LBP) provide information about garment textures by encoding local texture patterns by comparing the pixel intensities with their neighbors is very useful in distinguishing between a pedestrians [10]. Also, a deep learning technique, convolutional neural networks (CNNs) are popular in feature extraction. These networks have greatly enhanced pedestrian recognition by learning and extracting features such as shapes, textures, and context [11].

Ensuring the safety of motorists and pedestrians sharing the road is of utmost importance. Accurate pedestrian detection and identification, enabled by state-of-the-art deep learning algorithms, is essential to the success of our efforts. By incorporating cognitive algorithms into a convolutional bi-directional gated recurrent unit (Bi-GRU) model for pedestrian recognition, this research aims to push the limits of autonomous vehicle safety [12]. This process improves model understanding in dynamic pedestrian scenarios using Bi-GRU to store time context in addition to the ability of convolutional neural networks (CNNs) to capture detailed scene details Feature those

in ambiance, those in ambiance and crowds [13]. This ubiquitous approach is intended to greatly improve the accuracy and reliability of pedestrian detection methods, making autonomous vehicles safer and more responsive is more adept at dealing with real-world obstacles. In this work, we explore the key features and techniques we use in our model and create findings that reveal the potential to change the automotive safety feature of and about the whole new.

Academics and engineers have made great strides to improve autonomous vehicle safety as new techniques for deep learning model design and data preprocessing This review focuses on the use of Min-Max normalization, which provides the input data is better and increases the accuracy of the model in pedestrian detection Established it is optimized and standardized, resulting in more consistent and reliable results. In addition, the addition of the Bi-GRU (Bidirectional Gated Recurrent Unit) layer in the model framework introduces an additional period of pedestrian detection This layer provides the model with an important contextual understanding about dynamic pedestrian conditions because it can capture time dependence in input data Bidirectional information processing is possible, and it greatly improves the safety of the autonomous vehicle by enabling the image to carry protective information. In addition, the addition of focus improves the accuracy of the model in detecting pedestrians, especially in complex and multidimensional environments where pedestrian access or movement may be obstructed is unobservable, this dynamic distribution of weights across data points assures that the model focuses on the most relevant cases. Attention is a variable that enhances pedestrian visibility and contributes significantly to the overall safety of involved vehicles by reaching critical objects faster. If driven together, these developments make a significant contribution to the field and point to future advancements in autonomous driving safety and reliability.

Key contributions of this framework are,

- The proposed system increases the ability of the model to accurately detect pedestrians and enhance the input data quality by using Min-Max normalization. This pre-processing step provides reliable and consistent results.
- The two GRU layer uses the temporal relationships of input data to provide pedestrians with a description of the relevant context. The use of two-way information processing enhances the understanding of the dynamic pedestrian model and contributes to the safety of autonomous vehicles.
- The model focuses on the most pertinent information thanks to the attention layer, which dynamically distributes weights to different data regions. This is essential for precise pedestrian detection in complex scenarios. This technique enhances autonomous vehicle safety by more effectively acquiring and processing critical attributes.
- The convolutional layer improves the model's capacity to identify complex shapes, patterns, and textures in images, which is crucial for precise pedestrian identification in a variety of settings. By incorporating it, autonomous vehicle safety is further reinforced by

ensuring a more thorough grasp of dynamic pedestrian circumstances.

The research's remaining portions are listed below. Section II provides a review of the literature. The issue statement is covered in Section III. The suggested technique for detecting neurological diseases is then covered in Section IV. Section V discusses the results and discussions. Section VI discusses the conclusion.

II. RELATED WORK

Chen et al. [14] proposes a thorough method for deep learning-based pedestrian recognition and tracking in challenging circumstances, with an emphasis on problems like small-target people and partially obstructed pedestrians in crowded areas. A notable improvement to the YOLO detection algorithm involves the addition of channel attention as well as spatial attention modules. The capacity of the model to represent crucial feature information is eventually improved by these modules, which aid in amplifying important feature data in both channels and spatial dimensions. These modules' incorporation into Darknet-53's backbone network exemplifies an organized method of feature extraction. It is a well-known choice to use the DeepSort tracking technique in conjunction using the Kalman filter algorithm to estimate the mobility status of pedestrians. The tracking procedure is further strengthened by the Mahalanobis distance and evident feature for similarity estimates and the Hungarian method for ideal target matching. This method strengthens the tracking system by integrating deep learning for identification with conventional tracking methods. It is necessary to do preliminary testing of the enhanced YOLO pedestrian detection system and DeepSort tracking technique in the same setting. The findings show a considerable decrease in missed detections and false positives, a more robust handling of tracking failures caused by occlusion, and an essential increase in detection precision for small-target pedestrians. These encouraging results point to the suggested approach's efficacy in enhancing the functionality of intelligent vehicle-pedestrian identification and tracking systems, particularly in challenging and congested environments.

Lu et al. [15] proposes an innovative method for predicting vehicle trajectory for connected and autonomous cars that operate in mixed traffic situations. For these vehicles to be safe and sustainable, accurate forecasting of trajectory is essential. This task is complicated by several variables, including individual vehicle motions, the state of the road, and interactions with other nearby cars. This problem is successfully addressed by the suggested method, Heterogeneous Context-Aware Graph Convolutional Networking with Encoder-Decoder architecture, which simultaneously extracts hidden contexts from each historical trajectory, the dynamic driving scene, and the interactions between vehicles. The design of the method, which uses 2-dimensional Convolutional Networks with temporal attention to represent the changing scene context from scene photos and Temporal Convolutional Networks to capture personal environments from previous vehicle trajectories, is praiseworthy. Spatial-temporal dynamic Graph Convolutional Networks, which incorporate both individual and scene settings as node representations, are a powerful option for modelling

inter-vehicle interaction patterns. It is well thought out to combine these three circumstances and use them as input to the decoder to produce future trajectories. The credibility of the study is increased by the verification of the proposed framework on real-world datasets comprising various driving circumstances. The findings validate the assertion that the model beats state-of-the-art techniques in terms of prediction accuracy and stability regardless of vehicle conditions. The vehicle trajectory prediction field for connected and autonomous cars gains significantly from the work presented in this paper, which offers a thorough and practical solution to complicated real-world traffic situations [16].

Pustokhina et al. [17] addresses an important problem essential to improving the safety of vulnerable road users: the actual detection of anomalies in pedestrian areas. The expanded network of surveillance cameras and the amount of film recorded make manual verification and labeling of anomalies difficult and time-consuming. As a result, surveillance systems automation, especially those based on deep learning theories, has become increasingly popular in computer vision. To overcome these challenges, our research focuses on the development of a deep learning anomaly detection technique (DLADT-PW) for pedestrian roads. The aim of the DLADT-PW method is to detect and classify different types of deformation in pedestrian traffic, such as the presence of cars, skateboarders, or jeeps. Mask area convolutional neural network (Mask-RCNN) incorporating a dense connected mesh work in models after the pre-processing stage in order to reduce noise and detect. The image can be enhanced before phase. The study provides evidence of the effectiveness of the DLADT-PW method by running detailed simulations and analyzing the results from different angles. The findings confirm the excellent performance of the DLADT-PW model and demonstrate its potential for accurate identification. By developing a computerized anomaly detection algorithm that can quickly and segmentally detect anomalies in pedestrianized roadways, this research significantly enhances the field of computer vision, including pedestrian safety. In this context, deep learning models are used, especially masked RCNN and DenseNet, and emphasis is placed on implementing state-of-the-art techniques. The capabilities of the model are further confirmed through comprehensive analysis and empirical analysis, indicating the potential for useful application in real-world monitoring systems for providing vulnerable road users security has increased.

Islam et al. [18], it introduces a vision-based approach to customized safety messages (PSMs), which addresses an important part of passenger safety in Internet-connected vehicles in vehicular Internet-connected (V2P) communication is needed in situations out of this, but pedestrians face a major obstacle as it relates to the lack of low-level connectivity with nearby connected vehicles -which involve telephony or especially- long distance communication (DSRC) devices. The main contribution of the study is a vision-based system of real-time PSM using video feeds from roadside traffic cameras according to SAE J2945. According to the paper's analysis, safety for pedestrians has been provided the planned netted vehicle is an example of the feasibility of this strategy. The presented results highlight the effectiveness of the vision-based

system in real-time collision warning to avoid future vehicular and pedestrian accidents, especially in time-to-collision (TTC) values in the emphasis. The study confirms that, in a connected vehicle context, our vision-based pedestrian safety notification system satisfies the latency criteria for the PSCW safety application. The important topic of pedestrian security within the environment of linked automobiles is addressed in this research, which is noteworthy. Its vision-based methodology provides a novel approach to the problem of pedestrian communication in the absence of specialized equipment. The creation of a useful safety application and the approach's proven effectiveness in real-time collision warning serves to further highlight its potential. Its legitimacy and application in the automobile sector are improved by adhering to SAE standards. To offer a more thorough understanding of the suggested approach, the study might utilize more information on the technical facets of the vision-based system, the specific data streams employed, and potential difficulties in real-world application.

The examined literature focuses on important advancements in deep learning and computer vision for problems relating to pedestrian safety and traffic safety. In the study, a better YOLO-based system for pedestrian tracking and recognition is introduced. By using attention modules to solve problems such as tiny targets and occluded pedestrians, the system improves detection accuracy and provides stable tracking in congested situations. In different research, a novel method for simulating complicated vehicle interactions and improving trajectory prediction accuracy is presented for predicting vehicle trajectories in mixed traffic settings using graph convolutional networks. A thorough analysis of current LSTM-based short-term traffic prediction algorithms is presented, together with a classification and assessment of their advantages and disadvantages, to help researchers choose the best method for certain traffic situations. Another study explores automated anomaly detection at pedestrian crossings and presents a Deep Learning anomaly detection technique that can identify a wide range of anomalies and improve pedestrian safety. Using roadside traffic cameras and adhering to industry standards, a vision-based system for generating Personal Safety Messages in connected vehicle contexts is discussed, enabling real-time collision warnings and ultimately enhancing pedestrian safety and communication in the absence of specialized equipment. Through creative approaches and useful solutions, these studies jointly increase traffic forecasts, intelligent transportation systems, and pedestrian safety.

III. PROBLEM STATEMENT

Pedestrian safety in the context of autonomous vehicles is still a major concern, according to the literature review, which draws from the discussion above. This is especially true in situations where there are small targets among the pedestrians, partial obstructions in crowded areas, and no personal communication devices. While recent research shows that deep learning, better detection algorithms, and vision-based techniques have potential, a holistic and cohesive solution is required to maximize pedestrian recognition and tracking for autonomous vehicle safety. Thus, Convolutional Bi-GRU, a concept-based model that combines traditional detection

methods with deep learning for accurate and reliable pedestrian identification [19]. The main objective is to increase the detection accuracy of target pedestrians, and to reduce missed detections, false positives, and failures due to occlusion and tracking failures so especially the research objective of improving the safety of autonomous vehicles in harsh and crowded situations is maximized. The advantages of recurrent and convolutional neural networks are well combined in the Conv-Bi-GRU model. CNNs perform exceptionally well when extracting features from images, and this integration improves the model's ability to extract and analyze spatial and temporal complexity from video data, and provides improve our understanding of the temporal relationships observed in Bi-GRU walking trajectories.

IV. PROPOSED FRAMEWORK OF ATTENTION BASED CONVOLUTIONAL BI-GRU MODEL

The approach adopted in this study is based on a structured design with several main components. In order to train and test the model, in the first phase of data collection, a large dataset of pedestrians should be obtained. The next step in processing the data is minimum-maximum normalization, which involves scaling the pixel values to the standard range. Concept-based convolutional two-GRU model, a deep learning system designed for pedestrian detection is the core of the methodology. This model has several layers, such as a conceptual approach for highlighting relevant semantic features in the data and bidirectional gated repetitive units (Bi-GRU) for capturing time descriptions. The data are extracted with convolutional layers of space objects to better understand pedestrians' events. A fully connected layer and SoftMax activation provide the final result, enabling the model to better classify pedestrians. Considering all things, this technology is designed to improve the safety of autonomous vehicles by preventing crashes and accidents, in addition to being exceptionally effective at detecting pedestrians and giving way it is possible to approach the front with an autonomous vehicle. Fig. 1 shows the block diagram of the proposed model.

Fig. 1. Block diagram of proposed attention based convolutional Bi-GRU model.

A. Data Collection

The pedestrian dataset used in this study, sourced from Kaggle, consists of extensively documented videos capturing people using crosswalks in various contexts. The dataset is divided into three distinct segments, each providing valuable insights into pedestrian behavior. The first segment, titled "Crosswalk," is a 12-second clip showing individuals safely crossing the street using designated means, offering a clear understanding of compliance with pedestrian safety regulations. The second segment, a 25-second video titled "Night," highlights pedestrian behavior in low-light conditions, providing insights into how lighting influences crosswalk use. The dataset includes accurate bounding box annotations for pedestrians, meticulously encoded in a .csv file, making it highly suitable for analyzing and training machine learning models. For training and testing, the dataset was split into 70% for training and 30% for testing, ensuring a balanced evaluation of the model's performance [20].

A. Pre-Processing using Min-Max Normalization

Min-max scaling is a data processing technique, sometimes called normalizing, in which the pixel values of images in a data set are converted to a specific range, usually 0 to greater in computer vision, including safety-related applications for pedestrian detection and new autonomous vehicles. If you want to make sure that each pixel value falls within a defined, constrained range, min-max scaling comes in handy. This creates a model of deep learning and a smooth meeting [21]:

$$x_{sv} = \frac{x - x_{min}}{x_{max} - x_{min}} \quad (1)$$

whereas, the scaled value is x_{sv} . The initial pixel value is represented by x . The smallest pixel value in the collection is denoted by x_{min} . The dataset's highest pixel value is represented by the value x_{max} .

This preprocessing step enhances model performance by reducing the impact of varying pixel intensities and ensuring that the model learns from data with consistent value ranges. In the context of pedestrian detection, this consistency improves the model's ability to accurately recognize and differentiate

pedestrians from background elements, leading to better detection accuracy and robustness in safety-critical applications.

B. Pedestrian Recognition Using Attention-based Convolutional Bi-GRU Model to Improve Autonomous Vehicle Safety

Using the Attention-Based Convolutional Bi-GRU Model and deep learning for pedestrian recognition, this model optimizes autonomous vehicle safety by utilizing pre-trained feature vectors in the input layer to represent the important attributes related to pedestrian recognition. This study may effectively examine and comprehend the many attributes of pedestrians due to these vectors, which are pre-configured to encode pertinent information about them. Preprocessed data is fed into the input layer in the form of images. These images have usually been through operations like scaling, cropping, and potentially color normalization. The input layer is where the data enters the neural network; it doesn't do any computation.

$$X_i = (x_1, x_2, \dots, \dots, x_{n-1}, x_n) \quad (2)$$

In Eq. (2), the feature vector of the i^{th} pedestrian data instance is represented by X_i , the attribute vector of the i^{th} characteristic inside the pedestrian data is represented by x_i , and the length or dimensionality of the input data is indicated by X . An image sequence's temporal dependencies are intended to be captured by the Bidirectional Gated Recurrent Unit (Bi-GRU) layer. It has the ability to analyze data both forward and backward, which allows it to gradually capture context. The temporal properties of the input data are represented as a series of feature vectors as this layer's output. As illustrated in Fig. 2, this model utilizes visual features that reflect pedestrian scenarios as input data. The Bi-GRU layer is split into two halves that each evaluate the image features in both forward and reverse directions at the same time. The GRU algorithm then processes these successive picture features and produces an output vector with specified dimensions. Four crucial computing components are involved in the GRU action. The reset gate is part of the initial element.

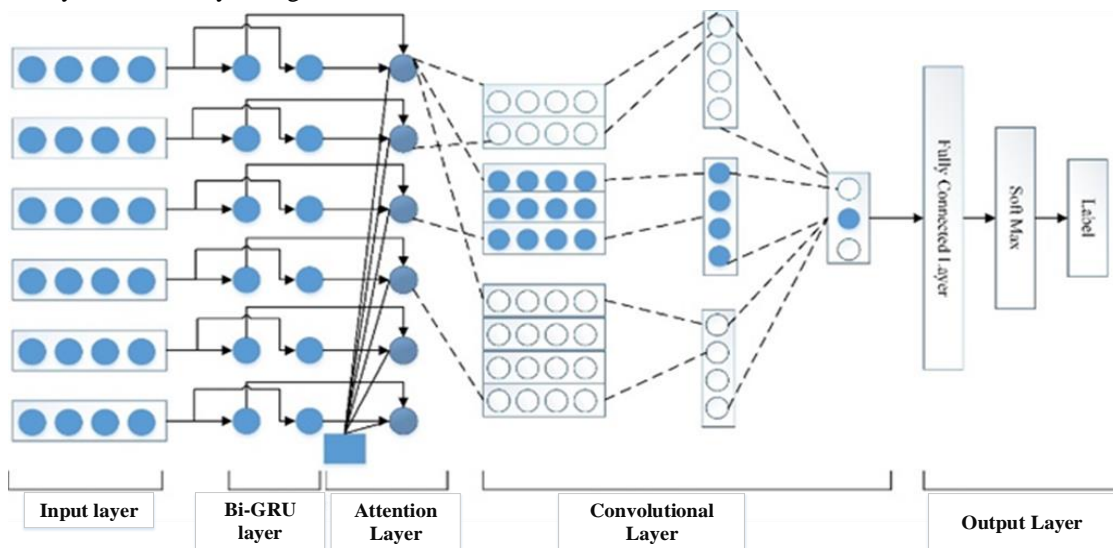

Fig. 2. Architecture of proposed attention-based convolutional Bi-GRU model.

$$Re_t = \tau(w_r x_t + u_r h_{t-1} + b_r) \quad (4)$$

$$\mathbb{Z}_t = \tau(w_z x_t + u_z h_{t-1} + b_z) \quad (5)$$

In order to determine the output of the current instant, GRU first computes the candidate memory content from Eq. (6), where w and u represent weight information and b represents bias.

$$h^*_t = \tanh(wx_t + uRe_t h_{t-1} + b) \quad (6)$$

The results from the preceding mentioned operations are the basis on which the GRU ultimately computes the output using Eq. (7). The Bi-GRU layer can record contextual information about every component in the input data for pedestrian identification.

$$h_t = (1 - \mathbb{Z}_t)h^*_t + \mathbb{Z}_t h_{t-1} \quad (7)$$

To concentrate on pertinent areas or frames within the input data, the attention mechanism is essential. In order to emphasize areas of interest, it dynamically assigns weights to various input sequence segments. This is especially crucial for spotting pedestrians in complex circumstances. The input is represented in an attention-weighted manner by this layer. Each Bi-GRU layer output is given weight by the attention mechanism, as shown in Fig. 2. The weight's magnitude indicates how important the semantic material is. To put it simply, locations with greater weights attract more "Attention," a sign that they have a significant influence on the final pedestrian recognition categorization result. For computing attention, the formula is denoted by Eq. (8) and Eq. (9). The attention weight a_{ik} and the related weight parameters (w_{a2} and w_{a1}) are represented in Eq. (10), together with the sequence data length t_h .

$$G_t = \sum_{t=1}^{t_h} a_{ik} h_t \quad (9)$$

$$a_{ik} = \text{softmax}(w_{a2} \tanh(w_{a1} h_t)) \quad (10)$$

Applying the Convolutional Layer to the spatial representation of the input data is common practice in Convolutional Neural Networks (CNNs). It is essential for recognizing pedestrians' visual traits, such as edges, forms, and textures, since it extracts pertinent aspects and patterns from the attention-weighted input. The computation of the convolution layer is carried out as follows:

The convolution layer receives its input from the attention layer's generated intermediate semantic information, where $G_{i:k}$ denotes the grouping of features pertaining to the i^{th} and k^{th} items in the context of pedestrian recognition.

$$G_{i:k} = G_i \oplus G_{i+1} \oplus \dots \oplus G_k \quad (11)$$

Three different convolutional kernels are applied to obtain deep features. Throughout this procedure, 'f' stands for a hyperbolic tangent function, w for the weight parameters, 'm' for the convolution kernel width, and 'b' for the bias term.

$$t_i = f(wG_{i:k+m-1} + b) \quad (12)$$

After that, the model uses maximum pooling to merge the convolution results and identify important features. The final output of the entire convolution layer is then formed by combining the pooled results. 'n' stands for the number of

convolution results, and 'j' for the number of convolution kernels. The computations are performed as follows.

$$t_k = [t_1, t_2, \dots, t_{n-1}, t_n] \quad (13)$$

$$\hat{t}_k = \max(t_k) \quad (14)$$

$$\hat{t} = [\hat{t}_1, \hat{t}_2, \hat{t}_3] \quad (15)$$

In this study, the input of the fully connected layer is the output of the convolutional layer of the output layer. Then, use the SoftMax function to find as much as possible in each segment. The pedestrian detection part of the input has the highest potential. The calculations are written as the following formula, where WD represents the weighting parameters of the mesh and BD represents the bias term.

$$d_k = w_d \hat{t} + b_d \quad (16)$$

$$o_i = \frac{\exp(d_k)}{\sum_k \exp(d_k)} \quad (17)$$

To improve the safety of autonomous vehicles, a specific pedestrian detection method using a concept-based convolutional bi-GRU model approach is presented using deep learning methods and are mixed, such as convolutional layers, attention mechanisms, and bidirectional gated recurrent units (Bi-GRU). Important attributes are extracted by the convolutional layer using weights assigned by the model to key semantic descriptions by attention mechanism Pedestrians should be classified reliably by the model due to SoftMax activation and the fully connected layer it provides for the final output. This approach shows promise for increasing the safety of autonomous vehicles by helping to avoid collisions, and for better pedestrian detection.

V. RESULTS AND DISCUSSION

Autonomous vehicle safety was experimentally optimized using a deep learning-based pedestrian recognition system, analyzed with a concept-based convolutional bi-GRU model. The approach in this study is organized with several key features. In the first phase of data collection, a large dataset of pedestrians was obtained. This dataset, used for benchmarking, includes extensively documented videos with accurate bounding box annotations, capturing pedestrian behavior in various scenarios such as crosswalks and low-light conditions. The next step in processing the data involved min-max normalization, which scales pixel values to a standard range. The key component of the method is the concept-based convolutional bi-GRU model, a deep learning system built for pedestrian recognition. This model consists of several layers, enabled by bidirectional gated recurrent units (Bi-GRU) to capture temporal patterns and important semantics in the data. Crucial output for the attention mechanism, which highlights essential sections and enables accurate pedestrian classification, is provided by a fully connected layer and SoftMax activation. The goal of this technology is to enhance the safety of autonomous vehicles by preventing collisions and accidents through highly effective pedestrian detection, offering a promising direction for the future of driverless transportation.

The Table I provides a comprehensive summary of a neural network model's architecture and parameters. It details each

layer's type, output shape, and the number of parameters involved. The model begins with a 1D convolutional layer ('Conv1D') followed by a max pooling layer to down-sample the feature maps. It then uses a flattening layer to reshape the data for dense layers, which include two fully connected ('Dense') layers with 128 units each and one final dense layer with a single output unit. The total number of parameters, including those in the convolutional and dense layers, is 131,905, which are all trainable, indicating the model's complexity and capacity for learning from data.

TABLE I. MODEL ARCHITECTURE AND PARAMETERS SUMMARY

Layer (type)	Output Shape	Param #
conv1d_1 (Conv1D)	(None, 28, 64)	448
max_pooling1d_1 (MaxPooling1D)	(None, 14, 64)	0
flatten_1 (Flatten)	(None, 896)	0
dense_2 (Dense)	(None, 128)	1,14,816
dense_3 (Dense)	(None, 128)	16,512
dense_4 (Dense)	(None, 1)	129
Total params	1,31,905	(514 KB)
Trainable params	1,31,905	(514 KB)
Non-trainable params	0	(0.00 Byte)

A. Performance Evaluation

For comparison the SVM, Random Forest Classifier and Faster R-CNN methods performance is compared with the proposed Attn-Based Convolutional Bi-GRU model. Precision, recall, F1-score, and accuracy were utilized as evaluation criteria for comparison. The model was evaluated using these parameters.

Fig. 3. Performance of the proposed attn-based convolutional Bi-GRU model.

A novel pedestrian recognition method is assessed using an Attn-Based Convolutional neural networks Bi-GRU model; the outcomes are displayed in Fig. 3 of the suggested model's performance metrics. The proposed model works remarkably well, demonstrating its high overall consistency in pedestrian recognition with an accuracy of 99.4%. It also shows exceptional accuracy at 99%, suggesting a minimal amount of false identifications, and remarkable recall at 98.9%, exhibiting its ability to reliably identify the majority of genuine

pedestrians. The model's remarkable pedestrian recognition ability is validated by the F1-Score, which stands for an ideal balance between recall and precision and is notably high at 99.1% (see Table II).

TABLE II. PERFORMANCE METRICS OF ATTN.-BASED CONVOLUTIONAL BI-GRU MODEL WITH EXISTING METHODS

Method	Accuracy	Precision	Recall	F1-Score
SVM [22]	82.3(%)	88.16(%)	72.92(%)	79.82(%)
Faster R-CNN [23]	84(%)	96.6(%)	92.6(%)	94.6(%)
Random Forest [22]	90.2(%)	90(%)	80.8(%)	85.18(%)
Proposed Attn-Based Convolutional Bi-GRU Model	99.4(%)	99(%)	98.9(%)	99.1(%)

Accuracy, precision, recall, and F1-Score are only a few of the performance variables used in the Table I to compare different models from machine learning. Despite a modest recall of 72.92%, the Support Vector Machine, also known as the SVM, accurately classifies positive cases, achieving an accuracy of 82.3% and a precision of 88.16%. With an accuracy of 84%, a far better precision of 96.6%, as well as a much better recall of 92.6%, the faster R-CNN algorithm performs better than SVM, resulting in a strong F1-Score of 94.6%. With an F1-Score of 85.18%, the Random Forest algorithm performs exceptionally well, with accuracy of 90.2%, good precision of 90%, and recall of 80.8%. But the most effective model is known as the Proposed Attn-Based Convolutional Bi-GRU Model, which achieves an amazing 99.4% accuracy, 99% precision, 98.9% recall, and a remarkable 99.1% F1-Score, indicating that it can accurately classify either positive or negative instances. This shows that the suggested model performs better than any other approaches, which makes it a viable option for the specified classifying task.

The proposed attention-based convolutional bi-GRU model was compared with SVM, Faster R-CNN, and Random Forest due to their established use and performance in pedestrian detection tasks. SVM was chosen for its robustness in classification but is limited in capturing complex patterns and temporal dependencies. Faster R-CNN, a deep learning model known for high accuracy in object detection, served as a strong benchmark, though it struggles with temporal context. Random Forest, an ensemble learning method, was included as it performs well in various recognition tasks but may not handle the spatial and temporal complexities of urban environments effectively. These comparisons highlight the superior performance of the proposed model, particularly in accuracy, precision, recall, and F1-score, demonstrating its potential to significantly enhance pedestrian detection in autonomous vehicle systems.

The proposed Attn.-Based Convolutional Bi-GRU Model, Random Forest, Faster R-CNN, and Fig. 4 shows the Support Vector Machine (SVM) over all the remainder of the four machine learning models together with their accuracy, precision, recall, and overall F1-Score performance metrics. Notably, the SVM produces an F1-Score of 79.82% accompanied by a somewhat low recall of 72.92%, a strong

precision of 88.16%, and a reasonable accuracy of 82.3%. Faster R-CNN, on the other hand, obtains an incredible F1-Score of 94.6% with an increase in accuracy of 84%, a significantly higher precision of 96.6%, and an astounding recall of 92.6%. With an accurate rate of 90.2%, the approach known as Random Forest achieves a great F1-Score of 85.18% by balancing recall at 80.8% and precision at 90%. On the other hand, the Proposed Attn.-Based Convolutional Bi-GRU Model is clearly the strongest performance, with an astonishing F1-Score of 99.1%, near-perfect precision of 99%, recall of 98.9%, and astounding accuracy of 99.4%. This graph demonstrates how the proposed model outperforms the other methods across the board, suggesting that it has a lot of potential for solving the present categorization challenge.

Fig. 4. Graphical depiction of the performance metrics of proposed Attn.-based convolutional Bi-GRU model with existing approaches.

Fig. 5 shows the training accuracy graph, within the framework of the proposed Attn-Based Convolutional Bi-GRU model, shows how well the model classifies pedestrians using the training dataset throughout its training iterations, or epochs. This graph shows how the model is learning and if it is becoming more accurate or if the training data may be overfitting. However, the effectiveness of the model on a separate, untested dataset that was not used for training is depicted on the testing accuracy graph. This graph sheds light on how well the model can use its knowledge of pedestrian detection to situations outside of the training set. A high testing accuracy shows the model's competence in consistently identifying pedestrians in a variety of real-world scenarios, and those is essential for improving protection for autonomous vehicle applications. A substantial training accuracy suggests that the framework successfully acquired from the training data.

Fig. 6 shows a graphical depiction of the training and testing loss for the proposed Attn-Based Convolutional Bi-GRU model, which illustrates how the model's loss function varies across the training and assessment stages.

Fig. 7 shows that the ROC curve depicts the performance of the model in binary classification tasks, especially for the proposed Attn-based Convolutional Bi-GRU model. When the

threshold for classifying pedestrians is different, the sensitivity of the model changes, as detected by the ROC Curve. The model's ability to accurately identify pedestrians while avoiding false positives is reflected by a high number of true positives. In this case, the ROC curve generally exhibits a positive trend as the threshold increases from 0 to 0.7, indicating that the model is good at discriminating pedestrians from pedestrians, which is important for the safety of the application of the autonomous vehicle.

B. Discussion

Improved road safety and autonomous vehicles were the two main outcomes of the study. When it comes to detecting pedestrians, the algorithm is exceptionally accurate at 99.4%, reducing the probability of accidents and increasing road safety. Challenges in real-world urban environments, such as poorly lit areas, are prevented, and complex pedestrian behaviors, which are often too numerous for available algorithms to handle, and can pose risks to user safety [19]. Convolutional two-GRU architecture's attention methods allow the model to focus on relevant data, improving its performance in complex urban environments. False alarm reduction with 99% accuracy ensures autonomous vehicles work more efficiently, safely and efficiently on public roads. Advanced deep learning algorithms. This project is a great illustration of how it can accelerate adoption and ultimately change the landscape of safe and efficient travel.

In pedestrian detection, attention mechanisms and Bidirectional Gated Recurrent Units (Bi-GRU) offer significant advantages by improving the model's ability to focus on relevant features and capture temporal dependencies. Attention mechanisms allow the model to emphasize critical regions of the input data, such as specific areas where pedestrians are likely to appear, enhancing the model's ability to differentiate between pedestrians and other objects or background noise. This selective focus leads to more accurate and reliable detection. Meanwhile, Bi-GRU units, which process data in both forward and backward directions, capture temporal patterns and contextual information from sequential data, such as video frames. This bidirectional approach helps the model understand the dynamic and evolving nature of pedestrian movements over time, improving its performance in complex and variable environments. Together, these techniques enhance the model's ability to accurately identify pedestrians and adapt to changing conditions, crucial for autonomous vehicle safety.

The proposed attention-based convolutional bi-GRU model outperforms existing models primarily due to its integrated approach, which leverages the strengths of both attention mechanisms and Bidirectional Gated Recurrent Units (Bi-GRU). The attention mechanism enhances the model's ability to focus on crucial parts of the input data, effectively distinguishing pedestrians from background elements and improving detection accuracy. Bi-GRU units, by capturing temporal dependencies from both directions, provide a comprehensive understanding of dynamic pedestrian movements, which is vital in real-world scenarios where pedestrians' positions and actions constantly evolve. However, potential weaknesses include the increased computational complexity and resource requirements associated with training and deploying such a sophisticated model. Additionally, while the model excels in controlled environments, its performance may degrade in highly unpredictable or extremely cluttered scenarios. Despite these limitations, the combined use of attention mechanisms and Bi-GRU units represents a significant advancement in pedestrian detection, offering a robust solution that enhances autonomous vehicle safety.

The research presented in this study, while demonstrating significant advancements in pedestrian detection accuracy, is subject to several limitations that warrant consideration. One

primary limitation is the increased computational complexity associated with the attention-based convolutional bi-GRU model, which may restrict its real-time applicability in resource-constrained environments. Additionally, the model's robustness has primarily been tested in controlled scenarios, raising concerns about its performance in highly unpredictable or densely cluttered urban settings. Furthermore, the reliance on specific datasets for training and testing poses questions regarding the model's generalizability across different geographical regions and pedestrian behaviors. For future work, efforts should focus on optimizing the model's computational efficiency, potentially through the development of lightweight architectures or the use of hardware accelerators like GPUs or TPUs. Expanding the evaluation to include diverse environmental conditions and pedestrian behaviors will be crucial to ensure the model's robustness and applicability. Additionally, integrating the model with other sensor modalities, such as infrared or radar, and exploring multi-sensor fusion frameworks could further enhance its effectiveness and contribute to the overall safety of autonomous vehicles.

VI. CONCLUSION AND FUTURE WORK

The use of Python as the implementation device is a crucial factor of the model's adaptability and applicability. This paper provides a comprehensive and beneficial technique to enhancing self-sustaining vehicle protection. The first and most important step in developing a strong pedestrian dataset is facts collecting. The subsequent level of pre-processing standardizes the information the use of Min-Max normalization to get it ready for the advanced model. The Attention-Based Convolutional Bi-GRU Model, a deep studying architecture with awesome pedestrian identity abilities, is the brains in the back of this tactic. The version consists of bidirectional gated recurrent units (Bi-GRU) for temporal context seize, attention mechanisms for emphasizing semantic records, and convolutional layers for extracting spatial traits. A 99.4% accuracy price is executed, that's an outstanding improvement over preceding models via a median of approximately 17.1%. The results are outstanding. The demanding situations of identifying pedestrians in elaborate and dynamic metropolitan contexts are greatly addressed by using this accomplishment, which will ultimately lead to safer self-sustaining vehicle operation. This method offers a promising first step in the direction of the introduction of safer and extra dependable self-reliant motors, which may lessen dangers and improve the security of pedestrians and other street customers as autonomous transportation structures maintain to broaden. To increase the Attention-Based Convolutional Bi-GRU Model's performance and adaptability to changing real-world settings, extra improvements and adjustments may be investigated in future study.

Cryptographic Techniques in Digital Media Security: Current Practices and Future Directions

Gongling ZHANG

Luoyang Cultural Tourism Vocational College, Luoyang 471000, China

Abstract—Content privacy and unauthorized access to copyrighted digital media content are common in the dynamic, fast-paced digitalized media marketplace. Cryptographic methods are the foundation of modern digital media security, and they must ensure the security, integrity, and authenticity of digital media data. This article analyses cryptographic methods that are used to protect digital media content. The paper reviews the main cryptographic concepts, such as symmetric cryptography, asymmetric cryptography, hash functions, and digital signatures. The paper also discusses some popular approaches: encryption, Digital Rights Management (DRM), watermarking, and solutions based on blockchain. Finally, we highlight implementation challenges such as key management and scalability and identify emerging trends such as quantum-safe cryptography and privacy-preserving techniques. By presenting the current research results and discussing the directions for the future, the study aims to pave the way for secure, efficient, and robust cryptographic solutions for digital media protection, leading to sustainable development, innovation, and secure communication of digital content among users.

Keywords—Digital media; cryptographic; content security; digital rights management; watermarking, blockchain

I. INTRODUCTION

Digital content is now more dominant than tangible media in terms of dissemination and usage [1]. Inherent properties such as the ability to reproduce identical documents easily and disseminate them over the Internet through wired and wireless communication have relevant ramifications for intellectual property rights [2]. Thus, the sharing of the content generally takes place beyond the limits of copyright law [3]. Digital products have the potential to be copied, replicated, and distributed across the globe within minutes of issuance, making detection and enforcement very difficult [4]. The illegal redistribution and exploitation of intellectual information may result in substantial financial losses for content producers and owners, with industry estimates suggesting that these losses amount to billions of dollars each year [5].

Social media platforms facilitating global communication and information dissemination have become breeding grounds for image sharing [6]. With billions of images uploaded daily, concerns about illegal access, manipulation, and unauthorized distribution are growing. Applying digital image watermarks is emerging as a promising technique to address these security challenges [7]. However, effective watermarking depends on three crucial requirements: imperceptibility, robustness, and embedding capacity. The watermarked image should be visually indistinguishable from the original image so as not to impact the user experience [8]. The watermark should resist

attacks such as compression, noise, or cropping to ensure its durability and accuracy and protect copyright. The watermark should embed sufficient information to reliably identify the owner or copyright holder. These requirements often have trade-offs. For example, spatial domain watermarking techniques provide high embedding capacity and imperceptibility but are not robust to manipulation. Conversely, spectral domain techniques achieve higher robustness but may result in visible artifacts that impact imperceptibility.

To achieve an optimal balance between these competing demands, researchers have explored hybrid approaches that leverage both spatial and spectral domains. Nature-inspired metaheuristic optimization algorithms were employed to optimize the embedding strength of the watermark, aiming to find a balance between imperceptibility, robustness, and embedding capacity [9, 10]. However, developing effective fitness functions that balance exploration (searching for novel solutions) and exploitation (refining promising solutions) remains an ongoing challenge.

Digital transformation, driven by the Internet of Things (IoT) and the increasing demand for secure and real-time communication, fundamentally changes how we interact with information and the world around us [11]. IoT envisions a future in which nearly every object is connected to the Internet and generates and transmits massive amounts of data, including personal, sensitive, and confidential information [12]. While these advances offer unprecedented opportunities, they pose significant security challenges. Smart cities and advances like cryptocurrencies hold enormous potential to reshape the coming decade, but the inherent vulnerabilities of these technologies raise concerns about privacy and communications security [13].

The purpose of this article is to discuss the principles of cryptographic technologies that can be used to prevent unauthorized access to digital media content and its piracy. The article begins with an introduction to the importance of digital media security and the function of cryptography. Basic cryptographic principles of symmetric and asymmetric encryption, as well as hash functions and digital signatures, are examined. Various security strategies are then discussed, including encryption, Digital Rights Management (DRM), watermarking, and blockchain security solutions. The discussion also addresses the difficulties and disadvantages of applying these approaches, new trends and promoting possible developments. Finally, the paper offers a brief conclusion with key findings and suggestions for where further research should be conducted.

II. BACKGROUNDS

Information security protects data from unauthorized access, theft, alteration, or destruction. This covers various information formats, including text, images, audio, and video [14]. Two main approaches are used to ensure information security: cryptography and steganography. Cryptography uses complex mathematical algorithms to encrypt or scramble data into an unreadable format (ciphertext). This makes the data unreadable even if unauthorized persons intercept it. However,

encryption itself can sometimes signal valuable information. To counteract this limitation, steganography hides communication itself. Steganography embeds confidential messages in a seemingly innocuous cover object, such as an image or audio file. This allows data to be passed on unnoticed by eavesdroppers. Even if the cloak is intercepted, the information remains hidden, providing an additional layer of security. Fig. 1 illustrates the general process of digital media content encryption. A variety of multimedia encryption applications are also illustrated in Fig. 2.

Fig. 1. General process of digital media content encryption.

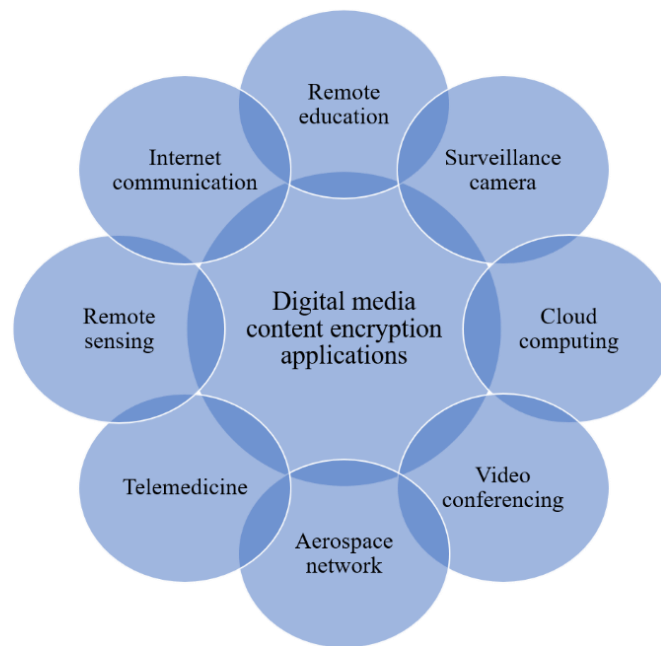

Fig. 2. Applications of multimedia encryption in various domains.

A. Symmetric Cryptography

This is also called secret-key cryptography, where the same secret key is used for encryption and decryption. This key should be kept secret by both the sender and the receiver to enhance the security of the passed information. The basis for the use of symmetric cryptography is the secrecy of the key and the choice of the algorithm used to encrypt the data. Symmetric encryption algorithms are generally classified into block ciphers and stream ciphers [15]. Block ciphers, like the Advanced Encryption Standard (AES), process data in fixed-size blocks during encryption. In contrast, stream ciphers, such as Rivest Cipher 4 (RC4), encrypt data one bit or byte at a time. The selection between block and stream ciphers depends on the application's requirements, such as prioritizing high-speed

encryption or resistance to specific attack types. Symmetric cryptography underpins the security of various digital media content due to its efficiency and speed. A comparison of common symmetric encryption algorithms is presented in Table I.

- **Content encryption:** To prevent unauthorized access, digital media files (videos, audio, images) are often encrypted using symmetric algorithms. Content providers can ensure that only authorized users with the corresponding decryption key can access the media. For instance, streaming services like Netflix and Spotify might leverage the Advanced Encryption Standard (AES) to protect their media files during transmission and storage.

- **DRM:** Symmetric cryptography is critical in enforcing DRM systems' access controls and usage policies. The media content is encrypted with a symmetric key securely distributed only to authorized users. The DRM system manages key distribution and revocation, guaranteeing that content decryption and access are restricted to legitimate users.
- **Secure streaming:** Real-time encryption of media content before transmission is essential for live streaming scenarios. Due to their ability to encrypt data on the fly, stream ciphers are particularly well-suited for this purpose. Encrypted streams are transmitted over networks, ensuring intercepted data remains unintelligible without the decryption key.
- **Storage encryption:** Symmetric encryption safeguards digital media stored on servers or user devices. By encrypting media files at rest, service providers can prevent unauthorized access in the event of a data breach or physical theft of storage devices.

TABLE I. SYMMETRIC CRYPTOGRAPHY

Algorithm	Type	Key size (bits)	Block size (bits)	Example use cases
AES	Block cipher	128, 192, 256	128	Secure file transfer and encryption of sensitive data
DES	Block cipher	56	64	Legacy systems, previously used in banking transactions
RC4	Stream cipher	40-2048	Variable	Secure network protocols (e.g., WEP, SSL/TLS)
3DES	Block cipher	112, 168	64	Financial services and legacy systems requiring higher security

B. Asymmetric Cryptography

Asymmetric cryptography, also known as public-key cryptography, utilizes a mathematically elegant solution for secure communication by employing two distinct keys for encryption and decryption: a public key and a private key [16]. Unlike symmetric cryptography, the public key is openly distributed, allowing anyone to encrypt data intended for a specific recipient. The private key, conversely, is meticulously guarded by its owner and serves as the sole means to decrypt the data. This clear separation of keys addresses a fundamental challenge in symmetric cryptography: secure key distribution. Public-key cryptographic systems are built upon mathematical problems that are difficult to solve practically without possessing the corresponding private key. Well-established algorithms in this domain include RSA (Rivest-Shamir-Adleman), ECC (Elliptic Curve Cryptography), and DSA (Digital Signature Algorithm). These algorithms mathematically guarantee that data encrypted with a public key can only be decrypted by the holder of the corresponding private key, offering a secure method for exchanging information even over untrusted channels. Asymmetric cryptography is critical in securing digital media content, and enhancing security and user trust. It provides several key advantages over symmetric cryptography, particularly in areas

where secure key distribution and verification of content authenticity are paramount. Table II presents a comparison of common asymmetric encryption algorithms.

TABLE II. ASYMMETRIC CRYPTOGRAPHY

Algorithm	Key type	Key size (bits)	Security level	Example use cases
RSA	Public/private	1024, 2048, 4096	High	Secure email, digital signatures, and SSL/TLS
ECC	Public/private	160-521	Very high	Mobile devices, digital signatures, and secure communications
DSA	Public/private	1024-3072	High	Digital signatures and secure document verification
ElGamal	Public/private	256-4096	High	Encrypted key exchange and digital signatures

- **Secure key exchange:** A primary application is a secure key exchange for symmetric encryption. Even if attackers intercept communication channels, the asymmetric system ensures the confidentiality of symmetric keys to encrypt media content. For instance, streaming services might leverage asymmetric cryptography to exchange encryption keys securely during the initial connection setup.
- **Digital signatures and content authentication:** Digital signatures, created using asymmetric cryptography, verify the authenticity and integrity of digital media. When content creators sign a media file with their private key, anyone can verify the signature using the corresponding public key. This ensures the content originates from the claimed source and has not been tampered with. This mechanism is widely used in software distribution and updates to guarantee the authenticity of digital media.
- **Certificate-based authentication and secure communication:** Digital certificates issued by trusted authorities rely on asymmetric cryptography to authenticate digital media distribution and consumption entities. These certificates ensure users connect to legitimate services and that media providers distribute content securely. For example, HTTPS protocols use certificates to secure communication between web browsers and streaming services.
- **Enhanced DRM:** Asymmetric cryptography strengthens DRM systems by facilitating secure key management and distribution. Public-key cryptography can encrypt content keys and distribute them only to authorized devices. These devices then use their private keys to decrypt the content keys and access the media. This restricts access to licensed users and devices, preventing unauthorized distribution and piracy.
- **Secure content delivery with Content Distribution Networks (CDNs):** CDNs leverage asymmetric cryptography to secure digital media distribution across

multiple servers. By encrypting media files with public keys and using private keys for decryption at endpoint servers, CDNs safeguard the integrity and confidentiality of media during transit, mitigating the risk of interception or tampering.

C. Hash Functions

Hash functions are cryptographic primitives that map arbitrary-length inputs to fixed-length outputs, typically represented as hexadecimal strings. These output values, or hash codes or values, possess the crucial uniqueness property. The corresponding hash value will be unique for any given input, and even minor alterations will result in a significantly dissimilar hash value. This phenomenon is known as the avalanche effect. Additionally, hash functions are deterministic, ensuring that identical inputs consistently produce the same hash value. Table III provides a comparison of common cryptographic hash functions.

TABLE III. HASH FUNCTIONS

Algorithm	Output size (bits)	Security level	Use cases
MD5	128	Insecure	Legacy systems and checksum verification
SHA-1	160	Insecure	Legacy systems and integrity checks
SHA-256	256	Secure	Digital signatures and integrity verification
SHA-512	512	Very secure	High-security applications and blockchain

A confluence of critical properties characterizes effective cryptographic hash functions. Determinism guarantees that identical inputs invariably produce the same hash value. Additionally, computation efficiency is paramount for real-world applications. Two fundamental properties ensure the robustness of hash functions against cryptographic attacks. Preimage resistance makes it computationally infeasible to retrieve the original input solely from the hash value. Collision resistance, on the other hand, safeguards against the possibility of finding two distinct inputs that generate the same hash output.

Furthermore, hash functions generate fixed-length outputs irrespective of the input size, enhancing their efficiency and facilitating comparisons. Common cryptographic hash functions include MD5 (though currently considered insecure) and SHA-1 (deprecated). The SHA-2 family, encompassing algorithms like SHA-256 and SHA-512, is now the recommended standard for secure hashing. Hash functions serve as a cornerstone for guaranteeing the integrity of digital media content. They provide a mechanism to verify that data remains unaltered or uncorrupted during transmission, storage, or manipulation.

- Data integrity verification: Hash functions safeguard digital media's integrity during transfers or storage across networks and diverse locations. By computing a hash value (unique digital fingerprint) for the original content, subsequent comparisons with the hash of the received or stored file can expose any modifications. This approach is essential for upholding trust in digital

media distribution channels, cloud storage solutions, and content delivery networks.

- Digital signatures and certificates: Hash functions are instrumental in creating digital signatures, a cornerstone of digital media security. When a digital signature is generated, the hash of the content is encrypted with the sender's private key. This encrypted hash, often called a digital signature, is transmitted with the media. The recipient can decrypt the signed hash using the sender's public key and compare it to the hash value computed from the received content. If the hash values match, it confirms the content's integrity and authenticity, signifying that it remains unaltered since the signature was created.
- Content verification in blockchain: Blockchain technology, with its potential for secure digital media management, leverages hash functions to verify the integrity of content stored on the blockchain. Each block within a blockchain incorporates a hash value referencing the preceding block, effectively creating an immutable chain of records [17]. This immutability ensures that any attempt to tamper with a single piece of content would necessitate altering all subsequent blocks, rendering such efforts highly impractical.
- Deduplication and data management: Hash functions are valuable in identifying duplicate files within extensive digital media libraries. Systems can efficiently detect and manage duplicate content by generating and comparing hash values for various files. This optimization translates to improved storage utilization and streamlined retrieval processes.
- Integrity checks in DRM systems: DRM systems rely on hash functions to safeguard the integrity of protected media content. Verifying that the content has not been tampered with is crucial for maintaining the integrity of protected materials and ensuring compliance with licensing agreements.

D. Digital Signatures

Digital signatures are cryptographic mechanisms underpinning the verification of authenticity and integrity in digital messages and documents. Analogous in function to handwritten signatures, they offer a significantly enhanced level of security. The process of creating a digital signature leverages public-key cryptography. A unique signature is generated by encrypting a cryptographic hash of the message or document with the sender's private key. This signature can be validated by anyone possessing the corresponding public key, assuring that the document has not been tampered with and confirming the sender's identity. Common digital signature algorithms are listed in Table IV.

Digital signatures offer crucial properties: authentication, integrity, and non-repudiation. Authentication verifies the sender's identity, guaranteeing that the message or document originates from a legitimate source. Integrity, achieved through hash functions, ensures that the content has not been altered during transmission. Any modification to the content will result in a failed verification process due to a mismatch between the

calculated hash and the one embedded within the signature. Finally, non-repudiation prevents the sender from denying having sent a digitally signed document, thereby establishing legal validity and accountability. Digital signatures are a cornerstone for securing digital media content across various distribution and access channels. Their ability to verify authenticity and integrity fosters trust and combats potential security threats.

TABLE IV. DIGITAL SIGNATURES

Algorithm	Key type	Key size (bits)	Security level	Example use cases
RSA	Public/private	1024, 2048, 4096	High	Document signing and software distribution
ECDSA	Public/private	160-521	Very high	Secure transactions and blockchain
DSA	Public/private	1024-3072	High	Secure communications and legal document verification
EdDSA	Public/private	256-512	Very high	Secure messaging and financial transactions

- Content distribution verification: When digital media like music, videos, or e-books are distributed online, digital signatures safeguard their authenticity. Content creators or distributors can cryptographically sign their media files. Users can then verify these signatures using the publicly available content creator key. This process ensures the content hasn't been tampered with or corrupted during distribution, protecting users from unknowingly acquiring compromised media.
- Software and firmware updates: Digital signatures are critical in software and firmware updates for digital media devices like streaming boxes, smart TVs, and gaming consoles. Manufacturers sign update files with their private keys. Devices verify these signatures before installing the updates, guaranteeing that only legitimate and unaltered updates are applied. This mitigates the risk of installing malicious software disguised as updates.
- Blockchain and content authentication: With its potential for secure digital media management, Blockchain technology utilizes digital signatures for transaction authentication and ownership verification of digital assets. The content owner signs every transaction involving digital media content, and these signatures are recorded on the blockchain. This creates a transparent and tamper-proof record of ownership and distribution history.
- Secure online transactions: In e-commerce platforms selling digital media like music, videos, and software, digital signatures guarantee the authenticity of the purchased content. Customers can verify that the digital products they receive are genuine and unaltered. This enhances trust and transparency in the transaction process for consumers and vendors.

- Copyright protection and legal evidence: Digital signatures offer legal proof of ownership and authenticity, which is crucial for copyright protection and legal disputes. Content creators can leverage digital signatures to establish their rights over their creations. These signatures can then be presented as evidence in court cases related to copyright infringement.

III. REVIEW OF APPROACHES

The widespread adoption of image formats, especially JPEG, has opened avenues for embedding additional information within these files. While steganographic techniques utilizing the least significant bits have been dominant, this research proposes alternative methods. Harran, et al. [18] demonstrated the feasibility of incorporating a digital certificate alongside its corresponding metadata directly into an image file. This metadata references the issuing entity responsible for the certificate. Despite variations across devices, operating systems, and applications, JPEG files exhibit remarkable structural consistency. The proposed approach strategically inserts references to the issuing company within the file's metadata. This integration offers a distinct advantage: the digital certificate remains tethered to the file it applies to, ensuring it travels together throughout the file's lifecycle. The research ultimately establishes the potential of file metadata to house additional data that bolsters the integrity, authenticity, and provenance of the digital content embedded within the file. This approach paves the way for innovative methods to secure and verify digital content using existing file structures.

Table V summarizes the proposed approaches for embedding and securing digital media, highlighting key techniques, advantages, and use cases. Gurnathan and Rajagopalan [19] proposed a steganographic technique for embedding secret messages within a cover image using LSB substitution to evade detection by potential interceptors. This work builds upon the core concept of LSB substitution but introduces modifications to improve image quality and message capacity while maintaining security. Inspired by existing approaches that divide cover images into blocks, the proposed method partitions the cover image and the secret message into equal-sized blocks (typically 8x8 pixels). This strategy aims to achieve a balance between embedding capacity and image quality. A key innovation lies in utilizing the Cuckoo Search (CS) algorithm. Unlike prior methods that employ a single substitution matrix for the entire image, the proposed approach leverages CS to find an optimal substitution matrix for each block. This approach aims to achieve a more nuanced embedding process, optimizing message concealment within each block while minimizing visual artifacts in the resulting stego-image (the image containing the hidden message). The final stage involves evaluating the quality of the stego-image, the message capacity, and the security level of the proposed method. These metrics are then compared to existing techniques based on the Joint Photographic Experts Group (JPEG) standard and Joint Quantization Table Modification (JQTM). Experimental results, as reported by the authors, demonstrate that the proposed method surpasses both JPEG and JQTM-based methods in terms of image quality, security level, and message embedding capacity.

TABLE V. PROPOSED APPROACHES FOR EMBEDDING AND SECURING DIGITAL MEDIA

Authors	Approach	Key techniques	Advantages
Harran, et al. [18]	Embedding digital certificates in JPEG files	Metadata embedding	Ensures certificate travels with the file, enhances integrity and authenticity
Gurunathan and Rajagopalan [19]	Steganography using LSB substitution with Cuckoo Search algorithm	LSB substitution, Cuckoo Search	Improves image quality and message capacity, optimizes message concealment
Gafsi, et al. [20]	Hybrid image encryption using asymmetric and symmetric cryptography	RSA, AES-256, SHA-2	High security, robust against cryptanalysis attacks
Panchal, et al. [22]	Document security using fingerprint biometrics	Biometric feature extraction, convolution coding	High true positive rate, no need to store encryption keys
William, et al. [21]	Hybrid cryptographic solution merging AES, ECC, and SHA-256	AES, ECC, SHA-256	Enhanced efficiency for text encryption, secure data integrity
Yasser, et al. [23]	Multimedia encryption using chaotic dynamics and 2D alteration models	Chaotic maps, hybrid chaotification	Strong key sensitivity, high resistance to attacks
Sanivarapu, et al. [24]	Image watermarking scheme using cryptographic techniques and QR code scrambling	QR code, DWT, SVD, chaotic logistic map	Resilient to image processing attacks, maintains minimal visual distortion
Alarifi, et al. [25]	Hybrid cryptosystem for securing HEVC video streams	DNA sequences, Arnold chaotic map, Mandelbrot sets	Robust and enhanced security for HEVC video streaming

Gafsi, et al. [20] presented a novel image encryption system designed to achieve high security for digital images. Their approach leverages a combination of asymmetric and symmetric cryptography to provide robust protection. The asymmetric component utilizes the well-established RSA algorithm. RSA employs a public key for encryption and a private key for decryption, ensuring secure key distribution and management. However, image encryption relies on the AES-256 algorithm in Counter (CTR) mode. This combination offers a strong foundation for image data encryption. Furthermore, the system incorporates the SHA-2 hashing function. SHA-2 serves as a cryptographic hash function, generating a unique fingerprint of the original image data. This fingerprint can be used for integrity verification, ensuring the image has not been tampered with during encryption or decryption. The effectiveness of the proposed system was evaluated using various established tools and tests commonly employed within the image cryptography community. These tests utilized a diverse set of standard, non-compressed images. The experimental and analytical results indicate that the encryption scheme offers robustness and resistance against known cryptanalysis attacks. These positive results suggest the proposed method achieves high performance and efficiency, making it suitable for applications requiring strong image protection in various domains, such as military communication and securing sensitive data for personal privacy.

William, et al. [21] proposed a novel cryptographic solution that merges three distinct cryptographic primitives: a symmetric algorithm (AES), an asymmetric algorithm (ECC), and a hash function (SHA-256). SHA-256 is a cryptographic hash function that generates a unique message digest from the input data. This digest is a fingerprint to verify data integrity and expose potential tampering attempts. The proposed hybrid approach resembles existing techniques that leverage AES for encrypting textual and graphical data. However, the authors posit that their solution offers enhanced efficiency, particularly text encryption, compared to prior methods. While acknowledging the current limitations in image encryption speed, they suggest that future advancements could optimize the solution for improved image encryption performance.

Panchal, et al. [22] proposed a novel document security mechanism that leverages fingerprint biometrics. This system

extracts unique features from a user's fingerprint captured by a biometric sensor. These features are then processed using convolution coding principles to generate a unique code. This unique code is the foundation for creating cryptographic keys for encrypting and decrypting user documents. A rigorous evaluation of the proposed approach, involving experimentation with various standard fingerprint images within a database, yielded impressive results. The system achieved a high true positive rate of 95%, indicating accurate identification of authorized users.

Furthermore, the system yielded a 0% false negative rate, ensuring no instances where authorized users were mistakenly denied access. This system offers several significant advantages. Firstly, it generates a unique key for each user, eliminating the need to store a central template of biometric data, which can be a security vulnerability. Secondly, the system avoids storing any encryption keys, further enhancing security. Finally, the reported efficiency suggests the system is suitable for real-world applications due to its speed and accuracy. These qualities make it a promising solution for developing robust data storage security systems.

Yasser, et al. [23] introduce novel multimedia encryption schemes that leverage chaotic dynamics and 2D alteration models to achieve high-security data transmission. Their approach revolves around a new perturbation-based data encryption method applicable to confusion and diffusion rounds. The core novelty lies in the hybrid chaotification structure, which combines multiple chaotic maps for enhanced media encryption. These blended maps generate control parameters for the permutation (shuffling) and diffusion (substitution) stages within the encryption process. The proposed schemes maintain the high encryption quality characteristic of chaotic systems and boast additional advantages. These include strong key sensitivity, resistance to unauthorized key derivation, and low residual clarity, minimizing the potential for intelligible information leakage from the encrypted media. Extensive security and differential analyses demonstrate the efficacy of the proposed schemes for securing multimedia transmissions. The encrypted media exhibits a high degree of resistance against various attacks. Additionally, statistical evaluations using established metrics for specific media types reveal that the schemes achieve low

residual intelligibility while maintaining statistically sound properties in the recovered data.

Sanivarapu, et al. [24] introduced a novel image watermarking scheme that utilizes cryptographic techniques to ensure copyright protection and content authentication. Their method centers around a watermark image containing a public-key/private-key pair generated through a cryptosystem. This watermark is then encoded into a quick response (QR) code. The QR code is scrambled using a chaotic logistic map to enhance security. The public and private keys serve a dual purpose: encrypting the data embedded within the watermark and facilitating its decryption during extraction. The scrambled QR watermark is then embedded into a color image using a single-level discrete wavelet transform (DWT) followed by singular value decomposition (SVD). The key plays a crucial role in this embedding process. Watermark extraction entails reversing the steps involved in embedding. The proposed method's effectiveness is evaluated through its resilience to various image-processing attacks commonly employed to remove watermarks. The authors compare their results with those achieved by state-of-the-art watermarking schemes, demonstrating that their method balances robustness (resistance to attacks) and imperceptibility (minimal visual distortion of the host image).

The burgeoning adoption of big data processing, cloud computing, and the IoT has fueled a surge in multimedia information consumption, particularly video. Within the Internet of Multimedia Things (IoMT), video is extensively streamed over communication networks, necessitating robust security measures. Unfortunately, existing methods for securing multimedia content transmission between cloud platforms and mobile devices often face limitations due to processing overhead, memory constraints, data size considerations, and battery power limitations on mobile devices. These limitations render such methods suboptimal for large multimedia files and unsuitable for the resource-restricted nature of mobile devices and cloud environments. High-Efficiency Video Coding (HEVC) is the latest video codec standard, enabling efficient storage and streaming of high-resolution videos while maintaining acceptable file sizes and superior quality. In this context, Alarifi, et al. [25] proposed a novel hybrid cryptosystem designed to safeguard the streaming of compressed HEVC video streams. This cryptosystem leverages a combination of Deoxyribonucleic Acid (DNA) sequences, the Arnold chaotic map, and Mandelbrot sets. The secure video transmission process commences with video encoding using the H.265/HEVC codec to achieve efficient compression. Subsequently, the proposed method employs the Arnold chaotic map for individual encryption of the three-color channels (Y, U, and V) within each compressed HEVC frame. Following this initial encryption step, DNA encoding sequences are established upon the resulting frames. Finally, a modified conditional shift process based on the Mandelbrot set is introduced to further obfuscate the encrypted data within the Y, U, and V channels. The authors conducted extensive simulations and security analyses to validate the proposed HEVC cryptosystem. The results demonstrate exceptional robustness and enhanced security compared to existing cryptosystems documented in the literature. This approach

offers a promising solution for securing HEVC video streaming in resource-constrained environments.

IV. RESULTS AND DISCUSSION

Because of its efficiency and speed, symmetric cryptography remains the cornerstone of digital media security. Symmetric algorithms such as AES and RC4 are widely used in content encryption, digital rights management, and secure streaming. Streaming services like Netflix use AES to protect media files during transmission and storage, ensuring that only authorized users can view the content. However, the biggest challenge is key management. The distribution and storage of secure keys represent a significant vulnerability, especially in large systems. Additionally, symmetric algorithms can be effective for real-time encryption, but their use of a single key raises security concerns if the key is compromised.

Asymmetric dual-key cryptography addresses some key management problems associated with symmetric cryptography. With public key cryptography, as demonstrated by RSA and ECC, encryption keys can be securely exchanged and content authenticity verified. Secure key exchange, digital signatures, and DRM enhancement rely heavily on asymmetric cryptography. Using asymmetric cryptography, digital certificates ensure users connect to legitimate services and media providers distribute content safely. Despite its advantages, asymmetric cryptography can be computationally intensive, which can be a problem for applications that require high-speed encryption.

Data integrity and authenticity are ensured in digital media security by hash functions. The SHA-256 feature is often used to create digital fingerprints for content, allowing unauthorized changes to be detected. Virtual signatures, blockchain content verification, and data deduplication in large media libraries are all based on hash functions. For example, blockchain technology secures digital media content by creating an immutable chain of records using hash functions. However, despite their effectiveness, hash functions have limitations. As computing power increases and new attack vectors emerge, collisions remain a problem, even with advanced algorithms like SHA-256.

The integrity and authenticity of digital content can be verified using digital signatures. In public key cryptography, digital signatures provide non-repudiation and ensure that the provenance and integrity of content can be independently verified. The review concluded that digital signatures make a significant contribution to verifying content distribution, software updates, and authentication of blockchain-based content. For example, a digital signature ensures that only legitimate software updates are distributed. This means there is no risk of devices becoming infected with malware. In resource-constrained environments, the implementation of digital signatures can be limited by the computational effort associated with signature generation and verification.

V. CHALLENGES AND FUTURE DIRECTIONS

Securing encryption keys remains one of the most significant challenges in cryptographic systems. In symmetric cryptography, securely distributing and storing keys can be problematic, especially as the number of users increases.

Although public keys can be distributed more freely in asymmetric systems, the private keys must be stored securely to prevent unauthorized access. The complexity of key management is further exacerbated in large-scale digital media systems where millions of users might be involved.

As digital media content and user bases grow, ensuring that cryptographic solutions scale effectively is crucial. High computational requirements for encryption and decryption can lead to performance bottlenecks, especially for real-time applications like live streaming. Finding a balance between robust security and system performance is essential for deploying cryptographic techniques in digital media systems.

Implementing strong cryptographic measures often introduces complexity for end-users. If accessing encrypted content or managing digital rights becomes too cumbersome, it can lead to poor user experience and lower adoption rates. Designing user-friendly cryptographic systems that provide robust security without compromising usability is a persistent challenge.

With many devices, platforms, and media formats, ensuring that cryptographic solutions are interoperable is challenging. Media content must be securely accessible across different devices and platforms without compromising security. Achieving interoperability while maintaining a high level of security requires standardization and widespread adoption of secure protocols.

Cryptographic techniques must evolve to stay ahead of emerging threats. As computational power increases, particularly with the advent of quantum computing, existing cryptographic algorithms may become vulnerable. Ensuring that cryptographic systems resist future threats is a significant challenge that requires ongoing research and adaptation.

Research into quantum-safe or post-quantum cryptography is crucial, given the potential threat of quantum computers rendering current cryptographic algorithms obsolete. Developing and standardizing cryptographic algorithms that can withstand quantum attacks will be essential for the long-term security of digital media content.

Using blockchain and other decentralized technologies can provide innovative solutions for digital media security. Blockchain can offer transparent and tamper-proof mechanisms for rights management, content distribution, and royalty payments. Smart contracts can automate and enforce access control and usage policies, reducing the reliance on centralized DRM systems.

As privacy concerns grow, incorporating privacy-preserving techniques such as homomorphic encryption, secure multi-party computation, and zero-knowledge proofs into digital media security solutions will become increasingly important. These techniques can ensure that user data is protected while still allowing necessary processing and verification.

Establishing and adopting interoperability standards for digital media cryptographic solutions can help address cross-platform compatibility challenges. Industry-wide collaboration is needed to develop and implement these standards to ensure

seamless and secure access to digital media across different devices and platforms.

VI. CONCLUSION

In the ever-evolving digital media landscape, ensuring content security and integrity is paramount to prevent unauthorized access and piracy. This paper has provided a comprehensive overview of the cryptographic techniques for safeguarding digital media assets. The study delved into various methods to protect digital media, including encryption, DRM, watermarking, and blockchain-based solutions, starting with the fundamentals of symmetric and asymmetric cryptography, hash functions, and digital signatures. While these cryptographic techniques offer robust mechanisms to secure digital content, they also present several challenges, particularly in key management, scalability, usability, interoperability, and resistance to emerging threats. Addressing these challenges is crucial for the continued advancement and effectiveness of digital media security. Looking forward, the development of quantum-safe cryptography, enhanced key management systems, advanced DRM solutions, and privacy-preserving techniques will be essential. Integrating blockchain technology and establishing interoperability standards will further strengthen the security framework for digital media. Additionally, improving user education and simplifying the interface for secure content access will help bridge the gap between robust security measures and user convenience.

Abstract—This study addresses the pressing challenge of detecting online gambling promotions on Indonesian Twitter using text mining algorithms for text classification and analytics. Amid limited research on this subject, especially in the Indonesian context, we aim to identify common textual features used in gambling promotions and determine the most effective classification models. By analyzing a dataset of 6038 tweets collected and using methods such as Random Forest, Logistic Regression, and Convolutional Neural Networks, complemented by a comparison analysis of text representation methods, we identified frequently occurring words such as 'link', 'situs', 'prediksi', 'jackpot', 'maxwin', and 'togel'. The results indicate that the combination of TF-IDF and Random Forest is the most effective method for detecting online gambling promotion content on Indonesian Twitter, achieving a recall value of 0.958 and a precision value of 0.966. These findings can contribute to cybersecurity and support law enforcement in mitigating the negative effects of such promotions, particularly on the Twitter platform in Indonesia.

Keywords—Social media; analytics; online gambling; intention classification

I. INTRODUCTION

In today's digital age, the landscape of social media platforms has undergone significant evolution, becoming an integral part of people's daily lives. Prominent social media accounts now have millions of followers [1], and they are utilized by various elements of society [2]. With billions of users worldwide, platforms such as Facebook, Twitter, Instagram serve as virtual hubs where individuals connect, share, and consume content. According to Digital 2024 Global Overview Report [3], as of January 2024, internet users in Indonesia spent an average of 3 hours 11 minutes a day accessing social media. This duration is above the global average of 2 hours 23 minutes, highlighting the strong attraction of social media for internet users in Indonesia.

Unfortunately, the strong appeal of social media in Indonesia has also led to a dramatic increase in exploitation of social media accounts for the promotion of online gambling in recent years, posing substantial challenges to regulatory authorities and law enforcement agencies. Online gambling promotion, particularly through social media platforms, has emerged as a crucial strategy for reaching potential players [4]. The widespread accessibility of online gambling sites, operating 24/7, is evident [5]. Furthermore, the prevalence of online gambling promotions on social media is notable, with influencers, social media personalities, and even celebrities actively engaging in such campaigns [6]. The ease of access

and widespread reach of social media platforms have facilitated the dissemination of these illicit promotions, exacerbating concerns surrounding the detrimental effects of online gambling on vulnerable individuals, including minors and those with gambling addiction issues [7].

Over the past 30 years, the internet has sparked profound changes, presenting three primary challenges for gambling marketing and public policy: (1) significant transformations in the gambling industry's scale, scope, and nature; (2) a surge in gambling advertising on social media; and (3) inadequate methodologies for analyzing the extensive volume of online advertising data [8]. Detecting online gambling promotions on social media presents multifaceted challenges, ranging from identifying the numerous tactics employed by promoters to evade detection to pinpointing the specific accounts engaging in such activities. Moreover, discerning the nuanced interactions and strategies utilized by these accounts adds another layer of complexity to the detection process. Traditional gambling advertising techniques have historically been inspected through manual content analysis [9] [10] [11]. Despite offering detailed insights into specific content characteristics, this approach is laborious and resource-intensive, leading to significant constraints on sample sizes [12].

In the face of these challenges, there exists an opportunity to utilize cutting-edge technologies, especially artificial intelligence algorithms such as machine learning or deep learning with a text classification or text analytics approach, to effectively address the widespread dissemination of online gambling promotions [13]. By harnessing the power of machine learning, researchers can develop robust detection mechanisms capable of identifying and categorizing online gambling promotions with high accuracy. Therefore, the aim of this study is to answer these research questions (RQ):

- What textual features are commonly utilized in online gambling promotions on Indonesian Twitter?
- How do classification models effectively perform in detecting online gambling promotion content in Indonesian Twitter data?

This includes investigating the frequently used textual features in online gambling promotions on Indonesian Twitter and determining the effectiveness of various text mining classification methods for detecting such content. Through this study, we aim to provide significant insights into the common characteristics and patterns found in such promotional content,

as well as to identify the most effective classification algorithms for this context. We expect that the results will contribute to various aspects, including the development of prevention strategies and regulations, enhancing cybersecurity measures, and preventing the spread of illegal content on social media platforms. Furthermore, these findings are anticipated to aid law enforcement efforts and protect social media users from the negative impacts of online gambling promotion.

II. RELATED WORKS

Based on our literature review, discussions on the detection of online gambling promotion content in social media are scarcely found. Therefore, we have endeavored to compile knowledge related to the characteristics of similar content and techniques used in previous studies. The literature we gathered covers topics including online gambling, spam detection, as well as text classification and the detection of harmful content users.

In our exploration of online gambling, we have gained insights into textual features and common patterns found in gambling advertisements. Although studies [14] and [15] lack detailed evaluation reports on advertisement classification, study [14] reveals high-frequency words used in gambling ads, suggesting a trend of positive language that highlights benefits, bonuses, and special deals, as observed across studies [7], [16]–[18]. Complementing this, study [7] specifically sheds light on the characteristics of online gambling ads in Indonesia, pointing out features such as bonuses, luck, financial gains, and the ease of joining. This finding aligns with our earlier literature review, which identified a scarcity of discussions on the detection of online gambling content, especially in Indonesia, underscoring the need for our comprehensive approach to understanding these promotional strategies.

In our study, we have reviewed various approaches for text and spam classification. Predominant algorithms such as Random Forest, Support Vector Machine (SVM), and Naïve Bayes, particularly when integrated with N-Gram analysis [19][20], are favored for their reported high accuracy rates, often exceeding 95%. Furthermore, applications of LSTM and Word Sequence [21] are also considered effective alternatives, achieving an accuracy rate of 88%. Other studies [22]–[24] have explored RNN, manual analysis, and topic modeling, though their effectiveness evaluations are not explicitly reported.

Focusing on spam classification, especially content promoting gambling, many papers compare different algorithms, preprocessing stages, and their evaluations. Studies [25] and [20] advocate the use of the SVM algorithm for spam detection, with study [20] achieving an F-Score of 96% through bi-gram and TF-IDF preprocessing. Study [26] employs a Thai BERT derivative, reaching an F-Score of 0.8, while other research, like study [27] using neural networks and GloVe, and study [28] employing logistic regression and Word2Vec, report high F-Scores of 99.73% and 93%, respectively. An alternative approach in study [29] utilizes regex-based rules for spam detection, although it lacks detailed evaluation.

Most of the studies we analyzed use English text data. For text analysis in the Indonesian context, several studies have demonstrated the application of various classification models and feature extraction techniques on Indonesian-language datasets. One notable study [30] utilized a Convolutional Neural Network (CNN) alongside GloVe (Global Vectors) for intent classification within the ATIS (Airline Travel Information System) dataset, achieving a commendable accuracy of 95.84%. In another study [31], the implementation of Naive Bayes combined with TF-IDF was employed for the classification of terrorism-related content on Indonesian Twitter, attaining an F-measure of 77%. Setiawan's research [32] applied Logistic Regression with Word2Vec for feature extraction to detect spam posts on Indonesian Twitter, resulting in an accuracy of 93.67%. Additional research efforts in spam detection on Indonesian Twitter include [33], which used CountVectorizer and KNN to achieve an accuracy of 79%, and another research [34], which employed CountVectorizer and Random Forest, achieving an accuracy of 85.1%. These studies underscore the versatility and effectiveness of different text classification approaches within the Indonesian linguistic framework.

In advancing our research on the detection of online gambling promotion content in social media, we encounter several challenges that are crucial to address. These include the determination of effective keywords for data retrieval from social media queries, streamlining the labeling processes, and the selection of appropriate models and textual features. The need for precise keyword selection and labeling is particularly acute due to the limited data availability from Twitter following recent policy changes. To address this issue, we conducted descriptive analysis of frequently occurring words in online gambling promotions on Indonesian Twitter to provide insights into more effective search keyword identification. This analysis will precede the predictive analysis of training on classification models to detect such online gambling promotional content, aiming to develop an optimized approach for our text mining processes.

III. METHODOLOGY

In this research, we aim to conduct both descriptive and predictive analyses to gain a comprehensive understanding of online gambling promotion on Indonesian Twitter, thus enhancing detection knowledge and capabilities. Our research process, depicted in Fig. 1, initiates the identification of query keywords for Twitter data collection. Once keywords are selected, Twitter data retrieval is carried out. The accumulated data are labeled and then undergo pre-processing steps such as tokenization, normalization, noise removal, and stemming. Post-preprocessing, experiments are conducted as specified in Table II to identify the optimal model for detecting online gambling content on Indonesian Twitter. The experimental outcomes are further discussed to interpret the findings. Finally, conclusions and reports are drafted based on the discussions and analyses conducted, culminating in the research.

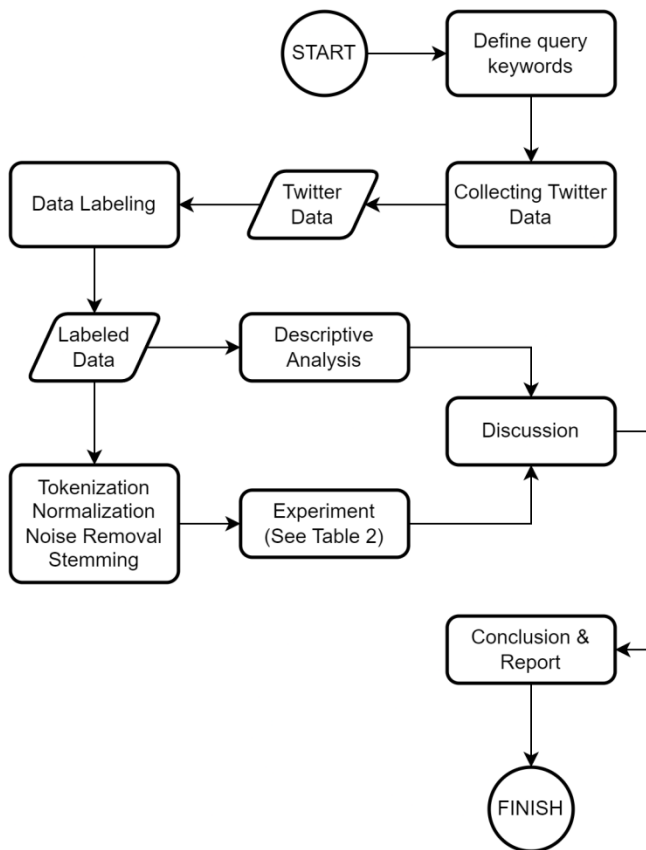

Fig. 1. Proposed workflow of this study.

Keyword query determination aims to ensure effective retrieval from Twitter searches. In identifying keywords, we refer to previous research on general online gambling promotion, characterized by a positive tone and suggestive of benefits and ease [7], [14]. Based on [7] and other studies published online [35], we use the query string "(slot OR gacor OR untung OR cuan) lang:id" to collect Indonesian Twitter samples containing online gambling content. We target a minimum of 5000 Indonesian language tweet samples for further analysis.

Upon sample data acquisition, data labeling ensues. We employ two annotators who have agreed upon the criteria for what constitutes online gambling promotion content, with examples outlined in Table I. The labeled data is then utilized for both descriptive and predictive analyses. In determining the label of a tweet, we provided clear labeling criteria to both annotators to minimize inconsistencies. A tweet was labeled as containing online gambling promotional content if it met one or more of the following criteria:

- Explicitly inviting individuals to participate in online gambling activities,
- Displaying links or names of online gambling platforms,
- Showing results from online gambling activities,
- Providing instructions on how to join online gambling activities.

TABLE I. EXAMPLE OF POSTS WITH ONLINE GAMBLING PROMOTION

Furthermore, we calculated the inter-annotator agreement using Cohen’s Kappa coefficient.

To address any disagreements between annotators, a reconciliation process was implemented. Disagreements were discussed in a joint session between the annotators, and if consensus could not be reached, a third expert annotator was brought in to make the final decision. This process ensured a thorough review and maintained consistency in labeling.

Descriptive analysis is conducted to depict the nature of online gambling content more comprehensively on Indonesian Twitter and aim to answer RQ 1. The steps for descriptive analysis derive from the study of online gambling content on Facebook [35], including temporal analysis, interaction count analysis, and examination of frequently occurring words besides search keywords, analyzed using a word cloud.

Predictive analysis aims to develop a classification model that detects online gambling promotional posts from the available dataset as the answer to RQ 2. After labeling, the data is tokenized, normalized, noise is removed, and stemming is conducted. The feature extraction and modeling phases, which determine the best algorithm for detecting online gambling promotion, are conducted through experiments listed in Table II. Algorithm selection for experimentation is based on previous research [30], [32], [34].

The selection of algorithms for this study was carefully considered to match the unique challenges presented by the task of detecting online gambling promotions on Twitter. Given the informal and varied nature of Twitter text, including the use of slang and abbreviations, Convolutional Neural Networks (CNNs) were chosen for their ability to capture complex patterns and contextual nuances within text. Random Forest was selected due to its effectiveness in handling high-dimensional data and its resistance to overfitting, which is essential when dealing with diverse textual features. Logistic Regression was included for its interpretability and as a

baseline model to compare performance, as it is widely used in text classification tasks. This combination of models was intended to leverage the strengths of each algorithm in addressing different facets of the data, ensuring a robust analysis of the factors contributing to the detection of online gambling promotions.

Evaluations are performed using a confusion matrix, focusing on recall and F-measure to minimize the potential oversight of online gambling content by the model. Due to the lack of reported training times in related studies, a direct comparison of computational efficiency between our model and those presented in [30], [32], and [34] cannot be conducted. Nevertheless, our results highlight the importance of including training time as a key metric for evaluating model performance, especially in contexts where computational resources are limited. We chose the F1 score and Recall as our primary evaluation metrics due to their relevance in contexts with imbalanced data. Recall is particularly important because it measures the model's ability to correctly identify all instances of the minority class, which is crucial in detecting online gambling promotions. The F1 score provides a balanced measure of both precision and recall, offering insight into the model's performance in minimizing false positives while still capturing true positives. These metrics were selected to ensure that the chosen model performs effectively even in the presence of class imbalance.

Once the optimal model is identified and descriptive analysis is complete, the report writing is finalized with discussions and conclusions.

TABLE II. EXPERIMENTAL LIST

Experiment	Text Representation	Algorithm
1	GloVe	CNN
2	GloVe	LR
3	GloVe	RF
4	Word2Vec	CNN
5	Word2Vec	LR
6	Word2Vec	RF
7	TF-IDF	CNN
8	TF-IDF	LR
9	TF-IDF	RF

These steps form the basis of our proposed research methodology, which aims to address the intricacies of detecting online gambling promotions in social media content effectively.

IV. RESULTS AND DISCUSSIONS

We successfully collected 6,038 Twitter data points based on the predetermined keywords. This result exceeds our target of 5,000 Twitter data points, allowing us to proceed with data annotation.

The data annotation was carried out by two annotators working independently. The annotation process involved assigning a label of "1" if the post contained online gambling

promotion content, and a label of "0" if the post did not contain such content. The annotation results were then evaluated using Cohen's Kappa coefficient, with the matrix presented in Table III.

TABLE III. ANNOTATION EVALUATION MATRIX

Label	Label 0 (Annotator B)	Label 1 (Annotator B)
Label 0 (Annotator A)	4308	41
Label 1 (Annotator A)	42	1647

Based on Table III, the Cohen's Kappa coefficient from the evaluation is 0.9659, indicating an almost perfect agreement between the annotators [36]. This result suggests that the labeled data can be used for the next steps in the analysis, which include descriptive analysis and data preprocessing. The comparison of the label counts for each category is shown in Fig. 2 that shows the imbalanced dataset as labeling results.

Our approach reflects a realistic scenario where data imbalance is common, and practitioners may not always have the opportunity or resources to apply complex rebalancing techniques. By evaluating model performance on the raw, imbalanced data, we aimed to identify algorithms that are naturally resilient to such conditions. This decision was based on the need to assess the practical utility of the models in environments where preprocessing capabilities may be limited.

Fig. 2. Number of labels.

We then proceeded with temporal analysis by visualizing the number of tweets labeled "1" per hour. The visualization results, as shown in Fig. 3, indicate that online gambling promotion content is often posted during the early morning and late afternoon to evening hours.

Interactions with tweets containing online gambling promotion content are relatively high, averaging 1.68 interactions per tweet, including quotes, replies, retweets, or favorites. This is five times higher than the average interactions per tweet labeled "0," which is 0.38 interactions per tweet. Three accounts with usernames indicative of online gambling operators have average interactions of 36, 29, and 24 interactions per tweet. This indicates that accounts and posts

TABLE VI. RESULTS OF EXPERIMENT'S SCENARIO

Vectorizer	Algorithm	Accuracy	AUC	Recall	Precision	F1 Score	Kappa	MCC	Training Time
GloVe	CNN	0.97462	0.99517	0.94268	0.96493	0.95363	0.93612	0.93632	7.81112

TF-IDF	RF	0.97878	0.99419	0.95829	0.96572	0.96183	0.94711	0.94726	0.63892
Word2Vec	CNN	0.97082	0.9939	0.94344	0.95303	0.94759	0.92736	0.92798	4.12421
Word2Vec	LR	0.93732	0.98075	0.86085	0.911	0.88469	0.84168	0.8428	0.04422
Word2Vec	RF	0.96119	0.9902	0.92247	0.9376	0.92967	0.90286	0.9032	2.06679

The combination of TF-IDF and CNN shows poor performance, particularly in recall and F1 score, indicating that this model is less effective in detecting online gambling promotion tweets. The combination of TF-IDF and Logistic Regression demonstrates excellent performance, similar to GloVe-CNN, but with significantly lower training time, making it more efficient. Random Forest with TF-IDF shows the best performance among all combinations, with very high evaluation metrics and still relatively efficient training time.

The combination of Word2Vec and CNN demonstrates excellent performance, approaching the performance of GloVe-CNN but with lower training time. Logistic Regression with Word2Vec shows good performance, though not as strong as the other top combinations. It's very low training time makes this model highly efficient. Random Forest with Word2Vec shows excellent performance, slightly below the performance of TF-IDF with Random Forest. This model is still very effective in detecting promotional tweets, with lower training time compared to TF-IDF with CNN.

Overall, the combination of TF-IDF with the Random Forest algorithm provides the best performance in identifying online gambling promotion content. The Recall value of 95.8% indicates that the TF-IDF with RF combination can minimize false negatives. The high Precision value of 96.6% shows that this combination effectively avoids false positives. This is also supported by a high MCC value and moderate training time.

TF-IDF with Logistic Regression and Word2Vec with Logistic Regression show a good balance between high performance and very low training time. GloVe with Logistic Regression and TF-IDF with CNN demonstrate significantly lower performance and are not recommended for detecting online gambling promotion tweets.

We conducted hypothesis testing based on the results presented in Table IV to determine if there is a significant difference between the performance of the TF-IDF with Random Forest (RF) combination and the Word2Vec with Convolutional Neural Network (CNN) combination. This analysis was undertaken because both combinations demonstrated high Recall and F1 Score with acceptable training times, along with the difference in text vectorization's method. The null hypothesis (H0) was "There is no significant

difference between the performance of TF-IDF with RF and Word2Vec with CNN," and the alternative hypothesis (H1) was "There is a significant difference between the performance of TF-IDF with RF and Word2Vec with CNN."

We performed hypothesis tests on two model evaluation metrics: Recall and F1 Score. The results of these hypothesis tests are presented in Table VII.

TABLE VII. HYPOTHESIS TEST RESULTS FOR RECALL AND F1 SCORE

	alpha	p-value	Results
Recall	0.05	0.130	Fail to reject H0: No significant difference
F1 Score	0.05	0.047	Reject H0: Significant difference

Table VII shows that the p-value for the recall metric is 0.130, which is greater than the significance level of 0.05. Therefore, we fail to reject the null hypothesis. This indicates that there is no statistically significant difference in recall between the TF-IDF + RF model and the Word2Vec + CNN model. In other words, both models perform similarly in terms of recall. The recall metric measures the ability of the model to correctly identify all relevant instances of online gambling promotion. The lack of a significant difference in recall suggests that both models are equally effective in identifying true positive instances of online gambling promotions on Indonesian Twitter. This could imply that both text representation methods (TF-IDF and Word2Vec) and classification algorithms (RF and CNN) are similarly proficient in capturing the relevant features needed for high recall in this context.

The p-value for the F1 score metric is 0.047, which is less than the significance level of 0.05. Therefore, we reject the null hypothesis. This indicates that there is a statistically significant difference in F1 score between the TF-IDF + RF model and the Word2Vec + CNN model. Specifically, the TF-IDF + RF model has a significantly better F1 score compared to the Word2Vec + CNN model. The F1 score is a harmonic means of precision and recall, providing a balance between the two. The significant difference in F1 score, favoring the TF-IDF + RF model, indicates that this model not only identifies true positives effectively (recall) but also minimizes false positives (precision). The higher F1 score suggests that TF-IDF + RF strikes a better balance between precision and recall compared

to Word2Vec + CNN, making it a more reliable model for this task.

Compared to the previous studies we use for reference, although the exact training times were not reported, the studies [30], [32], and [34] utilized models such as Random Forest and SVM, which are known for their differing computational complexities. Random Forest, for example, often requires more computational resources due to the ensemble nature of the algorithm, compared to a single-layer SVM model. By contrast, our study's use of a TF-IDF combined with Random Forest may offer a more balanced trade-off between accuracy and computational efficiency.

V. CONCLUSION

The conclusion of this study shows that, based on the analysis, textual features commonly utilized in online gambling promotions on Indonesian Twitter include words such as "link," "situs," "prediksi," "jackpot," "maxwin," and "togel." These words frequently appear in online gambling content on Twitter. This indicates that these words are effective textual features for detecting online gambling promotions on Indonesian Twitter, in addition to the initial textual features we used as keywords in our query string. Furthermore, the results of the classification model training indicate that the combination of TF-IDF and Random Forest is the most effective method for detecting online gambling promotion content on Indonesian Twitter. With a recall value of 95.8% and a precision value of 96.6%, this combination significantly minimizes false negative and positive detections. This research makes an important contribution to the development of strategies for preventing and regulating illegal content on social media and supports law enforcement efforts in addressing the negative impacts of online gambling promotion.

While our study focuses on detecting online gambling promotions on Indonesian Twitter, the proposed methodology could potentially be generalized to other languages and platforms. For instance, the tokenization and normalization processes would need adjustments to account for linguistic differences in languages like Japanese or Arabic. Furthermore, the high variability in content length and user behavior across platforms like Facebook and Instagram might require a reevaluation of the feature extraction techniques to maintain model accuracy.

For future research, it is recommended to apply and test this model on other social media platforms to broaden the generalization of the results, develop more efficient approaches for data annotation to enhance labeling accuracy and consistency, integrate sentiment analysis to gain a deeper understanding of the psychological impact of online gambling promotion content on social media users, and explore the use of other deep learning algorithms that may offer better performance with larger datasets.

With these suggestions, it is hoped that future research can be more comprehensive in addressing and preventing the spread of illegal content on social media.

Securing RPL Networks with Enhanced Routing Efficiency with Congestion Prediction and Load Balancing Strategy

Saumya Raj^{1*}, Rajesh R²

Research Scholar, Department of Computer Science, Bharathiar University, Coimbatore, India¹
Associate Professor, CHRIST (Deemed to be university) Bangalore, Bharathiar University, Coimbatore, India²

Abstract—Low power and Lossy Networks (LLNs) are essential components of the Internet of Things (IoT) environment. In LLNs, the Routing Protocol for LLN (RPL)-based Internet Protocol Version 6 (IPv6) routing protocol is regarded as a standardized solution. However, the existing models did not account for the issues with congestion and security when modeling the RPL. Thus, to resolve these issues, this paper proposes a novel Exponential Poisson Distribution-Fuzzy (EPD-Fuzzy) model and Kullback Leibler Divergence-based Tunicate Swarm Algorithm (KLD-TSA) for developing a reliable RPL model. The hash codes are first generated for the registered nodes at the network end in order to achieve security; the hash codes are subsequently compared via requests with the immediate nodes. Each node sends a request to its neighbors using the hash value; if the hash value matches, a path is formed. The parent nodes are then chosen and ranked using the Pearson Correlation Coefficient-Spotted Hyena Optimization Algorithm (PCC-SHOA) technique to minimize latency. To avoid congestion, the EPD-Fuzzy is employed to predict congestion; then, a genitor node is introduced in the congested scenarios. The big data and videos are split, compressed, and sent via multiple paths to reduce the losses in the RPL. Moreover, to avoid network traffic, a novel KLD-TSA load balancing is introduced at the user end. The experiential outcomes exhibited the proposed technique's effectiveness regarding Packet delivery ratio (PDR).

Keywords—Low power and Lossy Network (LLN); Routing Protocol for LLN (RPL); load balancing; Internet of Things (IoT); Internet Protocol Version 6 (IPv6)

I. INTRODUCTION

A platform for extending the communication paradigm to novel along with varied levels is provided by the IoT for researchers. In the IoT, computing, as well as sensor devices, are related to the internet that provides services anywhere and anytime [1]. The devices in the IoT are connected over the internet via a gateway node. In various applications like smart homes, smart farming, smart healthcare, et cetera, the IoT is wielded [2]. A network layer in the IoT architecture that utilizes diverse standards and protocols is required by the devices in those applications. Such standards and protocols are Wireless Personal Area Network (WPAN), Internet Protocol Version 4 (IPv4), IPv6 over Low Power WPAN (6LoWPAN), IPv6 and Transmission Control Protocol (TCP) [3]. However, the devices utilized in IoT are deployed as LLNs. The LLN, which features restrictions on processing speed, power, and

storage capacity make up an interconnected network of resource-constrained IoT devices [4].

Owing to the quality of radios and the minuscule size of LLN, the wireless links in LLN are lossy when analogized with other wireless networks; also, poor routing is provided by the weak routing protocols in LLN owing to the limitations like higher energy consumption as well as higher data loss within the network [5]. Thus, choosing the best routing protocol, which considers lower transmission range, lower power, along lower hardware capabilities, is significant in LLN [6]. Considering these issues, the IPv6 Routing Protocol for LLNs was standardized as a consequence of the working group efforts of the Internet Engineering Task Force (IETF), which identified RPL as the leading option to handle the routing requirements of a variety of LLN-centric applications [7].

A multi-hop routing tree rooted at a single LLN Border Router (LBR), also known as the sink node or gateway node, is constructed by the RPL, a distance-vector routing protocol, by creating Destination-Oriented Directed Acyclic Graphs (DODAGs) between nodes [8]. A sorted pair of nodes is chosen in the RPL to serve as a data packet source along with a target. Data packets are transmitted via intermediate nodes from one to another [9]; lastly, the data is passed to the internet via LBR. Although the RPL has the possible to enhance and prosper, it has limitations like load imbalance and disregard for stability [10]. Moreover, the network traffic is mounted by the load imbalance on the user side while accessing the data from the internet. Thus, to resolve these problems, a novel KL-TSA model is proposed for load balancing. Also, to enhance the RPL, a modified PCC-SHOA model is proposed for parent selection with an EPD-Fuzzy congestion prediction.

A. Problem Statement

Despite developing multiple measures for efficiently transferring data in the RPL, several problems are still unnoticed and need to be resolved. Some of such problems are,

- In prevailing works, energy efficiency is mostly concentrated on the RPL network and is not concentrated on node security and congestion.

*Corresponding Author.

- As reliability is affected by rate-limiting, optimum solutions are required by load balancing as well as congestion control.
- For example, collecting a substantial quantity of data leads to mounted traffic congestion in the network. The network's unpredictable and unreliable performance is yielded by the network traffic.

By considering these problems, the proposed technique aims to develop a reliable load-balancing model at the user end and develop a reliable congestion mitigation technique with optimal parent nodes at the network end. The major contributions of the work are as follows:

- The study introduces a genitor node-centric method with the PCC-SHOA-based parent node selection, offering a novel strategy for congestion control in the RPL.
- To identify parent node congestion during data transfer, a novel EPD-Fuzzy is used.
- Kullback-Leibler Divergence-Time Series Analysis (KLD-TSA) is a novel load-balancing model that is proposed to alleviate user congestion and enhance network performance.
- Effective network load balancing at the user results in a 4675 ms latency for 250 requests from users, demonstrating effective data handling and quick access time.

B. Motivation and Benefits of the Proposed Approach

The motivation of the proposed approach comes from the issues that currently exist in the RPL protocol: Energy efficiency, load balancing, congestion control, and reliability. Although various improvements have been made, most of the current solutions consider only one-by-one problems and ignore some very critical factors that bring performance degradation, latency, and instability, mainly in IoT environments with heavy traffic. This work gives a holistic solution to dynamic user-centric load balancing through the introduction of a KLD-TSA model, a method of selecting parent nodes using PCC-SHOA for the optimization of traffic distribution, and an EPD-Fuzzy congestion prediction mechanism in an effort to reduce energy waste and enhance stability. It reduces latency and improves access times, hence making the network more reliable with better energy efficiency to meet a more scalable, flexible, and sustainable IoT network that will help different types of applications, including mission-critical services like healthcare and smart city infrastructure.

The paper's formation is systematized as: Section II implies the recent related works of RPL for IoT. Section III states the proposed approaches. Section IV elaborates on the experimental outcomes. Section V ends the paper conclusion and a better suggestion for future enhancement.

II. RELATED WORKS

This section examines current research on load balancing, congestion, and the RPL network routing mechanism.

Safara *et al.*, (2020) [11] established a priority-centric energy-efficient routing (PriNergy) technique for IoT systems. The RPL model developed its own routing protocol, which determined routing method through contents with an emphasis on energy consumption. The results showed that the PriNergy mechanism decreased the overhead on the use of energy. However, the energy consumption increased when the speed of nodes increased, this influenced the PriNergy model's performance.

Conti *et al.*, (2020) [12] presented a strong multicast communication protocol for LLNs. A lower-overhead cluster-centric multicast routing mechanism was welded on the RPL protocol's top by the presented technique. The implementation outcomes proved the protocol's efficacy over conventional protocols regarding Packet Delivery Ratio (PDR) to 25%. But the model's overall energy consumption was more than the prevailing techniques.

Mutalemwa & Shin, (2020) [13] employed secure routing protocols for safeguarding source nodes in wireless networks with multiple hops of communication. Two phantom-centric source location privacy routing protocols were developed by the presented technique. The outcomes exhibited that the protocols had better performance features with controlled energy consumption as well as PDR. However, the model's complexity reduced data transmission reliability.

Hassan *et al.*, (2020) [14] introduced a Control layer-centered trust mechanism for supporting secure routing in RPL-grounded IoT applications. The technique was named CTrust-RPL, which assessed the nodes' trust grounded on the forwarding behaviors. The presented model's outcomes proved the superiority of the model with 35% more energy efficiency. Yet, CTrust-RPL could be confronted with energy preservation, scalability, along decentralization issues.

Preeth *et al.*, (2020) [15] deployed a proficient parent selection approach in the RPL by utilizing Ant Colony Optimization (ACO) along with coverage-centric dynamic trickle systems. For parent selection, an energy-efficient RPL protocol with ACO-grounded multi-factor optimization was generated by the study. The outcomes exposed that the E-RPL had 90% of PDR over 30 node topologies. Although it was a better model, the E-RPL could not achieve better routing overhead when the DODAG was increased.

Seyfollahi & Ghaffari, (2020) [16] explored a Lightweight Load balancing and Route Minimizing solution for RPL (L²RMR). The L²RMR scheme encompassed an Objective Function (OF) together with a routing metric grounded on the path route minimization. The outcomes exhibited that the developed model could enrich the energy consumption, End-to-End delay, along average Packet Loss Ratio (PLR). However, the L²RMRscheme could not perform reliably during high traffic betwixt the nodes.

Manikannan & Nagarajan, (2020) [17] propounded a framework for the RPL/6LoWPAN-centric IoT network with the firefly approach. An RPL-based firefly optimization algorithm was developed to establish a stable and dependable protocol mobility management framework. The experiment proved that the mPRL-firefly optimizer enhanced the PDR by

an average of 2.31% more than the other prevailing algorithms. Nevertheless, the average power consumption in the developed system increased when contrasted with the conventional RPL model.

Chiti *et al.*, (2021) [18] implemented a green routing protocol with power transfer for IoT. An OF for RPL grounded on a composite metric, which considered the parent node's remaining power together with the child node, could handover to the parent node as per the Wireless Power Transfer (WPT) concept. The performance evaluation exhibited remarkable energy saving, which prolonged the network lifetime. Yet, for a long-range, the model could not perform routing efficiently.

Bidai, (2022) [19] enriched the RPL for supporting video traffic for Internet of Multimedia Things (IoMT) applications. A multi-Path version of RPL (MP-RPL), which leveraged the multi-parent feature provided by RPL for constructing various end-to-end paths of diverse qualities regarding radio link quality, was wielded by the enhanced model. The simulations exhibited that feasible and acceptable Quality of Service (QoS) was provided by the presented model when contrasted with the conventional single-path RPL. Since the conventional RPL performs better, the model is limited to the average end-to-end delay.

Karami and Derakhshanfard, (2020) [20] illustrated a Routing Protocol grounded on Remaining Time to encounter nodes with Destination nodes (RPRTD) utilizing an Artificial Neural Network (ANN). The routing was carried out by identifying the contact node with more effective conditions. The results showed that the RPRTD model efficiently and with higher accuracy anticipated the time needed for interacting nodes with the destination node while requiring less storage. However, with the ANN model, the RPRTD framework took more time for training in the LLNs.

Royae *et al.*, (2021) [21] demonstrated a context-aware system for RPL load balancing of LLNs in the IoT. Therefore, load balancing and Automata-ant colony-centric Multiple Recursive RPL (AMRRPL) were developed to prevent congestion. The Cooja simulator experiments showed that the AMRRPL algorithm significantly improved with increased PDR and network lifetime. Nevertheless, the node ranking took more time to converge, which could cause a delay.

Sahraoui & Henni, (2021) [22] developed a Secure and Adaptive Multi-Path RPL (SAMP-RPL) for enriched security along with reliability in the heterogeneous IoT. For IPv6 RPL, the SAMP-RPL relied on three variants of adaptive together with safe multipath routing. The outcomes of the Cooja simulator exhibited the SAMP-RPL model's efficacy for enhanced dependability and security of communication at lower costs. The simulation on the Cooja platform triggered the inaccuracy issues.

Yassien *et al.*, (2021) [23] developed the RPL and Load Balancing Time-Based (LBTB) model to optimize the load balancing procedure with the capability for attaining superior network reliability as well as service time. The LBTB was employed with the modification of the trickle Timer algorithm. The outcomes displayed that higher performance

was achieved regarding time-saving and power-saving. However, the imbalance among the nodes caused a congestion problem.

Musaddiq *et al.*, (2020) [24] employed an RPL for the heterogeneous traffic network. Here, various RPLs under heterogeneous traffic were evaluated; also, a protocol named Queue and Work-Load-based RPL (QWL-RPL) was introduced. The outcomes displayed that QWL-RPL could enhance the heterogeneous traffic network's performance concerning the amount of overhead, jitter, along average delay. However, for scheduling, the control messages as well as service discovery had issues associated with overhead and convergence time.

Hadaya & Alabady, (2021) [25] designed an enhanced RPL protocol for the IoT environment. An enhancement in the RPL OF is suggested by the presented work that considered 3 metrics, namely Expected Transmission count (ETX), residual energy, and load. The outcomes exposed that the RPL protocol was enhanced by the model concerning total power consumption, PLR, along PDR. However, the nodes' data security was not efficiently maintained since it was learned with only a limited number of Cognitive Packet Network's features.

A. Research Gap

Literature research gaps in the improvement of RPL protocols for IoT networks are based on some key challenges. While energy efficiency, scalability, and security have improved, there are related trade-offs that need to be addressed. On the other hand, energy efficiency improvements mostly come at a cost in terms of performance under different conditions, including high traffic or node mobility. On their part, scalability issues are manifested with increased network size, contributing to increased routing overhead. The reliability is poor, and security enhances the complexity under high traffic for the architecture. Current context-aware and adaptive protocols are overload with long convergence times, having computational overhead. Multimedia support suffers due to end-to-end delays. Decentralized approaches that extend the lifetime of the network remain underdeveloped. There is also a need for better support of multimedia services and QoS to reduce latency, particularly in real-time IoT applications. Other challenges include decentralize and efficiently manage over long distances. A critical research gap is thus the development of scalable, reliable, energy-efficient RPL-based solutions that ensure efficient handling of high traffic, enhanced security, support for real-time multimedia, and uniform performance across different IoT environments.

III. PROPOSED ROUTING APPROACHES IN THE RPL

The RPL concept was promoted by the rapid development of the IoT. However, in prevailing models, secure packet delivery and traffic congestion control were hardly performed; also, much importance was not given to the user-side traffic. Thus, to overcome these issues, a novel EPD-Fuzzy-centric congestion control in the RPL is proposed with the KL-TSA load balancing technique. Fig. 1 depicts the architecture of the proposed RPL.

Fig. 1. Framework of the proposed RPL.

A. Node Registration

The proposed model begins with the registration of nodes participating in the network. All the nodes are registered in the network with their ID (ID), IP (IP), and MAC (M) Address. The registered details are mathematically represented in Eq. (1),

$$reg \leftarrow \langle ID, IP, M \rangle \quad (1)$$

Here, reg specifies node registration.

B. Hash Code Generation

During the registration, the hash code is generated for nodes utilizing the hybrid Diffie Hellman Secret Key-based Anchor Hashing (DHSK-Anchor Hash). In the DHSK-Anchor Hash, the keys are generated with the Diffie Hellman Algorithm (DHA), and then the generated keys are hashed with the Anchor hash. The DHSK-Anchor Hash procedure is explicated further.

1) *Key generation*: During the node registration, the keys are generated for every single node utilizing the DHA.

- Public and private key generation

The sender and the receiver side agree on a prime (e) and generator (r) in DHA. After that, the private keys k and z are chosen by the sender and the receiver side. With these values, the public keys generated at both sides are expressed in Eq. (2) and Eq. (3),

$$p = r^k \text{ mod } e \quad (2)$$

$$a = y^z \text{ mod } e \quad (3)$$

Where, p, a portray the public key generated at the sender side and receiver side, correspondingly. Afterward, p, a are shared between the sender and receiver.

- Shared secret key calculation

After the public key is exchanged, the symmetric secret key (s) is generated at both sides, which is expressed in Eq. (4),

$$s = a^k \text{ mod } e = p^z \text{ mod } e \quad (4)$$

Here, $a^k \text{ mod } e$ is assessed at the sender's side, $p^z \text{ mod } e$ and is assessed at the receiver's side.

2) *Anchor hash*: After the keys are generated, the hash value is computed utilizing the anchor hashing technique which $ID_{sender}, ID_{receiver}, p, a$ and s are considered the key values (ϖ). Hence, the anchor hashing is given as follows,

a) *Anchor representation*: In the anchor hashing, a set of integer arrays (ϑ) is utilized for representing the anchors, which is mathematically represented as in Eq. (5),

$$\vartheta = [0, 1, \dots, d] \quad (5)$$

where the size of the array is portrayed as d . After that, a bucket (B) of size $d - 1$ is selected from the integer set ϑ . Here, the bucket encloses $ID_{sender}, ID_{receiver}, p, a$ and s . The current working buckets ϑ is symbolized as W , where $W \subseteq \vartheta$. Therefore, the bucket within the integer set is signified as $\vartheta[B]$, which is expressed as in Eq. (6),

$$\vartheta[B] = \begin{cases} 0 & \text{if } B \in W \\ |W_B| & \text{if } B \in \aleph \end{cases} \quad (6)$$

Where, \aleph represents the stack of the removed bucket and W_B indicates the size of the working set.

b) *Hashing*: In anchor hashing, a hashing function H is wielded to map the key values of the buckets, which is mathematically denoted in Eq. (7),

$$u_B(\varpi) \equiv \nabla(B, \varpi) \text{ mod } \vartheta[B] \quad (7)$$

Here, $u_B(\varpi)$ denotes the hashed output. During the path creation, each node sends a request to neighboring nodes with the $u_B(\varpi)$. A path will be created between such nodes if the neighboring nodes give the same hash value.

C. Optimal Parent Node Selection Using PCC-SHOA

During the path creation, the parent nodes are selected through which the data packets are forwarded. Here, utilizing the PCC-SHOA, the parent nodes get selected. In the conventional SHOA, position updation has more variation between the prey and the hyena. Therefore, the Pearson Correlation Coefficient (PCC) technique is included in the SHOA model. Spotted hyena optimizer (SHO) is a recently created popular metaheuristic algorithm that draws its main inspiration from social ties between hyenas. The females in the family of spotted hyenas are the dominant ones. The spotted hyenas follow their prey using their inherent senses of sight, hearing, and scent. Spotted hyenas make a sound to interact with one another while searching for a new food source. They rely on a pack of about 100 hyenas who are their

closest companions for hunting. Thus, the working steps of PCC-SHOA are given further.

1) *Initialization*: The PCC-SHOA's input parameters are initialized in which the Spotted Hyena (SH) population(H) is the node involved in the path creation that can be mathematically formulated as in Eq. (8),

$$H = \{h_1, h_2, \dots, h_l\} \text{ or } h_x, x = 1, 2, \dots, l \quad (8)$$

Where, h_l specifies the position of l^{th} SH, l signifies the population size. Also, the SH has four behaviors, namely Encircling, hunting, attacking, and searching for prey.

2) *PCC-based encircling prey*: In the PCC-SHOA algorithm, the best SH has obtained whose position is near the prey. The ability to locate their prey and encircle them is possessed by spotted hyenas. Since the search space is unknown in advance, the best contender at this time is assumed to be the spotted hyena that is closest to the target or prey. Once the optimal search solution has been determined, the locations of the other search agents are updated. By calculating the fitness function, the best position is attained. In the proposed model, the lower Residual energy, Transmission count, Distance, and bandwidth are considered as the fitness function. Afterward, during encircling, the distance between h_x and the prey position (α_{pos}) is calculated utilizing the PCC as in Eq. (9) and Eq. (10),

$$\lambda_{dist} = \left| \vec{C} \cdot \frac{\Sigma(\vec{\alpha}'_{pos} - \alpha'_{pos})(\vec{h}_x^l - h_x^l)}{\sqrt{\Sigma(\vec{\alpha}'_{pos} - \alpha'_{pos})^2 \Sigma(\vec{h}_x^l - h_x^l)^2}} \right| \quad (9)$$

$$\vec{h}_x^{l+1} = \vec{\alpha}'_{pos} - \vec{Q} \cdot \lambda_{dist} \quad (10)$$

where, λ_{dist} specifies the distance between SH and the prey, \vec{C}, \vec{Q} symbolizes the vector coefficients, \vec{h}, h' indicates the current and the mean position of SH, h_x^{l+1} implies the position of SH x in the iteration $l+1$, and iteration is signified as l . α, α' represent the current and the mean position of prey. The \vec{C}, \vec{Q} values are mathematically expressed as Eq. (11) and Eq. (12),

$$\vec{C} = 2 * \vec{R}_1 \quad (11)$$

$$\vec{Q} = 2 * \vec{\omega} \cdot \vec{R}_2 - \vec{\omega} \quad (12)$$

Here, \vec{R}_1, \vec{R}_2 symbolizes the random vectors and $\vec{\omega}$ portrays the reduction vector, which is computed as in Eq. (13),

$$\vec{\omega} = 5 - \left(I \times \frac{5}{I_{max}} \right) \quad (13)$$

where the maximum iteration is notated as I_{max} . To ensure that exploration and exploitation are properly balanced, $\vec{\omega}$ falls linearly from 5 to 0 for the maximum iterations. With an increase in the number of iterations (MaxIteration), this method allows for further development. By modifying the values of \vec{C} and \vec{Q} , spotted hyenas can update their position in relation to the location of their prey.

3) *Hunting prey*: Spotted hyenas can detect prey, hunt in packs, and depend on a network of reliable companions. Assume that the prey is known to the best search agents, whichever is optimal, in order to define spotted hyena behaviour mathematically. Other search agents should update their location in accordance with the best solution and move in the direction of the best search agent. Here, the mathematical model is constructed by considering the best SH that knows the optimal position, whereas the other SHs update their corresponding position towards the best positions. This mathematical model is specified in Eq. (14),

$$\vec{\lambda}_{dist} = |\vec{C} \cdot \vec{h}_x^* - \vec{h}_x| \quad (14)$$

$$\vec{h}_x = \vec{h}_x^* - \vec{Q} \cdot \vec{\lambda}_{dist} \quad (15)$$

Where, \vec{h}_x^* specifies the first best spotted SH position, \vec{h}_x denotes the other SH positions near \vec{h}_x^* which is defined in Eq. (15). Therefore, the cluster ($\vec{\mathcal{R}}$) with the number of the optimal solution is represented in Eq. (16),

$$\vec{\mathcal{R}} = \vec{h}_x + \vec{h}_{x+1} + \dots + \vec{h}_{x+l} \quad (16)$$

Here, l indicates the number of SH in the best position and is defined in Eq. (17),

$$l = \text{count}_{nos}(\vec{h}_x^*, \vec{h}_{x+1}^*, \vec{h}_{x+2}^*, \dots, (\vec{h}_x^* + \vec{M})) \quad (17)$$

where nos indicates the number of solutions and counts all candidate solutions after addition with \vec{M} , which are significantly close to the best optimal solution in the search space and \vec{M} is a random vector with a value of [0.5, 1].

4) *Attacking*: For performing the attacking behavior, $\vec{\omega}$ is reduced. Moreover, the variation in the \vec{Q} is reduced to change the value of $\vec{\omega}$. The SH attacks the prey when $|Q| < 1$ and the prey attacking is equated as in Eq. (18),

$$\vec{h}_x^{l+1} = \frac{\vec{\mathcal{R}}}{l} \quad (18)$$

Update \vec{h}_x^{l+1} if the fitness of the current position (\vec{h}_x^{l+1}) is better than the previous position, and by continuously updating \vec{h}_x^{l+1} , the optimal solution (parent nodes) is attained.

5) *Prey search*: The SHs search for their prey in the cluster vector ($\vec{\mathcal{R}}$). Moreover, the SHs diverge from each other to attack and search the prey. The prey search is grounded on the changes in the \vec{Q} , which is utilized to randomly search the prey. If ($|Q| > 1$), the SHs leave the prey and move to the next prey or else perform the attack on the selected prey. By this mechanism, global searches can be attained. Hence, the final parent nodes selected \vec{h}_x^{l+1} or orn_δ are signified as in Eq. (19),

$$P = \{n_1, n_2, \dots, n_q\} \text{ or } orn_\delta \quad (19)$$

Where, P illustrates the parent node set and n_q represents the q^{th} selected parent node. The pseudocode of PCC-SHOA is given in Algorithm 1.

Algorithm 1: Pseudocode of PCC-SHOA

Input: Nodes $\{h_1, h_2, \dots, h_l\}$ or h_x ,

Output: Selected parent node

Begin

Initialize SH population, l , \vec{R}_1, \vec{R}_2 , and maximum iteration

l_{max}

Set $I = 1$

While ($I \leq l_{max}$) **do**

Calculate fitness

Determine λ_{dist} using PCC

Define $\vec{R} = \vec{h}_x + \vec{h}_{x+1} + \dots + \vec{h}_{x+l}$

If reducing factor ($\vec{Q} > 1$) **{**

Update position using $\vec{h}_x^{l+1} = \vec{\alpha}_{pos}^l -$

$\vec{Q} \cdot \lambda_{dist}$

} Else {

Update position using $\vec{h}_x^{l+1} = \frac{9\vec{R}}{l}$

}

End If

If the fitness of \vec{h}_x^{l+1} greater than \vec{h}_x^l **Then**

Update \vec{h}_x^{l+1}

Else

$I = I + 1$

End If

End While

Return optimal value

End

After that, the rank is assigned to each selected parent node as per the fitness values of the parent nodes.

D. Data Splitting and Compression

After all the nodes are connected, the source node senses the data to be transferred to the destination node. If the sensed data size is huge, the files are split into small files, then compressed and sent to the destination node via multiple paths. This process is done to reduce the data loss in the LLN. The split parts are compressed with the Lempel–Ziv–Welch (LZW) lossless compression, then the data is transferred via nodes. The big file (D) is split into a small file as in Eq. (20),

$$D = \{v_1, v_2, \dots, v_k\} \text{ or } v_o \quad (20)$$

Hence, the k^{th} small file is illustrated as v_k . By utilizing the LZW algorithm, this small file v_o is compressed. The file v_o is compressed utilizing a table-centric lookup model in the LZW algorithm by performing encoding of the information in the file. The table formed is named dictionary or code table. The number of entries commonly accepted in the table is 4096; also, a single byte from the input file v_o is coded with the

codes 0-255. While encoding is initiated, only the first 256 entries are present in the dictionary. The compression is attained by utilizing the 256 codes through 4095 entries for representing the sequence of bytes.

During compression, LZW identifies repeated sequences in v_o , then added to the dictionary. Suppose the string in the file v_o is represented as $ababc$, which is compressed with LZW is given as in Eq. (21),

$$ababbabc = 12452 \quad (21)$$

This compressed value is sensed in the source node and transmitted to the server. Fig. 2 elucidates the flow diagram of the proposed system,

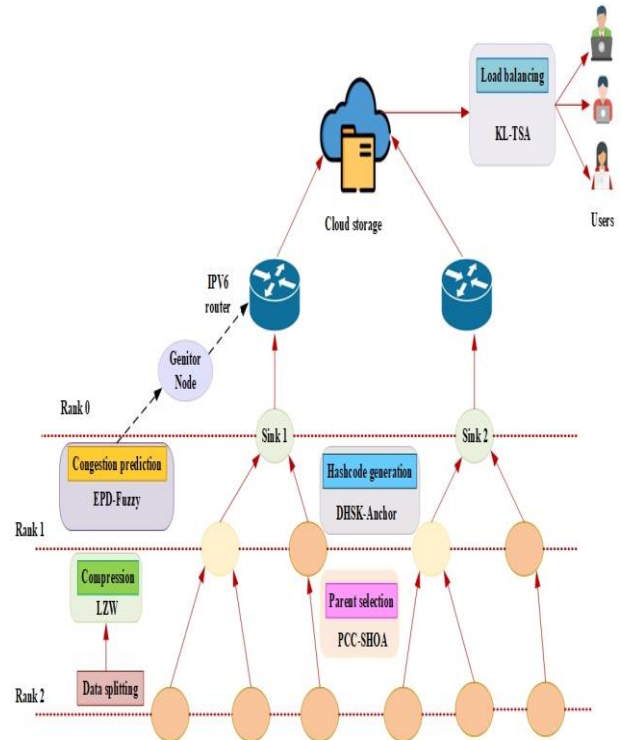

Fig. 2. Flow diagram of the proposed RPL.

E. Congestion Prediction Using Novel EPD-Fuzzy Model

During the data transfer, a novel EPD-Fuzzy detects the congestion among the parent nodes. Fuzzification, rule evaluation, and defuzzification are the three processes performed by the fuzzy algorithm. However, the fuzzy inference process has a lower level of rule generation processing than the prevailing Fuzzy algorithm. Thus, to resolve this issue, the Exponential Poisson Distribution technique is included in the prevailing Fuzzy algorithm. Hence, the congestion prediction with the EPD-Fuzzy is stated as follows,

1) *Fuzzification*: Primarily, the incoming number of packets (g), the number of outgoing packets (t) and the hop count (w) data $\{n_\delta\}$ are given as the crisp set to the fuzzy control system, which gets mapped by a membership function for generating fuzzy sets. Hence, the membership function is represented in Eq. (22), Eq. (23) and Eq. (24),

$$m(g) = \frac{\exp(-\zeta \times \tau)(\zeta \times \tau)^g}{g!} \quad (22)$$

$$m(w) = \frac{\exp(-\zeta \times \tau)(\zeta \times \tau)^w}{w!} \quad (23)$$

$$m(t) = \frac{\exp(-\zeta \times \tau)(\zeta \times \tau)^t}{t!} \quad (24)$$

Where, $m(\cdot)$ signifies the EPD membership function and ζ, τ elucidates the center and width of the fuzzy set.

2) *Rule generation*: After the membership function is defined, the $m(n_\delta)$ is correlated to generating the fuzzy rules as in Eq. (25), (26) and (27),

$$\rho(g) = \begin{cases} \exp\left(\frac{\psi[m(g)-m(g')]}{m(g^*)-m(g^*)}\right) & \text{if } m(g) = \{g \in (g^*, \infty)\} \\ 1 & \text{else} \end{cases} \quad (25)$$

$$\rho(w) = \begin{cases} \exp\left(\frac{\psi[m(w)-m(w')]}{m(w^*)-m(w^*)}\right) & \text{if } m(w) = \{w \in (w^*, \infty)\} \\ 1 & \text{else} \end{cases} \quad (26)$$

$$\rho(t) = \begin{cases} \exp\left(\frac{\psi[m(t)-m(t')]}{m(t^*)-m(t^*)}\right) & \text{if } m(t) = \{t \in (t^*, \infty)\} \\ 1 & \text{else} \end{cases} \quad (27)$$

where $\rho(\cdot)$ implies the fuzzy rules generated in the inference, $*,'$ are the membership function's lower bound and upper bound. After that, the fuzzy rules are aggregated by utilizing IF-THEN statements. The aggregation method is given by *max*, which is also named *OR* operator, which is expressed as in Eq. (28),

$$\Delta = \max(\rho(g), \rho(w), \rho(t)) \quad (28)$$

Where, Δ specifies the aggregated outputs with the result of the implication technique.

3) *Defuzzification*: A process that converts fuzzy values to crisp values is named defuzzification. Hence, by computing the centroid technique, the crisp value is attained. Here, the center of the area of the fuzzy set is attained, which determines the crisp output (congestion rate) f .

F. Genitor Node

Here, a novel genitor node is included, which acts as the parent node for sending data if the ($f > Th$) is predicted by EPD-Fuzzy; where, Th indicates the threshold value. The sensed data is securely transferred to the cloud server via these processes.

G. KLD-TSA-based Novel Load Balancing

Conversely, users who want to access data from the cloud server give requests to access the data. But, multiple requests at the same time mount the network traffic. To avoid such congestion in the network, Load balancing is performed in the proposed model. Here, for load balancing, KLD-TSA is wielded. In the prevailing Tunicate Swarm Algorithm (TSA), the conflicts among the search agents are more, which affects the algorithm's performance. Hence, to avoid conflicts, Kullback Leibler Divergence (KLD) is introduced in the prevailing TSA. Tunicate is capable of locating food sources in the ocean. On the other hand, the food source in the specified search space is unknown. To locate the optimal food

supply, tunicates use two different behaviors. Swarm intelligence and jet propulsion are these tendencies. Thus, the proposed load balancing is given further.

The users who request to access the resources from the server are considered as the initial population of tunicates and the position of the tunicate population is expressed as in Eq. (29),

$$J = \{j_1, j_2, \dots, j_\rho\} \text{ or } j_y \quad (29)$$

where the tunicate population is denoted as J , j_ρ represents the position of the tunicate ρ , and ρ indicates the population size. To attain the optimal solution, the tunicates perform jet-propulsion and swarm behavior. The mathematical model of jet propulsion satisfies three behaviors: Prevent conflicts, move toward the best search agent, and remain close to the best tunicate. Utilizing the fitness value, the best search agent is computed. Here, fitness is considered as less response and waiting time.

a) *Prevent conflicts among agents*: In the proposed KLD-TSA, the initialization of the new position of the search agent (\vec{N}) to avoid inter-agent conflict is given by utilizing the KLD in Eq. (30).

$$\vec{N} = \sum_{y=1}^{\rho} \Omega(\vec{V}_y) \ln \frac{\Omega(\vec{V}_y)}{\theta(\vec{S})} \quad (30)$$

Where, \vec{V}_y is the gravity force of tunicate y , and \vec{S} are the social forces betwixt tunicates. The gravity force is expressed in Eq. (31),

$$\vec{V} = r_2 + r_3 - \vec{G} \quad (31)$$

$$\vec{G} = 2 \cdot r_1 \quad (32)$$

Here, r_1, r_2 and r_3 epitomize the random values that lie in the range of 0 to 1. The water flow advection in the deep sea is symbolized by \vec{G} and is defined in Eq. (32). \vec{S} stands for the social dynamics among search agents. The vector \vec{S} is computed as in Eq. (33),

$$\vec{S} = [A1 \min_{\max} \min] \quad (33)$$

Here, the initial and subordinate speeds of social interaction are represented by A_{\min} and A_{\max} .

b) *Move towards the best neighbor*: After avoiding the conflicts betwixt the agents, the search agents move toward the direction of the best agent as in Eq. (34),

$$\vec{T} = \overrightarrow{\vec{F}_l} - L(\vec{J}_y^{lt}) \quad (34)$$

where \vec{T} indicates the distance between the tunicates and the food, \vec{F}_l symbolizes the food location, L is a random value between $[0, 1]$, and \vec{P}_i signifies the tunicate positions.

c) *Keeping close to the best agent*: The search agent is able to stay in the direction of the optimal search agent (food source). Now, the tunicate move towards the prey is computed as in Eq. (35),

$$\vec{j}_y^{it} = \begin{cases} \left(|\vec{F}_i|^2 + |(N)(T) \sin \theta|^2 \right)^{1/2} \text{ for } L \geq 0.5 \\ \left(|\vec{F}_i|^2 - |(N)(T) \sin \theta|^2 \right)^{1/2} \text{ for } L < 0.5 \end{cases} \quad (35)$$

Where, θ signifies the angle between N and T . The updated position of tunicates in relation to the location of food sources is represented by \vec{j}_y^{it} .

d) *Position update*: The tunicate's swarm behavior is updated by updating the position of all search agents concerning the first two best search agents is revealed as follows in Eq. (36),

$$|\vec{j}_y^{it+1}| = \left(\frac{|\vec{j}_y^{it}|^2 + |\vec{j}_y^{it+1}|^2}{4+r^2} \right)^{1/2} \quad (36)$$

Where, $|\vec{j}_y^{it+1}|$ is the magnitude of the updated position of the tunicates. After that, the fitness $|\vec{j}_y^{it+1}|$ is evaluated. If the fitness $|\vec{j}_y^{it+1}|$ is greater than the $|\vec{j}_y^{it}|$, then the position is updated. Therefore, the optimal solution (i.e., optimal user) is obtained by updating the position. Thus, by selecting the optimal user, traffic is avoided. Hence, the network load is balanced. The pseudocode of the proposed KLD-TSA is given in Algorithm 2.

Algorithm 2: Pseudocode of KLD-TSA

Input: Users

Output: optimal user

Begin

Initialize tunicate population, parameters $\vec{N}, \vec{V}, \vec{S}$, and maximum iterations $I_{t_{max}}$

Calculate fitness

Set Iteration $I_t = 1$

While ($I_t \leq \omega$) **do**

Update New position using KLD

Move toward the best search agent

If ($L \geq 0.5$) {

Update tunicate position using $\left(|\vec{F}_i|^2 + |(N)(T) \sin \theta|^2 \right)^{1/2}$

} **Else If** ($L < 0.5$) {

Update tunicate position using $\left(|\vec{F}_i|^2 - |(N)(T) \sin \theta|^2 \right)^{1/2}$

}

End If

Update the position of all tunicate

End while

Set $I_t = I_t + 1$

Return $|\vec{j}_y^{it+1}|$

End

IV. RESULTS

Here, the proposed RPL methodologies' performance is experimentally evaluated with conventional techniques to demonstrate the reliability of the proposed protocol model. The performances are experimentally verified on the working platform of JAVA and the cloud sim simulation tool.

A. Performance Analysis

Here, the proposed protocol's performance is assessed in three phases, namely hash code generation, parent node selection, and load balancing. Here, regarding hash code generation time, the performance of the proposed hash code generation model DHSK-Anchor hash is comparatively analyzed with Anchor hash, SWIFFT, SHA512, and MD5 techniques.

The time taken to generate the hash value is named hash code generation time. The hash code generation time attained by the proposed protocol is 2163ms, which is 3051ms, 5178ms, and 5972ms lower than the prevailing SWIFFT, SHA-512, and MD5 techniques. This shows that the proposed RPL outperforms the conventional models. Fig. 3 elucidates the pictorial representation of hash code generation time.

Fig. 3. Time analysis for hash code generation.

Fig. 4 depicts the graphical analysis of iteration vs. fitness for the proposed and existing algorithms.

Fig. 4. Fitness vs. iteration analysis.

The Fitness value evaluation of the proposed PCC-SHOA approach and the conventional SHOA, LOA, DFOA, and HHOA selection algorithms is elucidated in Fig. 4. Here, at the 25th iteration, the proposed PCC-SHOA obtained an optimal parent node whose fitness is 2423, which is higher when contrasted with the fitness value achieved by the prevailing SHOA (2257), LOA (2148), DFOA (2144), and HHOA (2046). This proves that the proposed PCC-SHOA converged much faster than the prevailing techniques. Fig. 5 depicts the graphical analysis of throughput.

Fig. 5. Throughput analysis.

To determine how efficiently the algorithms achieved better data transmission with the selected parent nodes, the throughput is evaluated. Fig. 5 demonstrates that the throughput is analyzed for 50 to 100 nodes. Here, the proposed algorithm achieved the highest throughput of 1281 for 50 nodes, which is higher than the prevailing approaches that attained 1054 for SHOA, 993 for LOA, and 828 HHOA approaches. This concludes that with the proposed PCC-SHOA, the parent with lower Residual energy, Transmission count, Distance, and bandwidth is selected, which could enhance the proposed RPL. Fig. 6 (a) and (b) illustrate the analysis of PDR and PLR.

(a)

(b)

Fig. 6. (a) PDR and (b) PLR analysis.

The PDR and PLR are the metrics evaluated to determine the rate of packets delivered successfully and the rate of packets dropped during the data transmission. Fig. 6(a) displays that the rate of packets successfully delivered by the proposed PCC-SHOA for 100 nodes is 1.78%, 9.37%, and 13.70% higher than the prevailing SHOA, DFOA, and HHOA approaches. Then, from Fig. 6(b), it is revealed that the PLR of the proposed algorithm is 3.15%, 6.45%, 7.12%, and 10.45% for 50, 100, 150, and 250 nodes, which are lower than the existing algorithms. This proves that with the use of PCC-SHOA-centric parent selection, more data is efficiently transferred with less loss, which is owing to the splitting and compression of large files.

Here, the latency, waiting time, and TAT performance of the proposed KLD-TSA approach are analyzed in comparison with the prevailing TSA, Cockroach Swarm Optimization Algorithm (CSOA), LOA, and DFOA approaches. Fig. 7 represents the latency attained by the proposed and the prevailing models.

Fig. 7. Latency of the proposed framework.

Here, latency is the delay that occurs between when the user requests access and the response. The Fig. 7 displays that the Proposed KLD-TSA approach has lower latency than all other algorithms followed by TSA, CSOA, et cetera. However, the latency attained by the proposed KLD-TSA is 3289ms for 150 users, whereas 4176ms, 5347ms, and 6981ms

latency were attained by the existing TSA, CSOA, and DFOA schemes. Thus, the overall time efficiency of the proposed model is proved by this analysis.

B. Discussion

The performance of the proposed PCC-SHOA parent node selection algorithm and KLD-TSA load balancing algorithm is compared to that of current techniques in the discussion section.

1) *Performance analysis of parent node selection:* In this phase, the proposed PCC-SHOA algorithm’s performance is comparatively analyzed with the prevailing SHOA, Lion Optimization Algorithm (LOA), Dragon Fly Optimization Algorithm (DFOA), and Harris Hawks Optimization Algorithm (HHOA) regarding the parent selection time, fitness value, throughput, response time, Turn-Around Time (TAT), PDR, and PLR. The time taken by various algorithms to select the parent node is illustrated in Table I.

TABLE I. TIME TAKEN TO SELECT PARENT NODES

Algorithms	Parent node selection time (ms)
Proposed PCC-SHOA	6034
SHOA	6513
LOA	8274
DFOA	9627
HHOA	10344

Among the prevailing algorithms, SHOA takes less time to choose the optimal parent node, which is 6513ms. Yet, with the implementation of the PCC technique in the SHOA, 479 ms lesser time is taken for choosing the optimal parent node, which displays the time effectiveness of the proposed PCC-SHOA approach.

The response and the turnaround time of the proposed and existing approaches for 50 to 250 nodes are illustrated in Table II.

TABLE II. RESPONSE TIME AND TAT

Metrics	Algorithms	Number of nodes				
		50	100	150	200	250
Response time (ms)	Proposed PCC-SHOA	3781	4796	5447	6145	6794
	SHOA	5142	6834	7402	9247	10375
	LOA	6753	7664	8314	9924	10852
	DFOA	7348	8016	9307	10267	11576
	HHOA	8457	9374	10493	11752	12055
TAT (ms)	Proposed PCC-SHOA	5423	6942	7581	9427	10524
	SHOA	7156	8123	9076	10072	11543
	LOA	8056	9365	10786	11898	12630
	DFOA	9546	10498	11966	12756	13277
	HHOA	10374	11863	13757	14624	15371

The time taken to send the data to the immediate node is named the response time, whereas the TAT is the time taken by the RPL to transmit data to the server. Here, the response time and TAT increase with the number of nodes. Here, for 250 nodes, the response time of the proposed PCC-SHOA is 6794ms, which is lower than the prevailing algorithms. Also, the best TAT is achieved by the proposed algorithm, which is 5423ms for 50 nodes.

2) *Performance analysis of load balancing:* The waiting and turnaround time determined for 250 users with the proposed KLD-TSA in comparison with the prevailing methodologies is illustrated in Table III.

TABLE III. WAITING TIME AND TAT OUTCOMES OF THE KLD-TSA APPROACH

Metrics	Algorithms	Number of users				
		50	100	150	200	250
waiting time (ms)	Proposed KLD-TSA	2781	4653	6447	7256	7649
	TSA	4133	6922	7464	8046	10953
	CSOA	5613	7914	8706	10264	11952
	LOA	7394	8672	9767	10527	11543
	DFOA	8857	9325	10335	11442	12594
TAT (ms)	Proposed PCC-SHOA	4423	6602	7921	9597	10554
	TSA	6969	8513	9276	10172	11643
	CSOA	7658	9265	10662	11658	12560
	LOA	9661	10598	11454	12656	13761
	DFOA	10456	11935	13746	14404	15879

The time taken by the users to access data after requesting is called waiting time, whereas TAT is the overall time taken to get data concerning the number of users. Here, the proposed model’s waiting time for 50 users is 2781ms, which is lower than the prevailing CSOA (4133ms), LOA (7394ms), and DFOA (8857ms) approach. Moreover, the proposed model’s TAT for 50 users is the least (4423ms). This exhibits that with the KLD-TSA data balancing, the data can be accessed from the server in the least time.

C. Comparative Analysis with the Related Works

Here, the PDR for 50 to 100 nodes is analyzed for the proposed routing protocol and the prevailing works of (Conti et al., 2020) [12], (Preeth et al., 2020) [15], and (Hadaya & Alabady, 2021) [25]. Table IV illustrates the comparative analysis of PDR with the proposed and existing algorithms.

TABLE IV. COMPARATIVE ANALYSIS WITH THE RELATED RESEARCH

Metric	Algorithms	Number of nodes		
		50	55	60
PDR (%)	Proposed EPD-Fuzzy	97.96	96.42	95.37
	(Hadaya & Alabady, 2021)	97.145	95.185	94.575
	(Preeth et al., 2020)	84.96	83.24	82.59
	(Conti et al., 2020)	82	81.16	79.60

The PDR metric is evaluated for determining the ratio of packets delivered successfully to the cloud server. The PDR is evaluated for 50, 55, and 60 nodes in Table IV, which displays that PDR is inversely proportional to the number of nodes that participated in the network. Here, the PDR is assessed for 55 nodes. With 55 nodes participating in the network, the PDR attained by the proposed routing protocol is 96.42%, which is 1.29%, 15.83%, and 18.80% higher than the prevailing works of [25], [12] and [15]. This proves that with the approaches introduced in the proposed routing protocol, more data packets are transmitted.

V. CONCLUSION

This paper proposes a genitor node-centric congestion control in the RPL with the PCC-SHOA-based parent node selection. The KLD-TSA-centric load-balancing model is proposed to avoid congestion among users. The proposed technique's experiments are performed on the Cloudsim simulator; also, the performance was assessed. The performance evaluation showed that the path between the nodes is created in less time since the hash codes are generated in less time. Moreover, the optimal parent node is selected with the fitness of 2423 in lesser time; also, with the selected parent node, the PDR of the proposed model gets enhanced by 95.23% more than the prevailing algorithms. At the user end, the network load is balanced with a latency of 4675ms for 250 user requests. After that, the proposed RPL model's overall efficiency is proved by attaining higher PDR than the conventional systems. These outcomes proved that the proposed protocol was superior to other routing protocols. Several data are still lost even after utilizing the LZW compression in the proposed model. The research indicates that to further minimize data loss, future work may incorporate sophisticated deep-learning models for congestion prediction and make use of modified compression techniques.

DECLARATIONS

Conflict of interest: The authors declare that they have no conflict of interest.

Ethical approval: This article does not contain any studies with human participants or animals performed by any of the authors.

Consent of publication: Not applicable.

Availability of data and materials: Data sharing is not applicable to this article as no datasets were generated or analyzed during the current study.

Competing interests: The authors declare that they have no competing interests.

Funding: This work has no funding resource.

Author's contributions: All authors contributed to the study conception and design. Material preparation, data collection and analysis were performed by Saumya Raj, Dr. Rajesh R. The first draft of the manuscript was written by Saumya Raj and all authors commented on previous versions of the manuscript.

All authors read and approved the final manuscript.

ACKNOWLEDGMENT

We thank the anonymous referees for their useful suggestions.

Abstract—Classification using machine learning algorithms in physical fitness tests carried out by students in educational centers can help prevent obesity and other related diseases. This research aims to evaluate physical fitness using percentiles of the tests and machine learning algorithms with hyperparameter optimization. The process followed was knowledge discovery in databases (KDD). Data were collected from 1525 students (784 women, 741 men) aged 6 to 17, selected non-probabilistically from five public schools. For the evaluation, anthropometric parameters such as age, weight, height, sitting height, abdominal circumference, relaxed arm circumference, oxygen saturation, resting heart rate, and maximum expiratory flow were considered. Physical Fitness tests included sitting flexibility, kangaroo horizontal jump, and 20-meter fly speed. Within the percentiles observed, we took three cut-off points as a basis for the present research: > P75 (above average), p25 to p75 (average), and < P25 (below average). The following machine learning algorithms were used for classification: Random Forest, Support Vector Machine, Decision tree, Logistic Regression, Naive Bayes, K-nearest neighbor, XGBoost, Neural network, Cat Boost, LGBM, and Gradient Boosting. The algorithms were hyperparameter optimized using GridSearchCV to find the best configurations. In conclusion, the importance of hyperparameter optimization in improving the accuracy of machine learning models is highlighted. Random Forest performs well in classifying the “High” and “Low” categories in most tests but struggles to correctly classify the “Normal” category for both male and female students.

I. INTRODUCTION

Machine learning (ML) is a subset of AI that involves building computer models capable of learning and making independent predictions or decisions based on the provided data [1]. In its operation, ML allows you to train a model to categorize data based on selected characteristics. It is classified into two broad categories: supervised and unsupervised. Unsupervised Machine Learning is used to conclude from data sets that contain input data without labeled responses. On the other hand, supervised machine learning attempts to discover the relationship between input attributes (independent variables) and a target attribute (dependent variable) [2]. This approach has a wide range of applications, including sectors like healthcare, education, and technological advancements. The applications are varied and can be integrated with the use

of wearable technologies to track physical activity and monitor health conditions [3].

Physical activity is any body movement that results in an increase in energy expenditure above the resting level. Regular physical activity has been shown to help prevent and control non-communicable diseases, such as heart disease, stroke, diabetes, and several types of cancer. According to the WHO, more than 80% of adolescents worldwide have an insufficient level of physical activity, and it recommends that children between 5 and 17 years old dedicate at least an average of 60 minutes a day to moderate to intense physical activities, mainly aerobic, throughout the week [4].

Lack of physical activity, poor eating habits, and sedentary behaviors, such as excessive use of technology to watch television, play video games, or use cell phones, and even lack of sleep, have led to an increase in the prevalence of overweight in recent years [5].

According to a UNICEF report from 2023, in Latin America and the Caribbean, there are nearly 49 million children and adolescents between 5 and 19 years old who are overweight, which represents 30.6% of the population, above the global prevalence of 18.2 percent. South America has the highest number of people affected, with 30 million overweight, followed by Central America with 16 million and the Caribbean with three million. Argentina, Bahamas, Chile, and Mexico have the highest prevalence, with more than 35 percent. Peru also has a high prevalence, at 25 percent. Furthermore, the report shows differences by sex: the prevalence is 27 percent in men and 27.9 percent in women [6].

The analysis by Andermo et al. [7] underlines the effectiveness of school initiatives that promote physical activity among children and young people. According to these results, these actions reduce anxiety, strengthen resilience, improve well-being, and promote positive mental health.

The motivations of interest concern the Health of Students, the high prevalence of overweight, and the significant lack of physical activity among students. This public health problem requires innovative solutions that can be implemented on a large scale. The potential of machine learning with the application of specifically supervised ML algorithms can provide new insights and tools to classify and evaluate the physical fitness of schoolchildren. This will allow for a more targeted and personalized intervention. Innovation in Physical

Education: Integrating advanced technologies such as ML into physical fitness assessment can revolutionize how physical activity is understood and promoted in educational centers. Optimizing hyperparameters in ML models ensures that predictions and classifications are as accurate as possible, which is crucial for designing effective interventions.

Therefore, the paper aims to explore the level of physical fitness and the application of machine learning algorithms optimized by hyperparameters to optimally classify the physical fitness of schoolchildren from educational centers so that artificial intelligence techniques can contribute to health and academic contexts.

Creating a supervised machine learning model optimized for classifying the physical fitness level of schoolchildren is a significant contribution. This model can accurately evaluate different physical parameters and provide a detailed classification that facilitates personalized intervention. Implementing and analyzing hyperparameter optimization techniques will improve the accuracy and effectiveness of predictive models. This methodological approach can be applied in other areas of study that use machine learning, providing a framework to improve the quality of predictions. The research will provide a detailed analysis of how machine learning can evaluate and improve school initiatives that promote physical activity.

The article is organized as follows: Section I with the introduction, Section II has the literature review, Section III develops the methodology used, and Section IV presents the results obtained. Finally, the discussion and conclusion are given in Section V and Section VI respectively.

II. LITERATURE REVIEW

There is more than one way to measure physical activity levels (whether manually, with questionnaires, wearable technology, or smart devices), which will help classify them into levels. In this sense, we present the main works carried out with the topic under study.

Trejo et al. [8] indicate that obesity is a problem worldwide. Even more so, with the advancement of technology, many schoolchildren lead sedentary lifestyles due to being immersed in social networks and virtual video games. According to the results obtained, children with obesity spend an average of three hours watching television programs or playing video games.

According to the study by [9], Physical Activity, Diet Quality, and Physical Condition should be assessed early, considering it a physiological need to contribute to a healthy lifestyle and improve the child's future quality of life. The school framework is taken at an early average age of 8 - 12 since it is considered the ideal environment to promote good, healthy behaviors.

Zhou et al. [10] show that predicting adherence or commitment to physical activity is of utmost importance since it prevents a relapse in exercise, using automatic prediction messages with Logistic Regression and Support Vector Machine (SVM) models. This research conducted tests on sedentary people, testing their resistance to physical activity for

a specific time. The Logistic Regression model demonstrated a slightly better performance than the Support Vector Machine (SVM). It should be noted that the precision in both models is high.

Alsareii et al. [11] mention physical activity is essential in controlling obesity and maintaining a healthy life. Tracking physical activities using state-of-the-art automatic techniques can promote healthy living and control obesity. This work introduces novel techniques to identify and record physical activities using machine learning techniques and wearable sensors.

Ahmadi, Pavey, and Trost [12] mention as the objective of the study the evaluation of the accuracy of Random Forest (RF) activity classification models for preschool children trained with data from free-living accelerometers in children in the range of four to nine years concluding that RF activity classification models trained with free-living accelerometer data provide accurate recognition of young children's movement behaviors under real-world conditions.

In study [13], students from public schools in Arequipa (Peru) were evaluated, and they performed the classification of motor competence based on the evaluation with the most popular machine learning algorithms optimized by their hyperparameters. The tests assessed using wearable technology were related to motor competence in schoolchildren aged 6 to 17. Different data was captured using a pedometer, accelerometer, and heart rate sensors. As a result, percentiles of schoolchildren were created. Regarding classification, the gradient boosting algorithm with its optimization of hyperparameters with the RandomizedSearchCV technique was the one that obtained the best precision of 0.95 and in the ROC-AUC curves with 0.98. Additionally, they developed software that implemented the model that was built.

Current research has identified several areas of intervention to optimize the classification of lack of physical activity in schoolchildren. Still, it has also highlighted significant gaps that must be addressed to improve the effectiveness of prevention and treatment strategies. Among them is the improvement of predictive models, which can be achieved by incorporating the configuration of hyperparameters. The comparison of tracking techniques, making an exhaustive comparison of different automatic fitness activity tracking techniques in terms of cost-effectiveness and accessibility, proposing practical solutions for implementation in school programs. The classification models can be integrated by incorporating Fitness Activity classification models into school programs and providing guidelines for their use by educators and parents. Algorithm optimization, performing a comparative analysis of the machine learning algorithms used to classify Fitness Activity, determining the most effective and accessible implementation in various contexts.

III. METHODOLOGY

It is necessary to perform data analysis as a fundamental process for classifying schoolchildren and obtaining valuable information on physical activity results. There are different methods and techniques to classify and perform data analysis. The KDD (Knowledge Discovery in Databases) process was

used for this research to extract knowledge from large volumes of data. It consists of a series of defined stages applied before using data mining techniques to search for hidden patterns in the data and analyze the patterns found. KDD uses a structured set of stages to address data mining projects, from understanding data to obtaining knowledge, as shown in Fig. 1; this represents how we use the methodology following the stages in the data process of physical activity, generating knowledge. The methodology used was KDD, which consists of six stages: Starting from Selection, followed by Preprocessing, Transformation, Mining, and Interpretation to reach the knowledge we want. Fig. 1 shows the KDD process.

Fig. 1. KDD process [14].

A. Data Selection

The selection of data sources consisted of searching the data for appropriate input attributes of physical activity, obtaining 1525 students (784 women, 741 men) from 6 to 17 years old, including children and adolescents; the sample selection was non-probabilistic. This means knowing what you want to obtain and what data will facilitate this process to achieve the results.

The evaluations of the motor competence tests were carried out in public schools in the city of Arequipa (Peru). The tests were carried out during physical education sessions. The schoolchildren were previously informed about the evaluation to be carried out.

For this research, anthropometric measurements were carried out in the facilities of each school, working with children and adolescents with the authorization of their parents or guardians. Data collection and evaluation were carried out by two physical education teachers with experience in similar work. It was assessed according to the standardized protocol of Ross and Marfell-Jones to capture the standing height and weight measurements. Body weight (in kilograms) was measured using a BC-730 electronic scale, with a range of 0 to 150 kg and a precision of 100 grams. Standing height was measured according to the Frankfurt plane using a portable stadiometer with an accuracy of 0.1 mm. To divide abdominal fat (AF) into categories by sex and age, the suggestions described by Fernández in [15] were followed.

B. Pre-Processing

Data was collected during the different physical education sessions to pre-process this research. Once collected, the following steps were carried out, shown in Table I, necessary for use in the classification algorithms:

1) *Data cleaning*: In this step, the data was cleaned, including incomplete data (where there are missing attributes or attribute values), noise (incorrect or unexpected values), and inconsistent data (containing values and characteristics with different names). Conflicting data were eliminated because they would allow inadequate analysis and incorrect results.

The data cleaning tasks to be executed by the Jupyter panel were written in Python 3. The Pandas library, used for data manipulation and analysis, uses the Python Scikit-learn library [16], as shown in greater detail in Table II.

Fig. 2 shows the distribution of the students' classes: High, Normal, and Low physical activity for both sexes.

2) *Data transformation*: The data was normalized to be on the same scale since some machine learning algorithms are sensitive to scales. The physical fitness tests considered according to the specialists were:

a) *Flexibility (cm)*: The dorsal-lumbar flexibility, sitting posture, and modified reach were measured.

b) *Horizontal jump (cm)*: The horizontal jump was measured by the number of attempts in the "kangaroo" test.

c) *Speed 20m (seconds)*: It was evaluated ten times in the 20-meter race and assessed in seconds with a stopwatch.

The percentile tables were used to consider the research [17]. These percentiles were divided into male and female ranges, and the parameters for each test taken for this investigation were shown.

TABLE I. DATA PRE-PROCESSING

Phases	Description
Data Cleaning	Errors in the data, such as empty spaces and punctuation marks not allowed, were detected and corrected.
Data integration	The data collected from the sessions was combined to provide a unified view by integrating them into a single format.
Data transformation	In this stage, categorical variables were normalized and standardized, and coding was carried out, transforming the data into a uniform format.
Data reduction	The data to be processed were identified for each record having ten input attributes.

TABLE II. APPLICATION OF TECHNOLOGIES

Technology	Description
Python 3.6	Python is the programming language we will use to analyze and process algorithms.
Colab	It is the environment that can run and program in Python. It provides a flexible environment for Python programming and other scientific computing tasks.
Scikit-learn	Python library includes various supervised and unsupervised machine learning algorithms, which are widely used for their ease of use, and a wide range of data analysis and modeling tools.

Fig. 2. Boxplot of the classes of female and male school children.

TABLE III. PERCENTILES OF THE FLEXIBILITY, HORIZONTAL JUMP, AND SPEED 20M TESTS FOR MEN AGES 6 TO 18

P75	6.2	5.4	5.67	5.54	5.29	4.94	4.63	5.35	4.81	5.19	5.12	4	4.05

Tables III and IV present the results of the evaluated tests and their corresponding percentiles: P25, P50, and P75. These percentiles were used as cut-off points in this research. Values close to the P75th percentile are considered excellent, while values at the P25th percentile are rated poor. The grade depends on the type of physical test and the objective. According to the studies, the following cut-off points were proposed for the diagnosis of physical fitness: 75 (High), 50 (Normal), and 25 (Low). The previously studied percentiles were fundamental for this research, providing a solid basis for establishing the cut-off points.

C. Transformation

For balance, the records were first sorted randomly, and then 80% were selected for training and 20% for testing. In summary, this process consisted of three phases: defining and determining the types of errors, finding and identifying instances containing errors, and correcting the discovered errors.

The registration of schoolchildren had the problem of imbalance in data sets, which is a significant problem in

classification operations. When one class is significantly more frequent than others, machine learning algorithms can become biased toward the majority class, resulting in poor performance in predicting the minority class. Data balancing helps mitigate this problem; for this reason, data balancing was carried out to correctly predict the minority classes for a data set in the data analysis.

D. Classification of Data Mining

This stage consists of searching for patterns of interest that can be expressed as a model based on Machine learning algorithms applied to physical fitness tests in schoolchildren. Data analysis determined that the classification results from physical activity tests are labeled- Low, Normal, and High. Likewise, classification was the most appropriate type of prediction for this research. For the classification model, a comparison of supervised machine-learning techniques is made. The most used optimizers and algorithms, according to the literature, are:

TABLE V. DESCRIPTION OF CLASSIFICATION ALGORITHMS USED IN THE STUDY

Algorithm	Description	Advantages	Limitations
Decisión Tree	Separates the data of an ensemble into smaller subsets with an increase in the depth of the tree. The objective increases the prediction using decision nodes [18].	Visual interpretation of all possible results requires little data cleaning, is unaffected by different values, and uses numerical and categorical variables.	The calculation is complex, which implies more time is needed to train the model; a slight change in the data can cause a significant change in the tree's structure.
Random Forest	Models are made up of many decision trees; when training each tree, it learns from a random sample of the data points and a subset of features [19].	The final predictions of the Random Forest are made by averaging the predictions of each tree, reducing the problem of overfitting and variance.	Regression algorithms have a higher computational cost and longer training time than decision trees. They do not predict beyond the range in the training data.
Naive Bayes	Probabilistic learning algorithm that uses the rule of Bayes' theorem together with prior knowledge, whose characteristics depend on the independence provided by the class [20].	The advantage of Naive Bayes is when the cost of incorrectly classifying a result as positive is high, it is crucial to have high precision to minimize false results.	Naive Bayes is limited by underperforming when faced with splitting data sets with high dimensionality. As the number of features increases.
Support Vector Machine	SVMs find a line or hyperplane between different data and calculate a maximum margin that leads to a homogeneous division of all data points [21].	Efficient in memory usage when processing.	Choosing the correct kernel and parameters can be computationally expensive.
Logistic Regression	Used for binary classification problems, the basis of logistic regression is the logistic function (sigmoid) that takes any number with an accurate value and assigns it a value between 0 and 1 [22].	It is a simple but effective algorithm closely related to neural networks. The training time is less than that of other algorithms.	Predicting complex data is problematic because it has a linear decision surface; in high-dimensional data sets, this can generate overfitting.
Neural Network	It uses interconnected nodes with a layered structure that resembles the human brain. It creates an adaptive system that computers use to learn from their mistakes and continuously generate improvements [23].	Neural networks help computers make intelligent decisions with limited assistance. They can learn and model complex, non-linear input-output data relationships.	Its limitation is that it has a forward propagation network, which uses a feedback process to improve predictions over time.
k-Nearest Neighbors KN	It uses K-nearest neighbor to make classifications or predictions about the clustering of a data point. The main idea is that all data points are close to each other to belong to the same class [24].	Speeds training time by storing the training set and learning from it only when making predictions.	They are computationally expensive. They must be preprocessed and scaled, and the observations will be used only during prediction, so this step is costly.
XG Boost	It implements Gradient Boosting to maximize training speed and model performance [25].	Training optimizes memory resources and distributed computing, allowing for handling large data sets.	High flexibility produces many hyperparameters that strongly interact with the model's behavior.
Gradient Boos	With an ensemble algorithm with numerical optimization, the objective is to minimize the loss of the model by sequentially adding decision trees [26].	Good predictive accuracy, flexibility to adjust to different kinds of data, and predictions are made by a majority vote of weak learners.	Gradient boosting will continue to improve to minimize all errors that cause excessive overfitting.

Hyperparameters are defined as extra parameters or parameters that the learning algorithm does not memorize directly. Hyperparameters are external configuration variables that, when performing data analysis, help us manage the training of Machine Learning models. We also call model hyperparameters, which are manually configured before training a model. Optimization was used by configuring hyperparameters; among the main fields, the following were chosen:

Random Forest:

- `n_estimators`: Number of trees in the forest.
- `max_depth`: Maximum depth of each tree.
- `min_samples_split`: Minimum number of samples required to divide a node.
- `min_samples_leaf`: Minimum number of samples required in a leaf node.
- `max_features`: Number of features to consider for the best split.
- `bootstrap`: Whether to use bootstrap sampling when building trees.

Gradient Boosting:

- `n_estimators`: Number of impulse stages to perform.
- `learning_rate`: Learning rate.
- `max_depth`: Maximum depth of the trees.
- `min_samples_split`: Minimum number of samples required to divide a node.
- `min_samples_leaf`: Minimum number of samples required in a leaf node.
- `max_features`: Number of features to consider for the best split.
- `subsample`: The fraction of samples used to train each base tree.

IV. RESULTS

We worked with the Anaconda Navigator platform with Jupyter Notebook because it already had established, well-supported libraries. Table V shows the different machine-learning techniques applied in this research.

For the work of the data obtained already cleaned, it was used for shaping, 80% allocated for training, and 20% designated for testing, together with the Jupyter Notebook, a commonly used tool for machine learning, using the scikit-learning library.

The configuration used for the machine learning algorithms was made regarding the hyperparameters. The configuration achieved by the best results obtained in Random Forest and Gradient Boosting, respectively, is shown:

```
'n_estimators': 200,  
'max_depth': 10,  
'min_samples_split': 5,  
'min_samples_leaf': 2,  
'max_features': 'sqrt',  
'bootstrap': False  
  
'n_estimators': 100, 20,  
'learning_rate': 0.1,  
'max_depth': 3,  
'min_samples_split': 5,  
'min_samples_leaf': 1,  
'max_features': 'sqrt',  
'subsample': 1.0
```

Tables VI to VIII show the results obtained once processed. In male schoolchildren, they compare traditional and enhanced machine learning techniques with configured hyperparameters for flexibility, speed, and horizontal jump data. Accuracy metrics, such as F1 score, recall, and precision, are also shown for schoolchildren.

Tables IX to Table XI show the results of applying machine learning algorithms with hyperparameter optimization compared to traditional ones in female schoolchildren.

The results shown in the Tables show that, for the classification techniques, the Random Forest achieved the highest precision in Male Flexibility, whose value is 0.97, indicating a more significant adjustment of the estimated prediction. For the f1-score metrics, the result was 0.97, in the case of recall 0.95.

The choice of hyperparameters has a critical impact on the performance of machine learning models. In this case, the optimized parameters allowed Random Forest to achieve outstanding results in classifying flexibility data in male schoolchildren. The precision, F1-Score, and recall metrics indicate a well-fitted model with adequate generalization capacity.

The Random Forest algorithm obtained the best results for most of the tests. The following Fig. 3 to Fig. 5 show the ROC-AUC curves generated by the Random Forest algorithm for the Physical Fitness tests evaluated on male schoolchildren.

Fig. 3 shows the ROC-AUC curve for the flexibility test where the High class (AUC = 0.88): The model distinguishes between the "High" category and the other categories well. Low (AUC = 0.84), the model also distinguishes between the "Low" category and the different categories. Normal (AUC = 0.58), the model performs significantly lower in distinguishing between the "Normal" category and the others, indicating that the model is ineffective in this classification.

Fig. 3. Random forest ROC-AUC curve for the male flexibility test.

Fig. 5. Random forest ROC-AUC curve for the men's 20m speed test.

Fig. 4. Random forest ROC-AUC curve for the male horizontal jump test.

Fig. 4 shows the ROC-AUC curve for the horizontal jump test. The "High" class has an AUC of 0.73, indicating that the model performs moderately in distinguishing between this category and the others. The "Low" class has an AUC of 0.85, demonstrating the model's good performance in differentiating this category from the rest. In contrast, the "Normal" class has an AUC of 0.41, reflecting a relatively poor performance of the model in distinguishing between this category and the others.

Fig. 5 shows the ROC-AUC curve for the speed 20m test. For the High class (AUC = 0.83), the model performs well in distinguishing this category from the others. The model performs moderately for the Low class (AUC = 0.74). However, the model's performance is low for the Normal class (AUC = 0.53), indicating that it is ineffective for this classification.

In summary, from the tests of male schoolchildren, the model performs well for the "High" categories in all tests, with AUCs of 0.88, 0.73, and 0.83, respectively. The model has excellent performance for the "Low" category in flexibility and horizontal jump, with AUCs of 0.84 and 0.85, respectively, and moderate performance in speed with an AUC of 0.74. The model shows overall poor performance for the "Normal" category in all tests, with AUCs of 0.58, 0.41, and 0.53, respectively, indicating that the model's predictive ability is limited.

In conclusion, the Random Forest model performs well in classifying the "High" and "Low" categories in most tests but struggles to classify the "Normal" category correctly.

Fig. 6 to Fig. 8 show the ROC-AUC curves generated by the Random Forest algorithm for the Physical Fitness tests evaluated on female schoolchildren.

Fig. 6. Random forest ROC-AUC curve for the female flexibility test.

Fig. 6 shows the ROC-AUC curve for the flexibility test in female schoolchildren. The "High" class has an AUC of 0.81, indicating that the model performs well in distinguishing this category from the others. The "Low" class has an AUC of 0.92, demonstrating excellent model performance for this category. On the other hand, the "Normal" class has an AUC of 0.57, suggesting that the model's performance is moderately poor in distinguishing this category from the others.

The ROC-AUC curve for the "horizontal jump" test is shown in Fig. 7. The "High" class has an AUC of 0.71, indicating that the model has moderate performance in distinguishing between the "High" category and the others. The "Low" class has an AUC of 0.73 and moderately performs in distinguishing between the "Low" category and the others. However, for the "Normal" class, the AUC is 0.39, suggesting that the model performs poorly in distinguishing between the "Normal" category and the others, indicating that it is ineffective in this classification.

Fig. 7. Random forest ROC-AUC curve for the female horizontal jump test.

Fig. 8. Random forest ROC-AUC curve for the women's 20m speed test.

Fig. 8 shows the ROC-AUC curve for the Speed 20m High test (AUC = 0.77). The model distinguishes between the "High" category and the other categories. Low (AUC = 0.90): The model distinguishes between the "Low" category and the others. Normal (AUC = 0.46): The model performs poorly distinguishing between the "Normal" category and the others.

In summary, from the results of the tests of female schoolchildren, the model generally shows good performance for the "High" categories in all tests, with AUCs of 0.81, 0.71, and 0.77, respectively. The model has excellent performance for the "Low" category in flexibility and speed, with AUCs of 0.92 and 0.90, respectively, and moderate performance in horizontal jump with an AUC of 0.73. The model shows overall poor performance for the "Normal" category in all tests, with AUCs of 0.57, 0.39, and 0.46, respectively, indicating the model's limited predictive ability.

In conclusion, the Random Forest model performs well in classifying the "High" and "Low" categories in most tests but struggles to classify the "Normal" category correctly.

V. DISCUSSION

This research used machine learning techniques to analyze the accuracy and effectiveness in classifying data related to male and female schoolchildren's flexibility, horizontal jump, and 20m speed. Algorithms evaluated included Decision Trees,

Random Forest, Support Vector Machine (SVM), Naive Bayes, Logistic Regression, K-Nearest Neighbor (KNN), Multi-Layer Perceptron (MLP), Gradient Boosting, XGBoost, LightGBM and CatBoost [27]. The data was divided into 80% for training and 20% for testing. Hyperparameter optimization techniques were used to improve the accuracy of the models, as seen in Tables VI to XI. For example, the hyperparameters configured for Gradient Boost included criteria such as 'entropy,' 'max_depth,' and 'n_estimators,' which were manually tuned before model training.

The comparative results of the traditional and enhanced techniques with hyperparameters showed significant variations in accuracy, F1 score, recall, and precision for male and female schoolchildren. For the male group, the optimized Random Forest model showed outstanding accuracy in classifying flexibility, with an accuracy of 0.97, an F1-score of 0.97, and a recall of 0.95. This suggests the model can correctly predict physical activity classes with a low false positive rate. In contrast, the analysis of the female group revealed that the Random Forest model was also highly effective in classifying flexibility with an AUC of 0.92, indicating high sensitivity and specificity.

The ROC-AUC curves presented in Fig. 3 to Fig. 8 show the effectiveness of Random Forest models in classifying physical activities in schoolchildren, like studies of children aged 6 to 12 years [28]. Specifically, for male flexibility, the ROC-AUC curve showed a significant increase towards the upper left corner with an AUC of 0.88, confirming the high sensitivity of the model to detect the 'High' classification of physical activity. For female flexibility, the AUC was 0.92 for the 'Low' class, indicating high sensitivity and a low false positive rate.

Comparison tables showed that hyperparameter-optimized models significantly improved accuracy and other critical metrics compared to their non-optimized versions. For example, the SVM increased accuracy from 0.46 to 0.82 for the female group in the horizontal jump test. Similarly, the Gradient Boost model showed substantial improvements in accuracy and F1-score across multiple tests.

Comparing our results with those of other recent studies, we observed a congruence in the effectiveness of the Random Forest [29] and Gradient Boosting [30] algorithms. In our research and previous studies, these algorithms have repeatedly demonstrated their superiority in precision and recall in physical activity classification. This suggests that using advanced hyperparameter optimization techniques can significantly improve the accuracy of machine-learning models.

The consistency in results across multiple studies reinforces the validity of our findings and underscores the importance of selecting and optimizing appropriate algorithms for specific data classification tasks.

Limitations in the quality and quantity of data available for training machine learning models can significantly affect their performance. The challenge will be obtaining a large and representative data set, which can be difficult, especially in specific studies such as classifying physical activities in

schoolchildren. Another limitation is that incorrect selection of relevant features can decrease the effectiveness of the models. Determining which features are most informative requires deep domain knowledge and sometimes a thorough process of trial and error. Although hyperparameter optimization can significantly improve model performance, it is a resource-intensive process that requires time and computational power. The challenge is identifying the optimal combination of hyperparameters for each algorithm, which can be complicated and requires advanced search and cross-validation techniques.

VI. CONCLUSION

It is demonstrated that the application of machine learning algorithms, together with the optimization of hyperparameters, is an effective strategy for classifying students' physical condition in educational centers. Using the Knowledge Discovery in Databases (KDD) process and collecting anthropometric data and physical fitness tests could accurately assess the physical fitness of a representative sample of students.

The results indicated that the Random Forest and Gradient Boosting algorithms were particularly effective in classifying physical activities with high levels of precision, F1 score, recall, and specificity. These models' ability to differentiate between levels of physical fitness (below average, average, and above average) with a low false positive rate suggests their practical applicability in monitoring and evaluating students' physical health.

Future work could explore integrating these models into educational and health platforms and evaluating their long-term impact on student health. Other parameters and physical tests could also be considered for a more complete evaluation. The continued evolution of machine learning techniques and the availability of more granular data promise to further improve the accuracy and usefulness of these models.

Dept. of Information Science-Faculty of Science and Engineering, Saga University, Saga, Japan²

Abstract—The modeling of micro traffic flow on a highway has been extensively observed and studied in various aspects, such as driver characteristics in car-following and lane-changing behaviors. Regarding car-following and lane-changing, an interesting aspect is how to model the movement conditions of vehicles on a highway that exhibit unique characteristics regarding the speed of four-wheeled or more vehicles passing through it. This condition occurs on the Porong Highway in Sidoarjo, East Java, Indonesia. Based on these conditions, this study develops a microscopic traffic flow model incorporating driver characteristics categorized into three types: careful drivers, ordinary drivers, and skilled drivers, each with distinct vehicle speed traits. These driver characteristics are integrated into the Nagel-Schreckenberg Stochastic Traffic Cellular Automata (NaSch STCA) model, which we refer to as the Modified NaSch STCA. The Monte Carlo simulation is employed to generate events through random numbers for the Occupied Initial State, Slowdown Probability, and Probability of Lane Changing. These three components are integral parts of the Modified NaSch STCA model. Experiments (simulations) were conducted on the constructed vehicle movement model, and one of the outcomes is that the travel time obtained from the NaSch STCA model is significantly faster than that obtained from the Modified NaSch STCA model. This condition is attributed to the unique vehicle speed characteristics on the Porong Highway, where the average speed $v_r = 38$ km/h is relatively lower than the average speed typically observed on a highway.

Keywords—Micro traffic flow; driver characteristics; cellular automata; Monte Carlo

I. INTRODUCTION

Modeling and simulation of microscopic traffic flow have been extensively pursued by researchers, including the development of micro-traffic flow models based on intelligent transportation systems with wireless communication [1]; calibration of microscopic car-following (CF) models to accurately replicate and study traffic behavior and phenomena [2]; estimation and prediction of traffic states by integrating statistical data in both congested and uncongested scenarios [3]. Intelligent transportation systems offer an alternative to enhance traffic environments by integrating the Internet of Things and smart algorithms. These systems collect and process data from various sources to improve transportation efficiency. Research conducted by study [4] reviews the smart techniques employed for predicting traffic flow in urban areas. Additionally, it proposes a general taxonomy where the

insights gained from traffic flow analysis merge with computational approaches. Microscopic urban traffic simulation using integrated modeling methods has been conducted, taking into account driver behavior characteristics related to car-following and lane changing. The results indicate that car-following behavior is more sensitive to variations in the status of adjacent vehicles and lane changes compared to lane-changing behavior during the lane-change process. This study also aids in analyzing travel characteristics and the impact mechanisms of vehicles in urban roads, serving as a guide for the development of sustainable transportation and autonomous vehicles in the future, and promoting efficient urban transportation system operations [5].

Microscopic traffic simulations are frequently employed to evaluate the effects of autonomous vehicles on safety and traffic flow. This study examines adaptive driver behavior by having drivers navigate the same route three times, each with a different level of autonomous vehicle penetration. The findings reveal that as the penetration level of autonomous vehicles increases, drivers adopt shorter waiting times, smaller following distances, and more consistent speeds closer to the maximum speed limit. These results indicate that driving behavior changes in response to variations in surrounding traffic composition [6].

Cellular automata have proven highly beneficial, not only in traffic flow simulation but also in diverse fields like pedestrian behavior for example: study a behavior-based cellular automata model that can represent heterogeneous crowd structures and explore the effects of different crowd compositions on pedestrian dynamics, particularly evacuation efficiency [7]. A multi-grid cellular automata model has been utilized to connect vehicle and pedestrian models. The enhanced Kerner-Klenov-Wolf (IKKW) model and a pedestrian movement model that incorporates Time to Collision (TTC) have been proposed. The application of these models to real-life scenarios has shown the impact of pedestrian intrusion behavior on traffic [8]. In the context of disaster mitigation, an expanded cellular automata model has been proposed for emergency evacuation dynamics involving pedestrians, utilizing parameters such as route change probability and group fields. Experiments were conducted to investigate the effects of this new extension, including the verification of related collective phenomena and the evaluation of safety performance metrics [9]. An LSTM-CA simulation for wildfire spread, combining Cellular Automata with Long

Short-Term Memory (LSTM), has been proposed. Real-world wildfire spread simulations have been conducted, and the accuracy of the wildfire spread predictions was verified using KAPPA coefficients, Hausdorff distances, and horizontal comparison experiments based on remote sensing imagery of wildfires [10].

Probabilistic Logistic Cellular Automata (LPCA) modeling has been carried out by integrating a basic logistic growth model with two-dimensional spatial dynamics to simulate the formation of regular patterns. The simulation results indicate that resource scarcity and environmental shape are the primary factors leading to the emergence of various regular patterns [11]. To prevent falling into local optima and to enhance convergence speed and global search potential, an advanced version of the Ant Colony Optimization (ACO) algorithm, known as the Cellular Automata-Based Enhanced Ant Colony Optimization Algorithm (CA-IACO), has been explored. Simulation results suggest that this algorithm is effective in addressing DDoS attacks, as it achieves high-quality solutions for identifying optimal nodes and reliable routing paths [12]. The phenomena observed in modeling and simulating various aspects using cellular automata indicate its capability to provide solutions to both simple and complex problems.

In the use of cellular automata for a particular problem, the role of randomness and Monte Carlo simulation is crucial. Many researchers emphasize the incorporation of randomness into the rules of cellular automata, such as using randomness in the probability of lane switching [13], [14]. Monte Carlo simulation plays a significant role in modeling and simulating dynamic systems using cellular automata, including calculating simulation data for traffic queuing problems [15] and predicting real-time traffic flow based on normal distribution [16].

In micro traffic flow modeling, driver behavior is a critical parameter. One aspect involves defensive maneuvers by drivers to avoid obstacles and braking, such as encountering a pedestrian appearing suddenly on the road ahead of the vehicle [17]. The smart road stud (SRS) not only drastically alters microscopic driving characteristics but also significantly influences driver decision-making processes during overtaking maneuvers [18]. On the other hand, research on modeling driving behavior in developing countries is conducted using microsimulation approaches with multi-agents, deemed suitable for accurately replicating driving behaviors [19]. Adaptive driver behavior is observed through repeated driving of the same route three times with varying penetration rates of automated vehicles. It is demonstrated that driving behavior changes as the traffic composition around them changes [20]. It is noted that following behavior is more sensitive to variations in lateral vehicle movements and lane changes [21].

In the context of micro traffic flow modeling, many researchers utilize driver behavior as a key parameter. However, this driver behavior is rarely depicted based on the micro traffic flow phenomena observed on highways, especially the phenomenon of vehicle speeds passing through the roadway. Cellular automata, as a method of dynamic system specific to micro traffic flow modeling, employs rules that require processes of randomness, including determining

initial density probabilities and lane-changing probabilities. This study employs Monte Carlo simulations for the randomness processes embedded within the cellular automata rules. A survey of vehicle speeds in micro traffic flow was conducted on the Porong Highway in Sidoarjo, East Java, Indonesia, focusing on four-wheeled vehicles: trucks/trailers, buses, public transportation, and private cars. The phenomenon of vehicle speeds passing through this highway served as the basis for categorizing driver characteristics. Based on normalized speed data from each vehicle type, drivers were categorized as follows: careful drivers for truck/trailer drivers, ordinary drivers for bus and public transportation drivers, and skilled drivers for private car drivers. A modified cellular automata model was developed based on these driver characteristic categories, and an analysis of traffic flow simulation results was conducted to assess the accuracy of the model. The results of this study are expected to benefit relevant stakeholders, such as government agencies involved in highway transportation. The findings, which include travel times based on vehicle speed characteristics, can provide valuable insights into the comfort and safety of driving on the Porong-Sidoarjo Highway in East Java, Indonesia.

This study continues with an explanation of the stochastic traffic cellular automata (STCA) model and Monte Carlo methods, which are discrete-time simulation models. It then addresses phenomena related to microscopic traffic flow characteristics observed on the Porong-Sidoarjo Highway in East Java, Indonesia, specifically focusing on driver and vehicle characteristics based on vehicle speed in Section II. The micro traffic flow phenomena is given in Section III. Proposed model is given in Section IV. This is followed by a section on testing the developed model and a discussion of the relevant results from these tests in Section V. The study concludes in Section VI with a summary of the research findings.

II. DISCRETE TIME SIMULATION MODEL: CELLULAR AUTOMATA-MONTE CARLO

A. Stochastic Model: Nagel-Schreckenberg STCA

In the realm of traffic simulation, modeling at the microscopic level has long been recognized as a intricate and time-intensive endeavor, requiring intricate models that portray the behaviors of individual vehicles. However, approximately ten years ago, a novel microscopic model emerged, drawing on the cellular automaton framework rooted in statistical physics. Its principal advantage lies in its efficient and swift performance during computer simulations, although it may exhibit slightly diminished accuracy at the microscopic level. These traffic models based on cellular automata (TCA) are dynamic systems characterized by discrete elements, where time progresses in distinct increments and space is represented in coarse units (for instance, roads divided into 7.5 meter per-cell, each either empty or occupied by a vehicle) [22].

In terms of randomness usage (probability), cellular automata models can be categorized into two types: deterministic models and stochastic models. One deterministic TCA model compares two acceleration models embedded within cellular automata, stating that the Acceleration Time Delay (ATD) model and Speed Adaptation (SA) model exhibit

spatiotemporal traffic congestion patterns consistent with empirical findings. In both models, the onset of congestion in free flow conditions on congested roads is associated with a first-order phase transition from free flow to synchronized flow; moving congestion spontaneously emerges only in synchronized flow [23].

Stochastic Traffic Cellular Automata (STCA) are widely used in modeling micro traffic flow. The basic model of STCA introduces a rule involving randomization, utilizing randomness within the TCA rules. This adaptation accounts for natural speed fluctuations caused by human behavior or various external conditions [24]. Incorporating this randomness into TCA transforms it into Stochastic Traffic Cellular Automata (STCA). Many researchers have developed STCA models from various aspects, focusing on updating acceleration in car-following or lane-changing behaviors.

Fig. 1. Time-space diagram of NaSch STCA (two lanes), where the vertical axis represents time-steps and the horizontal axis represents space (cells), road length $L = 500$ cells, density $k = 0.3$, slowdown prob. $P = 0.3$, prob. of lane changing $P_{lc} = 0$. Top image for lane 1 and bottom image for lane 2.

The STCA developed by Nagel-Schreckenberg is defined on a one-dimensional array with a lattice length L and operates as an open-loop system. Each location (cell) can either be occupied by one vehicle or remain empty. The speed of each vehicle is represented by an integer between zero and v_{max} . Updates in the NaSch STCA system consist of four sequential steps performed in parallel for all vehicles. The update rules in the NaSch STCA system (utilizing two lanes in this study) are as follows [22], [24]:

$$1) \text{ Acceleration: } v_{i,j}(t) \leftarrow v_{i,j}(t - 1) + 1$$

$$\text{If } v_{i,j}(t - 1) < v_{max} \text{ and } \delta \text{ } g_{s_{i,j}}(t - 1) > v_{i,j}(t - 1) + 1$$

$$2) \text{ Braking: if } g_{s_{i,j}}(t - 1) \leq v_{i,j}(t - 1),$$

$$v_{i,j}(t) \leftarrow g_{s_{i,j}}(t - 1) - 1$$

3) Randomization: with slowdown probability P and random number $\xi(t)$, if $\xi(t) < P \Rightarrow v_{i,j}(t) \leftarrow v_{i,j}(t - 1) - 1$.

4) Vehicle movement:

$$x_{i,j}(t) \leftarrow x_{i,j}(t - 1) + v_{i,j}(t)$$

where, $v_{i,j}(t)$ is the speed of the vehicle in the i -th lane and j -th position, and $g_{s_{i,j}}(t)$ is space gap, the distance between a vehicle and the vehicle in front of it. Fig. 1 shows one of the simulation results of NaSch STCA for two lanes with the specifications of a lattice length $L = 500$ cells, density $k = 0.3$, slowdown probability $P = 0.3$, probability of lane changing $P_{lc} = 0$. Vehicles move from left to right, and the system operates as an open-loop system.

B. Monte Carlo Simulation

The Monte Carlo simulation involved generating events through random numbers. This process comprised data collection, assigning random numbers, formulating models, and performing analysis. One reason for using a Monte Carlo simulation is that it typically applies to simulations utilizing stochastic methods to create new configurations of the system being studied [25]. On the other hand, the Monte Carlo Simulation procedure outlined by [15] and utilized in this research involves: (i) Step 1. Data collection, which uses a pseudo-random sequence; (ii) Step 2. Random-number assignment, where events are generated impartially by assigning random numbers in proportion to their probability of occurrence. The standard Monte Carlo method with pseudo-random sequences can achieve good convergence with N sample tests. In predicting traffic flow, the Monte Carlo Simulation serves as a mathematical tool to model risk or uncertainty in a system through the generation of random variables. The Monte Carlo Simulation model is designed to forecast traffic patterns. To create a new dataset with random probabilities, parameters such as the mean and standard deviation from the fitted normal distribution were utilized, as described by [16].

In other areas, the relationship between Cronbach's alpha and randomness was tested using Monte Carlo simulations, as opposed to issues with minimum sample width and bias. Simulation-generated artificial data were used to estimate the alpha coefficient for a K-item scale with a 5-point Likert-type format, answered randomly by 5K individuals, where K denotes the number of items. Each trial was conducted 5000 times, and one finding was that the probability of a Cronbach's alpha coefficient of 0.27 or higher for a K-item 5-point Likert scale, randomly answered by 5K people, is less than 5% [26].

The Monte Carlo simulation procedure, as generally outlined by [15], includes Step 1: Data collection and Step 2: Random-number assignment has been applied in this study. The Monte Carlo Simulation generates random numbers in three areas: the initial state of occupancy, randomization (slowdown probability), and lane-changing probability. These components are integrated into the micro traffic flow modeling addressed in this research. Below is an explanation of each section.

1) *Occupied initial state*: In this section, random numbers are generated using Monte Carlo, where the random value is generated to be less than a predetermined density percentage k of vehicles. If this condition is satisfied, the initial position of the vehicle is assigned to the corresponding cell, and its initial speed $v_{ij}(t)$ is set according to a normal distribution. All vehicles will be moved in parallel per time-step after generating their initial positions and velocities. Based on the density percentage, random positions $x_{ij}(t)$ of vehicles are generated on a lattice length L as specified. The highway specifications used in this experiment replicate conditions on the Porong-Sidoarjo Highway in East Java, Indonesia. The traffic flow direction under study is from the cities of Sidoarjo/Surabaya towards Malang/Banyuwangi (one-way). This highway has two lanes ($i = 1-2$), and typical straight road length is 3750 meters, thus if 1 cell = 7.5 meters, the lattice length of the road is 500 cells ($j = 1-500$). In the Cellular Automata model, cells occupied by vehicles are identified with the number 1, while unoccupied cells are identified with 0. Here is the syntax for generating random numbers based on Monte Carlo:

```
for j=1:n
  for i=1:2
    r=rand;
    if(r<k)
      x(1,i,j)=1;
      v(1,i,j)=floor(vmax/2+0.69*randn);
    end
  end
end
```

The initial conditions of vehicle speeds $v_{ij}(t)$ are represented in matrix form with indices $(1,i,j)$. Their values are computed using the floor function with the argument $\frac{v_{max}}{2} + 0,69 \times randn$, where $randn$ is a function that generates random numbers from a standard normal distribution. Therefore, $v_{ij}(1,i,j)$ will contain the value from this expression after it has been rounded down to the nearest integer using the floor function.

2) *Randomization (Slowdown probability)*: One of the rules in Nagel-Schreckenberg's STCA involves randomization, specifically reducing the speed by 1 cell per time-step for vehicles that satisfy the randomization condition stated in the rule. The value of the random number $\zeta(t)$ is generated using Monte Carlo methods, where its magnitude is less than a predefined probability value p (referred to as the slowdown probability). Here is the syntax for generating random numbers based on Monte Carlo, applied from the initial simultaneous movement of vehicles until the end of the specified time period.

```
for j=1:n
```

```
  for i=1:2
    if(x(t,i,j)==1)
      r=rand;
      if(r<p)
        if(v(t,i,j)==5)
          ...
          ...
        end
      end
    end
  end
end
```

3) *Probability of lane changing*: In this study, we refer to the structure of the Porong Sidoarjo highway where each direction has two lanes. Lane changes occur simultaneously between lane 1 and lane 2 as vehicles move over time. Monte Carlo plays a role in generating random numbers to determine which vehicles will change lanes. The random number generated is smaller than a predetermined lane change probability p_{lc} . The syntax for lane change from lane 1 to lane 2 is described below. This condition is equivalent to lane change from lane 2 to lane 1.

```
  for j=6:n
    if(x(t,1,j)==1)
      r=rand;
      if (r<plc)
        if(v(t,1,j)==5)
          ...
        end
      end
    end
  end
```

III. MICRO TRAFFIC FLOW PHENOMENA, VEHICLE TYPES, DRIVER CHARACTERISTICS

Traffic flow survey has been conducted in the area of Porong Sidoarjo Highway, East Java, Indonesia, where the traffic direction is specifically from the cities of Sidoarjo/Surabaya towards Malang/Banyuwangi (one-way). This highway serves as a main road connecting major cities including Surabaya, Sidoarjo, Malang, Jember, and

Banyuwangi. The economic growth among these cities is linked to the existence of Porong Sidoarjo Highway. The presence of this highway is highly significant and gives rise to distinct micro-traffic flow phenomena. The survey was conducted from March 23rd to March 30th, 2010. Speed data of vehicles was collected hourly over 24 hours a day for eight days, totaling 190 data points. The surveyed vehicle types included four-wheeled or more vehicles such as trucks/trailers, buses, public transportation, and private cars. Vehicle speed is measured using a speed gun.

A. Micro Traffic Flow Phenomena

The survey of speeds from four types of vehicles conducted every hour yielded speed data, where each vehicle type has several speed data points per hour. The mean speed data for each vehicle type per hour was calculated, resulting in 190 mean speed data points per vehicle type. The phenomenon of these mean speeds shows variability in the data. It is desired that the speed data have a normal distribution so that descriptive statistics such as mean and standard deviation can accurately depict the patterns of mean speed and its variability. This includes the potential to determine driver characteristics based on mean speed data. The phenomenon of mean speed data from four types of vehicles over 190 consecutive hours is depicted in Fig. 2.

The results of the vehicle speed survey were analyzed to determine the form of the population distribution or its probability by testing the hypothesis that a specific distribution serves as the model for the speed population. This study conducted hypothesis testing on speed data to assess whether the speed data or population follows a normal distribution or not. The hypothesis test employed a formal goodness-of-fit test procedure based on the chi-square distribution.

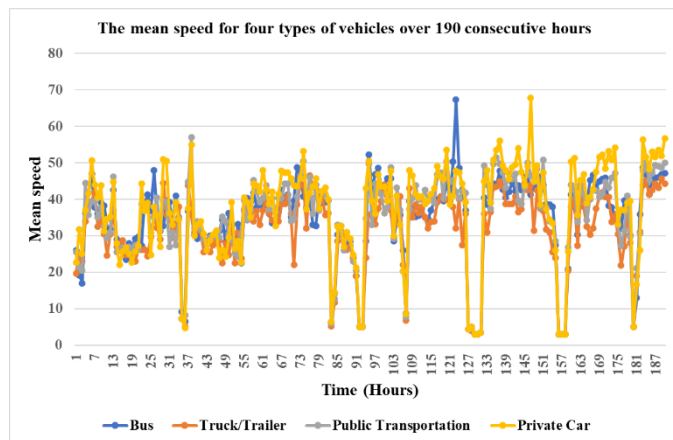

Fig. 2. The mean speed of four types of vehicles for 190 consecutive data points (190 hours).

The testing procedure requires several parameters: a random sample of size n ; class interval c ; observed frequency in class interval i , O_i ; expected frequency in class interval i , E_i (given from the hypothesized probability distribution). Eq. (1) is used as the test statistic to analyze whether the speed data pattern conforms to a normal distribution or not.

$$X_0^2 = \sum_{i=1}^c \frac{(O_i - E_i)^2}{E_i} \tag{1}$$

A statistical test is conducted on the population to determine if it follows the hypothesized distribution. The test statistic, X_0^2 has approximately a chi-square distribution with $c - p - 1$ degrees of freedom, where p represents the number of parameters of the hypothesized distribution estimated by sample statistics. The hypothesis is rejected if the calculated value of the test statistic $X_0^2 > \chi_{\alpha, c-p-1}^2$.

In this hypothesis test, conducted on data concerning the mean speeds of all types of vehicles, the sample size $n = 190$ is utilized. With a significance level $\alpha = 0.05$, the hypothesis test aims to determine whether traffic survey data (vehicle speeds) can be adequately modeled by a normal distribution. The test employs $c = 8$ class intervals, which, for a standard normal distribution, divide the distribution area into eight segments with equal probabilities: $[0, 0.32)$, $[0.32, 0.675)$, $[0.675, 1.15)$, $[1.15, \infty)$, and their mirrored intervals on the other side of zero.

Each interval has the probability $p_i = 1/8 = 0.125$, thus the expected cell frequencies $E_i = np_i = 190(0.125) = 23.75$. Note that the parameter values specified are $n = 190$; $\alpha = 0.05$; $c = 8$ cells; $p_i = 1/8 = 0.125$; and $E_i = np_i = 23.75$, which are consistent across all types of vehicles. Di sisi lain sebaran data kecepatan untuk semua jenis kendaraan memiliki mean $\mu = 35$ dan standard deviation $Std = 11.32$.

TABLE I. TEST THE DISTRIBUTION OF SURVEY DATA (MEAN SPEED) FOR ALL TYPES OF VEHICLES (FOUR TYPES OF VEHICLES)

Class Interval	Observed Frequency O_i	Expected Frequency E_i	$O_i - E_i$	$(O_i - E_i)^2$	$(O_i - E_i)^2/E_i$
$x < 22$	19	23,75	-4,75	22,56	0,95
$22 \leq x < 27$	12	23,75	-11,75	138,06	5,81
$27 \leq x < 31$	21	23,75	-2,75	7,56	0,32
$31 \leq x < 35$	19	23,75	-4,75	22,56	0,95
$35 \leq x < 39$	28	23,75	4,25	18,06	0,76
$39 \leq x < 43$	41	23,75	17,25	297,56	12,53
$43 \leq x < 48$	41	23,75	17,25	297,56	12,53
$48 \leq x$	9	23,75	-14,75	217,56	9,16
Total	190	190			43,01

A hypothesis testing procedure is employed to determine if the sample data set of mean speeds follows a normal distribution.

H_0 : The distribution takes on a normal form

H_1 : The distribution does not adhere to a normal form

The test statistic is

$$X_0^2 = \sum_{i=1}^c \frac{(O_i - E_i)^2}{E_i} = \frac{(19 - 23.75)^2}{23.75} + \frac{(12 - 23.75)^2}{23.75} + \dots + \frac{(9 - 23.75)^2}{23.75} = 43.01$$

Table I shows observed and expected frequencies for each cell, as well as the results of the chi-square distribution calculation.

- The chi-square table with $\alpha = 0.05$ and degrees of freedom = $c - p - 1 = 8 - 2 - 1 = 5$ (p represents the number of parameters in the hypothesized distribution, which in this instance are the parameters of the normal distribution specifically, the mean μ and the variance σ^2 . Thus, there are two parameters, so $p = 2$).

$$\chi_{\alpha, c-p-1}^2 = \chi_{0.05, 5}^2 = 11.07$$

- Conclusion: since $X_0^2 = 43.01 > \chi_{0.05, 5}^2 = 11.07$, rejecting H_0 suggests that the speed data for all vehicles does not follow a normal distribution.

The results of the hypothesis test using a chi-square distribution indicate that the distribution is not normal, meaning that the mean speed data (survey results) from four types of vehicles do not exhibit a normal distribution. As mentioned above, transforming traffic flow survey data (vehicle speed data) into a normal distribution provides a strong basis for more in-depth statistical analysis, simplifies data interpretation, and enhances the validity of the analysis results to support decision-making.

Normalization of the mean speed data for four types of vehicles was conducted individually for each vehicle due to varying extreme data (outliers) they possess. Below is the normalization applied to the mean speed data of the truck/trailer.

Normalizing the speed of trucks/trailers.

Here is the normalization mechanism for the mean speed data of trucks/trailers.

- Transform the data using the natural logarithm function.
- Remove the outlier data. After removal, the dataset consists of 170 entries, down from the original 190.
- The mean is 3.53 and the standard deviation is 0.20.
- Applying the hypothesis-testing procedure:
 H_0 : The distribution follows a normal form.
 H_1 : The distribution does not follow a normal form
- The statistical test value is

$$X_0^2 = \sum_{i=1}^c \frac{(O_i - E_i)^2}{E_i} = \frac{(27 - 21.25)^2}{21.25} + \frac{(17 - 21.25)^2}{21.25} + \dots + \frac{(21 - 21.25)^2}{21.25} = 8.26$$

Each interval has a probability $p_i = 1/8 = 0.125$, thus the expected cell frequencies $E_i = np_i = 170(0.125) = 21.25$ for each interval.

Table II shows observed and expected frequencies for each cell, as well as the results of the chi-square distribution calculation.

- The chi-square table with $\alpha = 0.05$ and degrees of freedom = $c - p - 1 = 8 - 2 - 1 = 5$ (p represents the number of parameters in the hypothesized distribution, which in this instance are the parameters of the normal distribution specifically, the mean μ and the variance σ^2 . Thus, there are two parameters, so $p = 2$).

$$\chi_{\alpha, c-p-1}^2 = \chi_{0.05, 5}^2 = 11.07$$

- Conclusion: Since $X_0^2 = 8.26 < \chi_{0.05, 5}^2 = 11.07$, accepting H_0 indicates that the speed data for the truck/trailer follows a normal distribution.

TABLE II. NORMALIZATION OF MEAN SPEED SURVEY DATA FOR TRUCK / TRAILER

Class Interval (Natural logarithmic numbers)	Observed Frequency O_i	Expected Frequency E_i	$O_i - E_i$	$(O_i - E_i)^2$	$(O_i - E_i)^2/E_i$
$x < 3,300$	27	21,25	5,75	33,06	1,56
$3,300 \leq x < 3,395$	17	21,25	-4,25	18,06	0,85
$3,395 \leq x < 3,466$	13	21,25	-8,25	68,06	3,20
$3,466 \leq x < 3,530$	18	21,25	-3,25	10,56	0,50
$3,530 \leq x < 3,594$	22	21,25	0,75	0,56	0,03
$3,594 \leq x < 3,665$	26	21,25	4,75	22,56	1,06
$3,665 \leq x < 3,760$	26	21,25	4,75	22,56	1,06
$3,760 \leq x$	21	21,25	-0,25	0,06	0,00
Total	170	170			8,26

Fig. 3. Mean speed normalized results for truck/trailer vehicles.

Fig. 3 illustrates the normalized mean speed results for trucks/trailers, based on 170 data points (after removing outliers). The normalized mean speed data yielded a minimum of 3.086 and a maximum of 3.839, with respective actual mean speeds of 22 and 47.

Using the same method, normalization was also performed on the mean speed data for buses, public transportation, and private cars. Table III summarizes the normalization process for these three vehicle types. The normalized data counts for buses, public transportation, and private cars are 160, 170, and

160 respectively. The degrees of freedom used for all three types of vehicles are the same, which is 5. However, the significance levels (alpha) differ: 0.05 for buses, 0.005 for public transportation, and 0.010 for private cars. All chi-square distribution calculations for the mean speed data of these three vehicle types yielded values smaller than the chi-square values in the table. This condition indicates that the distribution of mean speed data for buses, public transportation, and private cars can be assumed to be normal.

TABLE III. SUMMARY OF MEAN SPEED SURVEY DATA NORMALIZATION FOR BUS, PUBLIC TRANSPORTATION, AND PRIVATE CAR VEHICLES

Vehicle	Steps	Data Specifications	Decision
Bus	<ul style="list-style-type: none"> Change the mean speed data to the function of natural logarithmic Delete the extreme data (outlier's data) Applying the hypothesis-testing procedure (H_0 = normal distribution, H_1 = not normal distribution) 	Normalized amount of data = 160; Degree of freedom = 5; alpha = 0.05; Mean = 3,66; Std = 0,14; Chi-square Dist. = 8,93; Chi-square Table = 11,07; Chi-square Dist. (=8,93) < Chi-square Table (=11,07)	H_0 accepted; Normal Distribution
Public Transportation		Normalized amount of data = 170; Degree of freedom = 5; alpha = 0.005; Mean = 3,62; Std = 0,20; Chi-square Dist. = 15,98; Chi-square Table = 16,75; Chi-square Dist. (=15,98) < Chi-square Table (=16,75)	H_0 accepted; Normal Distribution
Private Car		Normalized amount of data = 160; Degree of freedom = 5; alpha = 0.010; Mean = 3,70; Std = 0,21; Chi-square Dist. = 13,70; Chi-square Table = 15,09; Chi-square Dist. (=13,70) < Chi-square Table (=15,09)	H_0 accepted; Normal Distribution

B. Driver Characteristics Based on Vehicle Speed Phenomena

The phenomenon of micro-traffic flow on Porong Sidoarjo Highway has been investigated. Based on speed surveys conducted on four types of vehicles (trucks/trailers, buses, public transportation, and private cars), mean speed data requiring normalization due to non-normal data distribution was obtained. The normalized mean speed data (in natural logarithm and real numbers) with min-max speed values are shown in Table IV. The vehicle speed phenomenon from the survey results and the normalization process of speed data are used as a basis to establish the characteristics of drivers passing through Porong Sidoarjo Highway. The normalized vehicle speed data obtained from the survey depict the characteristics of drivers crossing Porong Sidoarjo Highway more accurately. This condition considers how they regulate their speed according to their skill levels and safety preferences. Under these circumstances, driver characteristics are categorized into three groups: (i) Careful driver (for truck or trailer drivers); (ii) Ordinary driver (for bus and public transportation drivers); and (iii) Skilled driver (for private vehicle drivers).

TABLE IV. THE PHENOMENON OF VEHICLE SPEED TO DETERMINE DRIVER CHARACTERISTICS

Vehicle	Mean speed (natural logarithmic number)	Mean speed (real number)	(min - max) normalized speed	Driver characteristics
Truck/Trailer	3,53	34	22 - 47	Careful driver
Bus	3,66	39	27 - 52	Ordinary driver
Public Transportation	3,62	37	21 - 52	Ordinary driver
Private Car	3,7	41	26 - 57	Skilled driver

Characteristics of careful drivers regarding the speed phenomenon that occurs on Porong Sidoarjo Highway, East Java, Indonesia: (i) They are cautious, prioritizing safety over speed; (ii) They drive at a moderate speed, maintain distance from the vehicle ahead, and are ready to react quickly to changes in traffic; (iii) They drive at a speed lower than average to ensure safety and comfort. As for ordinary drivers, their characteristics are: (i) They typically follow basic traffic rules and drive at a comfortable speed that is appropriate for traffic conditions; (ii) They carefully follow the flow of traffic, adjusting their speed to the surrounding traffic conditions; (iii) They exhibit speeds close to the average. The characteristics of skilled drivers are: (i) They have a higher level of expertise in handling various driving situations; (ii) They can make quick decisions and maneuver vehicles effectively without compromising safety; (iii) They are capable of driving at speeds higher than average, yet within safe limits and well-controlled.

IV. THE PROPOSED MODEL OF MICRO TRAFFIC FLOW PHENOMENA

In the previous section, the characteristics of drivers were categorized based on the speed phenomena observed on Porong Highway in Sidoarjo, East Java, Indonesia. Using the results of a vehicle speed survey conducted on this highway, these characteristics were classified into three types: careful driver, ordinary driver, and skilled driver. This section involves mathematical modeling of the vehicle speeds for each driver type based on the phenomena observed on Porong Highway in Sidoarjo. Subsequently, these speed models are integrated into the NaSch STCA rules. Lane-changing behavior is also incorporated into the STCA model, considering two lanes as per the real conditions on Porong Highway in Sidoarjo.

A. Driver Characteristics Modeling

The three predefined driver characters exhibit fundamental differences in their speeds. Careful drivers maintain lower driving speeds below the average to prioritize safety and comfort. Ordinary drivers typically drive at speeds close to the average. Skilled drivers are capable of driving at speeds higher than the average, yet within safe limits and well-controlled. Here are the statements regarding the speed modeling for each driver character:

- careful driver: $1 \leq v_{cd} \leq \bar{v}_r$
- ordinary driver: $v_{od} = \bar{v}_r \pm 1$
- skilled driver: $\bar{v}_r \leq v_{sd} \leq v_{max}$

where, v_{cd} , v_{od} , and v_{sd} are the respective speeds of careful drivers, ordinary drivers, and skilled drivers in sequence, while \bar{v}_r represents the average speed for all vehicle types passing through Porong Highway in Sidoarjo.

Based on the speed data from the survey conducted on Porong Highway in Sidoarjo over 190 consecutive hours (eight days), the average speed for all vehicle types (referring to Table IV) \bar{v}_r is 38 km/h. Converting this to computational terms, where 1 cell equals 7.5 meters and 1 second corresponds to 1 time-step, the average vehicle speed passing through Porong Highway in Sidoarjo \bar{v}_r becomes 1.4 cells/time-step. In computational calculations, this is rounded up to 2 cells/time-step.

B. Lane Changing

The Porong Sidoarjo Highway features two lanes in each direction. An illustration of two lanes in one direction is shown in Fig. 4. A vehicle is represented by a small box. If a vehicle intends to change lanes, it must satisfy the condition that on the new lane, there is a distance of b units between itself and the vehicle behind, and a distance of a units between itself and the vehicle in front. By meeting these conditions, collisions between vehicles can be avoided.

Fig. 4. Illustration of a two-lane highway with lane-changing dynamics.

Many studies have focused on lane-changing behavior in multi-lane and dual-lane scenarios. One such study examines lane-changing on a two-lane highway, as investigated by [27]. Based on the illustration in Fig. 4, the lane-changing used in this research must satisfy the following conditions:

$$gs_{i=1,j}(t-1) < \min\{v_{i=1,j}(t-1), v_{max}\}$$

$$gs_{i=2,j-b}(t-1) > v_{max} \text{ and}$$

$gs_{i=2,j+a}(t-1) > gs_{i=1,j}(t-1)$ with probability of lane changing P_{lc} .

C. Modified NaSch STCA

The vehicle movement model in the micro-traffic flow simulation conducted on Porong Sidoarjo Highway refers to the phenomenon of vehicle speeds observed on that highway. Based on the survey results of vehicle speed measurements, drivers' characteristics are categorized into three types: careful drivers, ordinary drivers, and skilled drivers. The fundamental difference among them lies in the typical driving speeds they maintain while traversing Porong Sidoarjo Highway.

In this study, the proposed vehicle movement is a modification of the NaSch STCA vehicle movement, where vehicle speeds are differentiated into three types according to predefined driver characteristics. The modified NaSch STCA follows these rules:

$$1) \text{ Acceleration: } v_{i,j}(t) \leftarrow v_{i,j}(t-1) + 1$$

$$\text{If } v_{i,j}(t-1) < v_{max} \text{ and } gs_{i,j}(t-1) > v_{i,j}(t-1) + 1$$

Where

- for careful drivers applies $1 \leq v_{i,j}(t-1) \leq \bar{v}_r$
- for ordinary drivers applies $\bar{v}_r - 1 \leq v_{i,j}(t-1) \leq \bar{v}_r + 1$
- for skilled drivers applies $\bar{v}_r \leq v_{i,j}(t-1) \leq v_{max}$

$$2) \text{ Braking: if } gs_{i,j}(t-1) \leq v_{i,j}(t-1),$$

$$v_{i,j}(t) \leftarrow gs_{i,j}(t-1) - 1$$

3) Randomization: with slowdown probability P and random number $\xi(t)$, if $\xi(t) < P \Rightarrow v_{i,j}(t) \leftarrow v_{i,j}(t-1) - 1$.

4) Vehicle movement:

$$x_{i,j}(t) \leftarrow x_{i,j}(t-1) + v_{i,j}(t)$$

Together with the lane-changing rules stated in the previous session: $gs_{i=1,j}(t-1) < \min\{v_{i=1,j}(t-1), v_{max}\}$

$$gs_{i=2,j-b}(t-1) > v_{max} \text{ and}$$

$$gs_{i=2,j+a}(t-1) > gs_{i=1,j}(t-1)$$

with probability of lane changing P_{lc} .

V. EXPERIMENTAL RESULTS AND DISCUSSION

In this session, a trial was conducted on vehicle movement using a predetermined model known as the Modified NaSch STCA. As explained in the previous session, drivers are categorized into three types based on speed, which is characteristic of each driver (careful, ordinary, and skilled drivers). The determination of the number of each type of driver is based on probabilities (percentages) relative to the predetermined vehicle density. The probabilities for careful drivers, ordinary drivers, and skilled drivers are denoted as P_{cd} , P_{od} , and P_{sd} respectively.

A. Experimental Results

Fig. 5 illustrates a time-space diagram, one of the outcomes of the trial (simulation) of vehicle movement using the Modified NaSch STCA, replicating the phenomenon of vehicle movement on the Porong-Sidoarjo Highway. The specifications of this vehicle movement simulation are as follows: a two-lane highway with a lattice length of $L = 500$ cells, density $k = 0.3$, slowdown probability $P = 0.1$, probability of lane changing $P_{lc} = 0.4$, probability of careful drivers $P_{cd} = 0.1$, probability of ordinary drivers $P_{od} = 0.3$, and probability of skilled drivers $P_{sd} = 0.6$. The vehicles move in one direction, from left to right, replicating the movement from

the city of Sidoarjo / Surabaya towards Banyuwangi / Malang, and this movement system operates as an open-loop system.

Based on Fig. 5, it can be seen that with a vehicle density of $k = 50\%$ (0.5), where the probability of trucks/trailers (careful drivers) being present is 10% (0.1), the probability of buses and public transportation (ordinary drivers) is 30% (0.3), and the probability of private cars (skilled drivers) is 60% (0.6), all vehicles cover a distance of 500 cells = (500 x 7.5 meters) = 3750 meters. This results in a total travel time of $t = 3161$ time-steps ≈ 3161 seconds ≈ 52.68 minutes. This condition indicates that with the average speed per type of vehicle passing through the Porong Sidoarjo highway as shown in Table IV, where the minimum speed value of all types of vehicles = 22 km/h and the maximum = 57 km/h, the average speed for all types of vehicles = 38 km/h. This phenomenon highlights that with a vehicle density of $k = 50\%$ and an average speed $\bar{v}_r = 38$ km/h, the travel time for all vehicles over a distance of 3750 meters is 3161 seconds (52.68 minutes).

Fig. 5. Time-space diagram of Modified NaSch STCA (two lanes), where the vertical axis represents time-steps and the horizontal axis represents space (cells), road length $L = 500$ cells, density $k = 0.5$, slowdown prob. $P = 0.3$, prob. of lane changing $P_{lc} = 0.4$, prob. of careful drivers $P_{cd} = 0.1$, prob. of ordinary drivers $P_{od} = 0.3$, and prob. of skilled drivers $P_{sd} = 0.6$. Top image for lane 1 and bottom image for lane 2.

The comparison of the time-space diagram between NaSch STCA and Modified NaSch STCA is illustrated by one of the test results (simulations) as shown in Fig. 6. The test specifications employed are as follows: the road length 500 cells, with a vehicle density of $k = 0.3$, there is a 30% probability of slowdown ($P = 0.3$) and a 0% probability of lane changing ($P_{lc} = 0.0$). In the Modified NaSch STCA model, the probabilities $P_{cd} = 0.1$ for careful drivers, $P_{od} = 0.3$ for ordinary

drivers, and $P_{sd} = 0.6$ for skilled drivers. It can be seen that with the same specifications, over a distance of 500 cells (3750 meters), the travel time for all vehicles in the NaSch STCA model is 409 time-steps (409 seconds), while the modified model takes 1934 time-steps (1934 seconds). This indicates that the travel time in the NaSch STCA model is significantly faster than in the modified model. This phenomenon occurs because the average speed of vehicles traveling on the Porong Highway tends to be lower than usual.

Fig. 6. A comparison of time-space diagrams for two lanes between the NaSch STCA model and the Modified NaSch STCA. In this visualization, the vertical axis corresponds to time-steps, while the horizontal axis represents space measured in cells. The road length is $L = 500$ cells, with a density of $k = 0.3$. The probability of slowdown is $P = 0.3$, and the probability of lane changing is $P_{lc} = 0.0$. For the Modified NaSch STCA model, the probabilities are as follows: $P_{cd} = 0.1$ for careful drivers, $P_{od} = 0.3$ for ordinary drivers, and $P_{sd} = 0.6$ for skilled drivers. The top image shows the time-space diagram for the NaSch STCA model, while the bottom image depicts the Modified NaSch STCA model.

A comparison of travel time versus vehicle density was conducted between the NaSch STCA model and the Modified NaSch STCA model. The simulation specifications include a road length of 500 cells, a slowdown probability $P = 0.3$, and a lane-changing probability $P_{lc} = 0.3$. For the Modified NaSch STCA model, the probabilities for careful drivers, ordinary drivers, and skilled drivers are $P_{cd} = 0.1$, $P_{od} = 0.2$, and $P_{sd} = 0.7$, respectively. Travel time for vehicles was calculated for each density value incrementing by 0.1, ranging from 0.1 to 0.9. Detailed travel time results for each density value k increasing by 0.1 are shown in Table V. It can be observed that, for both models, travel time increases with higher vehicle density. At the same density value, the NaSch STCA model exhibits significantly faster travel times compared to the Modified NaSch STCA model. This condition is consistent across all density values. For instance, in this simulation, the NaSch STCA model yields a travel time of 138 time-steps for a density of $k = 0.1$, increasing to 1196 time-steps for a density of $k = 0.9$. Meanwhile, for the Modified NaSch STCA model, the travel time is 1364 time-steps at a density of $k = 0.1$, increasing further with each increment in vehicle density, reaching 5641 time-steps at $k = 0.9$. It can be stated that the travel time for the NaSch STCA model is significantly faster than for the Modified NaSch STCA model. This condition is

attributed to the unique vehicle speed characteristics on the Porong Sidoarjo highway, where the average speed for all vehicle types $\bar{v}_r = 38$ km/h is lower than the general average speed.

It is also noted the difference in travel time between the Modified NaSch STCA model and the NaSch STCA model. Table V shows that the difference for a density of $k = 0.1$ is 1226 time-steps. The travel time difference increases as vehicle density rises. For a density of $k = 0.9$, the travel time difference is 4445 time-steps. The simulation results are also generally illustrated in the line graph shown in Fig. 7.

TABLE V. VEHICLE TRAVEL TIME AND THE DIFFERENCES BETWEEN THE NSCH STCA MODEL AND THE MODIFIED NSCH STCA MODEL

Density k	The travel time (time-steps)		Difference (time-steps)
	NSch STCA	Modified NSch STCA	
0,1	138	1364	1226
0,2	252	1698	1446
0,3	394	1999	1605
0,4	509	2284	1775
0,5	672	3208	2536
0,6	802	3510	2708
0,7	939	4360	3421
0,8	1041	5094	4053
0,9	1196	5641	4445

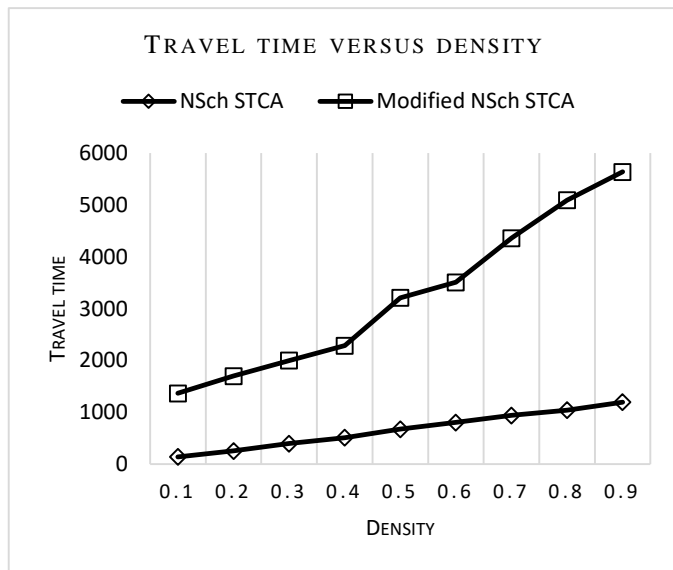

Fig. 7. Comparison of travel time with vehicle density between the NaSch STCA model and the Modified NaSch STCA model. The road length is $L = 500$ cells, the probability of slowdown is $P = 0.3$, and the probability of lane changing is $P_{lc} = 0.3$. Specifically for the Modified NaSch STCA model, the probabilities of the presence of careful drivers, ordinary drivers, and skilled drivers are $P_{cd} = 0.1$, $P_{od} = 0.2$, and $P_{sd} = 0.7$, respectively.

This study also examined vehicle travel time relative to the set travel distance, ranging from 100 cells to 500 cells. A comparison was made between the travel times of the NaSch STCA model and the Modified NaSch STCA model. Fig. 8

shows that the Modified NaSch STCA model exhibits significantly greater travel times for each specified distance compared to the NaSch STCA model.

The mean speed values produced by the modified NaSch STCA model were analyzed in relation to vehicle density. Simulation results with specifications of road length $L = 500$ cells; slowdown probabilities $P = 0.1, 0.50$, and 0.9 in sequence; and lane-changing probability $P_{lc} = 0.3$ are shown in Fig. 9. It is observed that higher vehicle densities lead to a decrease in mean speed. This condition aligns with the (k, \bar{v}_r) diagram model described.

Fig. 8. Comparison of travel time with distance traveled between the NaSch STCA model and the Modified NaSch STCA model. The road length is $L = 500$ cells, density $k = 0.3$, the probability of slowdown is $P = 0.3$, and the probability of lane changing is $P_{lc} = 0.3$. Specifically for the Modified NaSch STCA model, the probabilities of the presence of careful drivers, ordinary drivers, and skilled drivers are $P_{cd} = 0.1$, $P_{od} = 0.2$, and $P_{sd} = 0.7$, respectively.

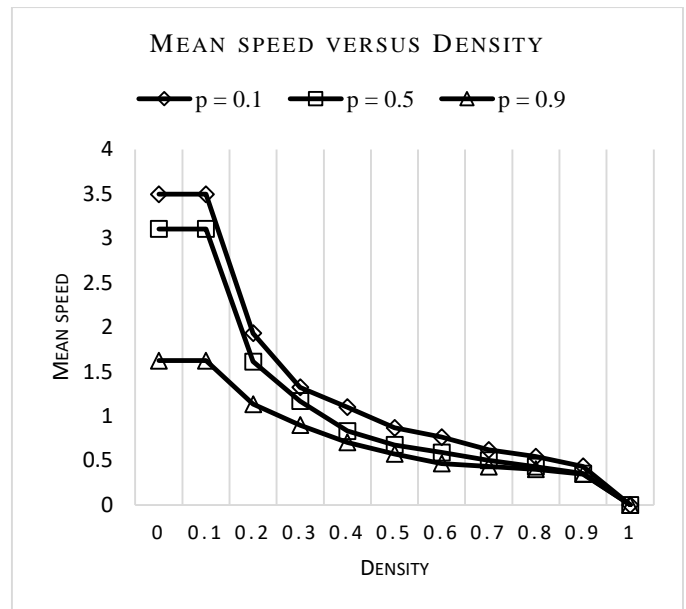

Fig. 9. Several (k, \bar{v}_r) diagrams from the modified NaSch STCA model (mean speed versus density) with the specifications: road length $L = 500$ cells; slowdown probability $P = 0.1, 0.5$, and 0.9 in sequence; lane-changing probability $P_{lc} = 0.3$.

Delayed acceleration and slowdown probability have been incorporated into the modified NaSch STCA model. Regarding delayed acceleration, this study references, which is described by Takayasu–Takayasu TCA (T^2 -TCA) in R2 as follows:

(R2) delayed acceleration:

$$v_i(t) = 0 \wedge g_{si}(t) \geq 2 \Rightarrow v_i(t + 1) \leftarrow 1$$

The presence of delayed acceleration and slowdown probability complements each other, as both impact the overall performance of the traffic system and contribute to increased travel time or congestion. When many vehicles experience delayed acceleration and there is also a high probability of slowdown, traffic can become more unstable and inefficient. This study demonstrates the effect of slowdown probability on travel time, with delayed acceleration incorporated into the Modified NaSch STCA model. It can be stated that the effect of slowdown probability on travel time is also influenced by the presence of delayed acceleration within the system. Simulation results for travel time in relation to slowdown probability are shown in Fig. 10. Observations were made for low, medium, and high densities, specifically $k = 0.3, 0.5,$ and $0.9,$ with a lane-changing probability $P_{lc} = 0.3.$

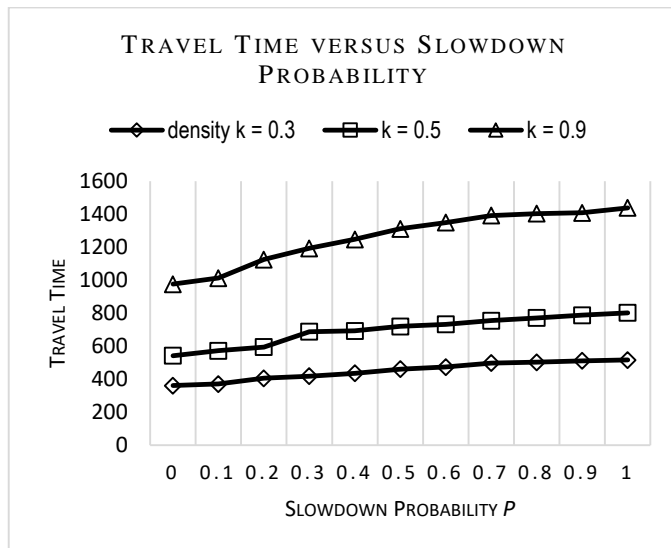

Fig. 10. Travel time observed as a function of slowdown probability P for densities $k = 0.3, 0.5,$ and 0.9 sequentially; with a lane-changing probability $P_{lc} = 0.3.$

B. Discussion

The workflow of this study is as follows: (i) Conduct a survey of traffic phenomena on the Porong Highway in East Java, Indonesia. The survey data includes vehicle types, vehicle speeds, traffic density, and questionnaire responses about the conditions experienced by road users on Porong Highway. (ii) Process the survey data and analyze the observed phenomena. (iii) Examine the patterns emerging from the data analysis. (iv) Identify research topics that can be pursued based on the available data.

Based on the phenomena observed from the survey data, a unique finding is the variation in vehicle speeds, where different vehicle types exhibit different average speeds. Consequently, a microscopic traffic flow model was developed

based on the speed characteristics of each vehicle type. Since vehicles are driven by individuals who influence their speed by accelerating or decelerating, the vehicle characteristics are inherently linked to the driver.

The discrete dynamic system model used is Cellular Automata, specifically the NaSch STCA model, which is a stochastic method utilizing random number generation. The random number generator employed in this model is the Monte Carlo method, integrated into the NaSch STCA with three components utilizing Monte Carlo simulation: the Occupied Initial State, Slowdown Probability, and Probability of Lane Changing. The innovation in this microscopic traffic flow modeling is the categorization of driver characteristics based on vehicle speeds observed on the Porong-Sidoarjo Highway, categorized into: careful driver, ordinary driver, and skilled driver, each with specific vehicle speed profiles.

The anticipated outcome is the alignment of the developed microscopic traffic flow model with the indications of vehicle travel times in relation to parameters such as density, travel distance, and slowdown probability. Traffic flow simulations on the Porong Highway have been conducted, producing vehicle travel times that replicate the actual traffic conditions on that road. The simulation specifications were adapted to match the conditions of the Porong Highway: the traffic flow under examination is from the Sidoarjo/Surabaya area towards Malang/Banyuwangi (one-way). This highway features two lanes ($i = 1-2$) and a typical straight road length of 3750 meters. Therefore, with each cell representing 7.5 meters, the lattice length of the road is 500 cells ($j = 1-500$).

For example, when using a slowdown probability $P = 0.3$ and a lane-changing probability $P_{lc} = 0.3,$ the Modified NaSch STCA model assigns probabilities of $P_{cd} = 0.1, P_{od} = 0.2,$ and $P_{sd} = 0.7$ for careful, ordinary, and skilled drivers, respectively. Vehicle travel times were computed for each density value incrementing by 0.1, from 0.1 to 0.9. Detailed results of travel times for each density increment are presented in Table V. For instance, the NaSch STCA model has a travel time of 138 time-steps at a density of $k = 0.1,$ which increases to 1196 time-steps at $k = 0.9.$ In contrast, the Modified NaSch STCA model shows a travel time of 1364 time-steps at $k = 0.1,$ which grows to 5641 time-steps at $k = 0.9.$ This indicates that the NaSch STCA model has significantly faster travel times compared to the Modified NaSch STCA model. This disparity is due to the unique vehicle speed characteristics on the Porong-Sidoarjo highway, where the average speed $\bar{v}_r = 38$ km/h is lower than the general average speed.

VI. CONCLUSION

The phenomenon of micro traffic flow on the Porong Highway in East Java, Indonesia, exhibits distinctive characteristics. A survey of vehicles with four or more wheels was conducted over eight days (190 hours) on this highway. The survey identified four types of vehicles: trucks/trailers, buses, public transportation, and private cars. The survey data revealed that these vehicles have average speeds of 34 km/h, 39 km/h, 37 km/h, and 41 km/h, respectively. Based on these speed characteristics, drivers of each vehicle type were categorized as careful drivers for trucks/trailers, ordinary

drivers for buses and public transportation, and skilled drivers for private cars.

Vehicle movement modeling was performed using the NaSch STCA (NaSch STCA) model, specifically the Modified NaSch STCA (Modified NaSch STCA), tailored to simulate conditions on the surveyed Porong Sidoarjo highway. The road length was 3750 meters ($L = 500$ cells), straight with two lanes in each direction. Simulation results with specific parameters (road length of 500 cells, density $k = 0.3$, slowdown probability $P = 0.3$, and probability of lane changing $P_{lc} = 0.0$) compared data between the NaSch STCA and Modified NaSch STCA models. The Modified NaSch STCA model included specific driver presence probabilities: 0.1 for careful drivers, 0.3 for ordinary drivers, and 0.6 for skilled drivers.

One of the comparisons between these models is their travel time, where the NaSch STCA model significantly outperformed the Modified NaSch STCA model. This outcome reflects the characteristic vehicle speeds on the Porong Sidoarjo highway, with an average speed for all vehicle types $\bar{v}_r = 38$ km/h.

For future research, it is essential to develop micro traffic flow modeling based on driver characteristics on a particular roadway, in collaboration with local government authorities. A more effective approach would be to combine Cellular Automata with artificial intelligence, enhancing the modeling of dynamic micro traffic systems and driver characteristic classification.

ACKNOWLEDGMENT

Special thanks to the Knowledge Engineering research team at the Politeknik Elektronika Negeri Surabaya (PENS), East Java, Indonesia, for their support and motivation throughout the completion of this research. Particularly, heartfelt gratitude goes to Professor Kohei Arai from Saga University, Japan, for his comprehensive guidance and in-depth discussions on the cellular automata methods employed in the modeling and simulation aspects of this research.

AUTHORS' PROFILE

Tri Harsono, He earned his Bachelor's degree in Mathematics from Sepuluh Nopember Institute of Technology, Surabaya in 1993, followed by a Master's degree in Information Technology from the same institution in 2005. He pursued his doctoral studies at Saga University, Japan, in the Department of Information Science, Faculty of Science and Engineering, from 2008 to 2011, and completed his PhD in September 2011. Since October 1993, he has been a lecturer in the Computer Engineering program at the Electronics Engineering Polytechnic Institute of Surabaya (EEPIS) or Politeknik Elektronika Negeri Surabaya (PENS). His research primarily focuses on modeling and simulation, particularly in micro traffic flow, evacuation systems, and prediction systems, with a specific interest in the behavior of objects within these systems. He is also focused on data analysis, particularly in recognizing patterns and

classifying data using cellular automata techniques and learning algorithms. His most recent research involves classifying medical imaging data with cellular learning automata.

Kohei Arai, He received BS, MS and PhD degrees in 1972, 1974 and 1982, respectively. He was with The Institute for Industrial Science and Technology of the University of Tokyo from April 1974 to December 1978 also was with National Space Development Agency of Japan (Current JAXA) from January, 1979 to March, 1990. During from 1985 to 1987, he was with Canada Centre for Remote Sensing as a Post Doctoral Fellow of National Science and Engineering Research Council of Canada. He moved to Saga University as a Professor in Department of Information Science on April 1990. He was a councilor for the Aeronautics and Space related to the Technology Committee of the Ministry of Science and Technology during from 1998 to 2000. He was a councilor of Saga University for 2002 and 2003. He also was an executive councilor for the Remote Sensing Society of Japan for 2003 to 2005. He is a Science Council of Japan Special Member since 2012. He is an Adjunct Professor of Brawijaya University, Kurume Institute of Technology and Nishi-Kyushu University. He also was Vice Chairman of the Science Commission "A" of ICSU/COSPAR for 2008-2016 then he is now award committee member of ICSU/COSPAR. He wrote 87 books and published 710 journal papers as well as 650 conference papers. He received 66 of awards including ICSU/COSPAR Vikram Sarabhai Medal in 2016, and Science award of Ministry of Education of Japan in 2015. He is now Editor-in-Chief of IJACSA and IJISA. <http://teagis.ip.is.saga-u.ac.jp/index.html>

Convolutional Neural Network Model for Cacao Phytophthora Palmivora Disease Recognition

Abstract—Cacao, scientifically known as *Theobroma cacao*, is a highly nutritious food and is extensively utilized in multiple sectors, including agriculture and health. Nevertheless, the agricultural sector encounters notable obstacles as a result of Cacao disease such as pod rot, predominantly attributed to the *Phytophthora* genus. The objective of this work is to conduct a comparative analysis to determine the most effective machine-learning technique for the detection of *P. palmivora* infection in Cacao pods. Few studies have delved into this topic previously, but this study focuses in utilizing a little larger dataset, achieving better model, and attaining higher accuracy. A total of 2000 images of cacao pods, both healthy and disease-infected were collected. Subsequently, the images were subjected to manual classification by a domain expert based on the discernible presence or absence of the disease. The study examined six machine learning algorithms, specifically Naïve Bayes, Random Forest, Hoeffding Tree, Multilayer Neural Network, and Convolutional Neural Network (CNN). The CNN model had 99% level of accuracy, the highest among the five machine learning algorithms in the testing phase. The methodology has the potential to significantly advance sustainable agricultural practices and disease management. To enhance the model's recognition capabilities, additional datasets encompassing a broader range of Cacao varieties is necessary.

Keywords—Machine-learning; Convolutional Neural Network; detection of *P. palmivora*

I. INTRODUCTION

Cacao (*Theobroma cacao*), also known as “superfood” or “the food of the gods”, has gained full attention by farmers, researchers, and even health enthusiasts [1]. Consumption of this product worldwide is estimated to be over 4.5 million tons annually and is still growing. The innovation of new products that requires cacao as an ingredient has increased the demand for such. Examples of these are not limited to cosmetics, pharmaceuticals, food and beverages, and health food supplement. The Philippines' geolocation and the humid temperature make it conducive for cacao production to flourish and possibly attenuate poverty; thus, local farmers' interest scaled up, and exporters push for a more productive cacao industry that can participate in the worldwide supply competition [2].

However, the yield of cacao production is affected by several diseases, with pod rots as the most common adverse conditions of the tree. *Phytophthora*, a genus of straminipilous organisms (formerly classified as oomycetes), is responsible for the devastating black pod rot, the most widespread disease affecting

cacao crops. Depending on environmental conditions, this disease can lead to annual losses of up to 90% in pod production. The entire plant can become infected, causing severe damage [3].

Traditionally, diagnosing infections relies on human experts. However, aside from the high cost and time-consuming nature, this approach can be impractical due to the scarcity of experts and potential geographic barriers, especially if the farm is remote. In such cases, the disease might affect a large number of pods. To address these challenges, researchers are turning to machine learning techniques for plant disease recognition as a viable solution.

Although few studies have previously explored this topic, this research aims to use a larger dataset to develop a better model and achieve higher accuracy.

Moreover, this study aimed to apply different machine learning techniques to the dataset for comparative analysis; and evaluate the accuracy of the models in recognizing the incidence of *P. palmivora* disease on Cacao pods. The dataset covers the cultivars Criollo, Forastero, and Trinitario; and the common variety of Cacao found at the Molave hill of the Visayas State University, Leyte, Philippines.

This research could play a crucial role in the early recognition of *P. palmivora* disease, which would allow for the prompt application of treatments. Consequently, this would lead to an improvement in Cacao production. The method proposed in this research represents a potentially significant advancement in eco-friendly and sustainable farming techniques, as well as in disease control within the Cacao industry. By promoting such practices, this research supports the United Nations' Sustainable Development Goals related to agriculture and innovation. Adopting these advanced methods would not only enhance crop yields but also foster more sustainable and environmentally responsible agricultural practices.

II. REVIEW OF LITERATURE

A number of studies have already been conducted to recognize pests and diseases in plants and fruit trees using computer vision for the past years. These endeavors have greatly helped the agricultural sector in achieving better harvest to feed the world.

A. Non-Cacao Plants / Trees

The study by [4] proposed a system for identifying leaf diseases using Complete Local Binary Pattern and K-means

clustering methods. The system's true positive and false positive rates were also measured. The authors suggest that their system will enable farmers to detect significant diseases and pest infestations in crops, thereby allowing them to take necessary preventive measures. On the other hand, [5] employed image processing and fuzzy logic classifier to detect prevalence of *P. palmivora* disease on jackfruit. The model effectively recognized and classified the infection with an accuracy rate of 90%. Also, [6] enhanced the application of convolutional neural network on detection of tomato fruit common physiological diseases by data augmentation technique, by adding grayscale processor and foreground extractor components, and by utilizing k-means clustering algorithm. The mean Average Precision of the model was 97.24%. Similarly, [7] created a strawberry grading system based on 3 attributes namely: color, size, and shape. The developed technology used K-means clustering method, multi-attribute Decision Making Theory, and a single-chip-microcomputer (SCM). The size processing error is below 6%, its color marking precision is 88.8%, the shape categorizing accuracy is 90%, and the strawberry fruit grading takes 3s. Relatively, [8] implemented a hybrid system using Artificial Neural Network (ANN), Fourier descriptors (FD) and spatial domain analysis (SDA) for identifying fruits and sorting. The 3 different angles of camera inclination were used in the testing and evaluation. The experimental results showed a 99.10% accuracy rate. Also, [9] developed a system to detect and classify Pomegranate fruit diseases employing k-means clustering segmentation, GLCM method, and Artificial Neural Network. Based on the evaluation, the system yielded an accuracy rate of 90%. The author in [10] implemented a system that identifies the deformity in orange fruits utilizing multi-class SVM with K-means clustering for disease classification and Fuzzy logic to calculate the level of infection severity. The system assessment outcome revealed 90% accuracy. Another study by [11] integrated advanced defect segmentation techniques and texture, combined color, and shape-based features with the Histogram of Oriented Gradients (HOG) feature descriptor and a Bagged Decision Trees classifier. This approach successfully distinguished between healthy and defective apples, achieving an accuracy rate of 96%. Also, [12] employed an enhanced fuzzy C-means (FCM) algorithm and the marked-watershed algorithm to improve the extraction of cucumber leaf spot disease from images, even under complex backgrounds. The study evaluated 129 cucumber disease images from a vegetable disease database, revealing an average segmentation error of just 0.12%. This method offers a reliable and robust segmentation approach for the classification and grading of cucumber diseases in agriculture, with potential applicability to other imaging-based agricultural assessments.

B. Cacao Tree

The author in [13] utilized the K-means algorithm in conjunction with a Support Vector Machine (SVM), leveraging color information in the $L^*a^*b^*$ color space as features to recognize and segment the affected areas. The study outcome revealed an 89.2% accuracy rate. The method can be employed in enhancing the performance of the SVM classifier particularly in differentiating clearly the healthy reddish color of the cacao pod from a disease of the same color. On the following year, Tan et al. developed a mobile app called Automated Tool for Disease Detection and Assessment for Cacao (AuToDiDAC) that

automates the detection, separation, and examination of the level of Black Pod Rot (BPR) infection in the fruit. K-means clustering algorithm and Support Vector Machine (SVM) were still utilized. Fifty (50) pod images were used in training the system while 10 were used in testing. The app showed only an accuracy mean of 85%. The author in [14] implemented another mobile app to identify cocoa diseases on cocoa plant utilizing digital image processing methods. The canker infection on cocoa pods was emphasized as a sample disease. Ten (10) images were utilized in training while 20 for testing the automated identifier. The experiment revealed a 100% accuracy in identifying the existence of canker disease on the pods. In the testing phase, the user had to feed infected pods only, though the article did not mention the type of infection. Another study detecting the condition of cacao pods by [15] got a 94% accuracy. In relation, [16] built a MobileNet model to identify pod diseases which yielded an 86.04% accuracy. In 2024, [17] developed a deep learning-based computational model to identify cocoa pod diseases with an accuracy of 34%.

This study aimed to achieve a higher accuracy rate in identifying the *P. palmivora* infection occurrence on cacao pod and would explore the following machine learning techniques: Naive Bayes Classification, Decision Stump, Random Forest, Hoeffding Tree, Multilayer Neural Network, and Convolutional Neural Network.

III. METHODOLOGY

The research framework adapted is shown in Fig. 1. Each phase of the framework is an integral part in the success of this endeavor:

1) *Image acquisition*: The dataset was captured using Vivo Y91 with 13 MP rear camera with an image resolution of 3120 x 4160 pixels. Collection of sample images was done between 10:00 in the morning until 3:00 in the afternoon at the cacao farm of the Visayas State University, Philippines. The camera was positioned 9 cm away from the cacao pod for both infected and not infected pods. The presence of *P. palmivora* on the Cacao pods was the focus of this study. These images were then manually classified by the domain expert, Dr. Arsenio D. Ramos of the VSU Horticulture Department.

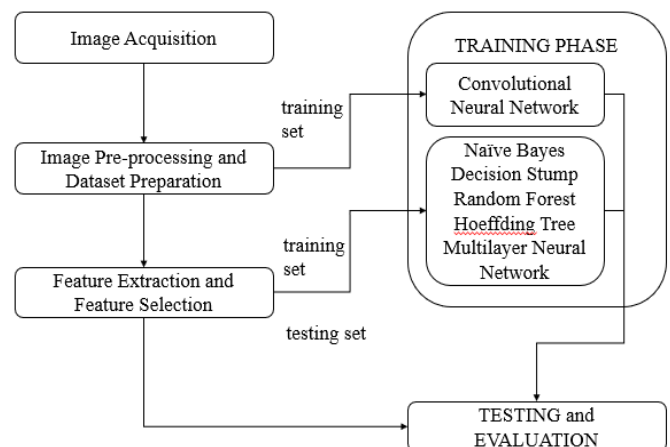

Fig. 1. Conceptual framework of the study.

The classified images were grouped and further divided into three subsets: 80.00% for training and 20.00% testing. The distribution of images among the classes in each subset is shown in Table I.

TABLE I. DATASET FOR THE STUDY

Class	Training	Testing	Total
Healthy	800	200	1000
Unhealthy	800	200	1000
Total (Dataset)	1600	400	2000

Fig. 2. Cropped image.

2) *Image Pre-processing*: The sample images for the training and testing phases were cropped to 150 x 150 pixels dimensions emphasizing the cacao texture. This applies to both healthy and infected datasets. Fig. 2 shows the cropping of an image of an infected pod.

These datasets were intended for use in all six (6) machine learning techniques.

3) *Feature extraction and feature selection*: Features such as color, shape and texture were extracted to characterize images using Haralick algorithm. Feature selection was carried out to determine the most suitable features for training the model and for attaining the best classification.

4) *Model training*: Training procedures were performed using different supervised machine learning algorithms that recognizes patterns and relationships from labeled training dataset. The different algorithms are the following: Naive Bayes Classification, Decision Stump, Random Forest, Hoeffding Tree, Multilayer Neural Network, and Convolutional Neural Network (CNN).

5) *Model testing and evaluation*: The generated models were verified to predict the untrained dataset. The performance of the models was evaluated and compared using the basic metric, the accuracy.

IV. RESULTS AND DISCUSSION

The Convolutional Neural Network (CNN) model exhibited outstanding performance by obtaining a 99% accuracy rate in detecting and classifying data throughout the testing phase, as evidenced in Table II, which presents a comparative comparison of six distinct machine learning algorithms. The CNN model demonstrated superior performance compared to the other tested

techniques, indicating its effectiveness and reliability for the given task.

A. Convolutional Neural Network (CNN) Architecture

Fig. 3 illustrates the overarching architecture of the convolutional neural network employed in this study. The network consists of a sequence of interconnected layers that have been tailored to obtain features from the input image, decrease dimensionality, and to finally categorize the input data. More precisely, the architecture employs a sequential model structure, consisting of three convolutional layers. The initial layer is assigned a total of 32 filters, the succeeding layer has 64 filters, and the third layer has 128 filters.

Following each convolutional operation, a Rectified Linear Unit (ReLU) activation function was applied. Subsequently, max pooling layers with a 2x2 filter size and a stride of 2 are employed to down sample the feature maps, effectively halving their dimensions. The resulting pooled feature maps were then flattened into a singular vector, facilitating their transition into the fully connected (dense) layers for further processing.

The first dense layer is comprised of 128 nodes, with each node being triggered by a Rectified Linear Unit (ReLU) function. In addition, a batch normalization layer is included to normalize inputs for the following layers, while dropout regularization was used to reduce overestimation by inhibiting complex co-adaptations during training.

Conversely, the output layer employs a softmax activation function with 2 units, allowing the model to predict the likelihood of each input belonging to one of the two distinct classes based on the highest probability assignment.

Table III illustrates the model's synthesis, showing the resulting output form and the parameters that were learned automatically throughout the training process. The calculation of parameters inside each layer follows the equation [18]:

$$\text{Number of parameters} = \text{weights} + \text{biases}$$

$$\text{Where: weights} = \text{input maps} \times (\text{filter size}) \times \text{output maps}$$

The initial convolutional layer, with a 3x3 filter, applied to an input image size of 150x150x3 (150 pixels wide, 150 pixels high, and 3 color channels), results in an output shape of 148. In this layer, 3 feature maps are used as input, while 32 feature maps are produced as output. This requires the use of 32 separate filters, each with dimensions of 3x3x3. By including a bias term for every attribute map, the total number of parameters adds up to 896.

TABLE II. MACHINE LEARNING TECHNIQUES COMPARATIVE ANALYSIS

Machine Learning Technique	Training Accuracy	Testing Accuracy
Naïve Bayes	75.31%	73.00%
Decision Stump	74.80%	68.70%
Random Forest	99.00%	89.00%
Hoeffding Tree	78.00%	77.25%
Multilayer Neural Network	86.25%	86.50%
Convolutional Neural Network	98.06%	99.00%

Fig. 3. CNN Architecture.

Consequently, the pooling layer conducts a straightforward substitution of a 2x2 neighborhood with its maximum value, thereby evading the inclusion of learnable parameters within this stratum.

When moving to the fully linked layer, the number of parameters is calculated by multiplying the number of input and output maps, and then adding an extra bias for each output. As a result, the two dense layers contain 73856 and 9470208 parameters, respectively.

Fig. 4 and Fig. 5 depict the visualization of model accuracy and loss per epoch, respectively. The line graphs indicate that the model was effectively learned, with consistent performance observed across both the training and validation datasets.

Fig. 4. The plot illustrating the training accuracy of the CNN model.

TABLE III. SUMMARY OF THE CNN MODEL

Layer (type)	Output shape	Param
conv2d_1 (Conv2D)	(None, 148, 148, 32)	896
activation_1 (Activation)	(None, 148, 148, 32)	0
max_pooling2d_1(Maxpooling2)	(None, 74, 74, 32)	0
conv2d_2 (Conv2D)	(None, 72, 72, 64)	18496
activation_2 (Activation)	(None, 72, 72, 64)	0
max_pooling2d_2(Maxpooling2)	(None, 36, 36, 64)	0
conv2d_3 (Conv2D)	(None, 34, 34, 128)	73856

V. CONCLUSION

This study successfully extracted color, shape, and texture features from digital images of cacao pods using the Haralick algorithm. These features were then partitioned and utilized to build and test classification models using various machine

learning techniques, including Naive Bayes Classification, Decision Stump, Random Forest, Hoeffding Tree, and Multilayer Neural Network. Additionally, the same dataset was employed to develop a Convolutional Neural Network (CNN) model with different feature extraction method. Among the six models developed, the CNN model achieved the highest accuracy at 99%, outperforming the other five machine learning algorithms during testing. This methodology holds significant potential for advancing sustainable agricultural practices and disease management.

VI. FUTURE WORK

Cacao cultivation encompasses a wide range of varieties, each with its unique characteristics and susceptibilities to diseases and pests. Expanding the dataset to encompass more cacao varieties ensures its applicability across more diverse agricultural contexts, catering to the specific needs and challenges faced by farmers cultivating different varieties. Also, training a dataset with artificial lights at any time of the day or in the absence of natural light may be done. The CNN model may be integrated in mobile app so that intended users can try the system while inputs from them may be solicited to improve the modeling.

ACKNOWLEDGMENT

The researchers wish to express their sincere appreciation to several key contributors, whose support was critical to the success of this project. They are especially grateful to Dr. Arsenio D. Ramos and Prof. Nestor I. Gaurana for their invaluable guidance and expertise. They also extend their thanks to the Visayas State University (VSU) for providing essential resources and institutional support. We recognize the Baybay City Agriculture Office for their assistance in local agricultural matters, and the Department of Computer Science and Technology at VSU for its guidance. Each of these individuals and organizations played a vital role in achieving the project's goals.

Abstract—Upper motor neuron syndrome is characterised by spasticity, which represents a neurological disability that can be found in several disorders such as cerebral palsy, amyotrophic lateral sclerosis, stroke, brain injury, and spinal cord injury. Muscle spasticity is always assessed by therapists using conventional methods involving passive movement and assigning spasticity grades to the relevant joints based on the degree of muscle resistance which leads to inconsistency in assessment and could affect the efficiency of the rehabilitation process. To address this problem, the study proposed to develop a muscle spasticity model using Mechanomyography (MMG) signals from the forearm muscles. The muscle spasticity model leveraged based on the Modified Ashworth Scale and focus on flexion and extension movements of the forearm. Thirty subjects who satisfied the requirements and provided consent were recruited to participate in the data collection. The data underwent a pre-processing stage and was subsequently analysed prior to the extraction of features. The dataset consists of forty-eight extracted features from the three-direction x, y, z axes (for both biceps and triceps muscle), corresponding to the longitudinal, lateral, and transverse orientations relative to the muscle fibers. Significant features selection was conducted to analyse if overall significant difference showed in the combined set of these features across the different spasticity levels. The test results determined the selection of twenty-five features from a total of forty-eight which be used to train an optimum classifier algorithm for the purpose of quantifying the level of muscle spasticity. Linear Discriminant Analysis (LDA), Decision Trees (DTs), Support Vector Machine (SVM), and K-Nearest Neighbour (KNN) algorithms have been employed to achieve better accuracy in quantifying the muscle spasticity level. The KNN-based classifier achieved the highest performance, with an accuracy of 91.29% with k=15, surpassing the accuracy of other classifiers. This leads to consistency in spasticity evaluation, hence offering optimum rehabilitation strategies.

Keywords—Spasticity; mechanomyography; Modified Ashworth Scale; machine learning

I. INTRODUCTION

A stroke is a sudden and chronic loss of neurological function caused by infarction or haemorrhage in the brain, spinal

cord, or retina, resulting in impaired motor function and significant restrictions in performing everyday tasks and overall well-being [1]. Most stroke patients experience movement difficulties, with approximately 30% of those affected experiencing spasticity [2]. Moreover, stroke remains the second most prevalent cause of fatality and the primary cause of impairment on a global scale, making it the third leading cause of death and disability worldwide [3], [4], [5]. On a global scale the prevalence of stroke has grown in correlation with the progress of modernisation, modifications in lifestyle, and a growing population of older individuals [6].

Upper motor neuron syndrome has been defined by spasticity, a neurological impairment that occurs in a variety of conditions, including cerebral palsy, amyotrophic lateral sclerosis, stroke, brain injury, and spinal cord injury [7]. Lance introduced the term "spasticity" in 1980 to define the upper motor neuron syndrome, a motor disorder marked by increased muscle tone and exaggerated tendon jerks that rely on movement velocity and result from the hyperexcitability of the stretch reaction [8], [9]. This description exclusively emphasises the impact of spasticity on involuntary movements, disregarding its effect on deliberate behaviours. The Modified Ashworth Scale (MAS) and the Australian Spasticity Assessment Scale (ASAS) are widely recognised as the most reliable methods for evaluating spasticity in clinical settings, with the MAS being a frequently employed tool in stroke rehabilitation [10], [11].

In addition, there are several other clinical tools available for assessing spasticity, such as Spinal Cord Assessment Tool for Spastic Reflexes (SCATS), Fugl-Meyer Assessment (FMA), Penn Spasm Frequency Scale (PSFS), and Modified Tardieu Scale (MTS) [12], [13]. However, these tools are less accurate compared to the MAS and ASAS. Furthermore, the conventional method that has been used to assess spasticity nowadays involves subjective measurement by the therapists [14]. Although, the therapists already been trained well in assessing the spasticity using MAS tool measurement, there might be a possibility of difference in identify the spasticity level. The variability can disturb the effectiveness of the rehabilitation process for the neurological disorder patients.

During the procedural application of the MAS, the therapist executes passive movement and assigns spasticity grades to the relevant joints based on the degree of muscle resistance experienced during passive stretching [15], [16].

The main objective of this study is to validate Mechanomyography (MMG) as a reliable signal by comparing the accuracy of various machine learning algorithms and demonstrate its clinical applicability in objective measurement. This study highlights the effectiveness of combining mechanomyography with machine learning as a superior approach for evaluating muscular spasticity in patients with upper limb neurological disorders.

The main contributions of this study include the introduction of MMG as a new and unbiased instrument for evaluating muscular spasticity, which has the potential to enhance current subjective approaches. The research also evaluates various machine learning algorithms to determine the best models for analysing MMG data, thereby improving the accuracy and consistency of spasticity assessments. Additionally, the study illustrates the practical applicability of MMG in clinical settings, highlighting its potential to standardize evaluations, optimize rehabilitation strategies, and ultimately improve patient outcomes. These contributions have substantial significance for the field of neurorehabilitation as it establishes an accurate and unbiased technique for evaluating spasticity, which can lead to enhanced diagnostic precision, individualized treatment strategies, and potentially improved long-term results for patients with upper limb neurological diseases.

The structure of the article is as follow: Section II describe on characteristics of electromyography and mechanomyography on clinical evaluation. Section III presents a comprehensive summary of the research carried out by researchers in the topic throughout the years. Section IV provide detailed explanations on the selection of subjects, the experimental setup, and the pre-processing and analysis of the data. Section V provides an explanation of the machine learning algorithms. Section VI provided and deliberated upon the experimental findings and the subsequent section explain the conclusion of the study findings.

II. ELECTROMYOGRAPHY AND MECHANOMYOGRAPHY

The utilization of electromyography (EMG) in routine therapeutic procedures represents a contemporary and pioneering approach to neurorehabilitation for individuals recovering from a stroke [17]. EMG has been used to record electrical muscle activity for quite some time, though it's currently limited to therapeutic purposes [18]. Additionally, EMG can be highly susceptible to interference from noise and variations in resistance, rendering it unreliable in diverse settings or during prolonged data collection, such as when an individual starts sweating [19], [20]. At the same time, the use of EMG sensors necessitates time-consuming skin preparation, including disinfection and abrasive paste application, along with electrode placement on multiple leg muscles which requires an expert environment for accurate sensor positioning and signal interpretation [21]. Mechanomyography (MMG) serves as an alternative or mechanical counterpart to EMG by quantifying muscle vibrations, or mechanical activity generated by active muscle, using sensors such as microphones or accelerometers [22], [23]. The invention of piezoelectric, microphone, and

accelerometers demonstrated the adequate detection of mechanical signals from the surface of skeletal muscles at low frequencies, known as MMG signals that tend to be contaminated by electrical noise [24], [25]. MMG provides a method that enables the detection and measurement of vibrations resulting from muscle contractions and stretching [26]. These vibrations propagate through the tissue and can be detected on the surface of the skin.

The characteristics of a reliable MMG transducer typically include high sensitivity within the muscle vibrational frequency range of 2 Hz to 100 Hz, low sensitivity to random noise, ease and standardization of sensor attachment, biocompatibility, suitability for clinical environments, and cost-effectiveness compared to other clinical assessment techniques [27]. Compared to EMG, MMG has not yet gained widespread acceptance, particularly in clinical settings. Despite not yet achieving widespread acceptance, particularly in clinical settings, MMG holds significant potential for various applications. These include controlling prosthetic devices, recognizing gestures in human-machine interfaces (HMIs), and studying the underlying physiological mechanisms of the neuromuscular system in scientific research [28]. Additionally, MMG offers greater convenience than EMG as it being highly responsive to skin conditions and reliable performance in dynamic settings, reducing the necessity for frequent cleaning, drying, and optimal skin condition maintenance throughout usage [29], [30]. MMG responses can be utilized in various medical contexts, including the clinical evaluation of neuromuscular tissue, biofeedback rehabilitation, and neural/myoelectric prosthetic control.

III. RELATED WORKS ON MACHINE LEARNING

Machine learning has become a popular data analytics technology that uses statistical methods to analyze observed data and make predictions or classify new data [31]. Multiple studies have investigated the effectiveness of machine learning in improving the provision of rehabilitation services, showcasing its capacity to enhance patient outcomes and improve clinical procedures.

For instance, Puzi et al. [32] developed An Automatic Muscle Spasticity Assessment System (AMSAS) to evaluate the muscle spasticity, specifically emphasizing the utilization of machine learning methods. The torque and angle signals generated by the arm muscles were examined to classify levels of spasticity according to the Modified Ashworth Scale (MAS). Twenty-five patients with varied degrees of spasticity were analysed, and seven features were retrieved. A Linear Support Vector Machine (SVM) classifier with four specified characteristics got the maximum accuracy of 84% when classifying spasticity levels. The variables of Three-Way Decision (TWD) including the first and second halves of the region, catch position, and post-catch stiffness, were found to have a significant association with MAS levels.

In another study, Puzi et al. [33] presented a new classifier that uses clinical data from the affected upper limb to accurately measure levels of muscle spasticity. The study proposes a methodical quantification strategy that utilizes the Modified Ashworth Scale (MAS) in conjunction with a one-way ANOVA test to assess the extent to which these features accurately

predicted test scores. subsequently, four important features were determined as the most significant for creating efficient classification models and were employed in the training process. The study showcased that the Support Vector Machine (SVM) classifier surpassed the Adaptive Neuro-Fuzzy Inference System (ANFIS) classifier, with an accuracy rate of 88.0%.

Additionally, Liu et al. [34] investigated on muscle spasticity, specifically targeting the wrist flexor and extensor muscles. The methods employed in this study utilise MMG signals to identify periods of muscular activity in real-time gesture recognition, which is essential for diagnosing muscle spasticity. Additionally, it has been utilised to offer significant observations on muscle exhaustion and torque, proving their potential in evaluating muscle spasticity. The study involved assessing eight distinct and atypical gestures, which included clapping, flicking the index finger, snapping the finger, flipping a coin, shooting, extending the wrist, bending the wrist, and creating a fist. The K-nearest neighbours (KNN) algorithm, with a value of K set to 7, achieved the maximum classification accuracy of 94.56% for the eight gestures.

Furthermore, Kim et al. [31] conducted a study aimed at assessing elbow spasticity by the application of machine learning techniques. This was achieved by employing sophisticated machine learning algorithms to meticulously analyse acceleration and rotation characteristics derived from the injured elbow's side. The acceleration and rotation properties of the elbows of affected patients have been examined to determine the degree of spastic movement, similar to the way the modified Ashworth scale (MAS) score was used. Achieving an accuracy of up to 95.4%, a random forest (RF) algorithm was used to classify spasticity. The learning problem was classified as supervised since the signals correlated with MAS scores, as evaluated by therapists. Additional features were extracted and incorporated into the existing feature set, resulting in enhanced classification performance.

These studies collectively illustrate the potential of machine learning in the precise assessment and classification of muscle spasticity, offering significant advancements in the field of rehabilitation.

IV. METHODOLOGY

A. Subjects

30 post-stroke subjects with upper limb spasticity participated in the study. This study has obtained approval by the Research Ethics Committee of the International Islamic University Malaysia (IIUM) under the identification number IREC 2023-025. Specifically, the subjects were diagnosed with spasticity in upper limbs (UL), with an age range of 18 to 80 years recruited from Sultan Ahmad Shah Medical Centre (SASMEC) and National Stroke Association of Malaysia (NASAM). The informed consent has been provided by the subjects prior to participation, and the study adhered to strict data protection procedures, ensuring that all subject information was managed in accordance with applicable data privacy regulations. The subjects recruited for this research were chosen from MAS levels 0, 1, 1+, 2, and 3. The MAS level 4 was omitted due to the absence of any noticeable bending and straightening movements during the evaluation. The pilot

examination was conducted by experienced therapists to evaluate the subjects movement capability and identify potential issues that can be addressed for the upcoming data collection. The demographic characteristics of the research subjects were detailed in Table I. MAS scores ranging from 0 to 3 were determined for the participants' affected muscles. Five groups were formed from the volunteers: MAS-0 (N=5), MAS-1 (N=16), MAS-1+ (N=3), MAS-2 (N=4) and MAS-3(N=2).

TABLE I. DEMOGRAPHIC DATA OF THE PATIENTS (DIVIDED INTO FOUR GROUPS)

Mas Level	Numbers (N)	Genders (M/F)	Affected Hand (Left/Right)	Age (Year)
0	6	3/3	2/4	44.3 ± 18.4
1	15	11/5	7/8	62.7 ± 10.1
1+	3	3/0	2/1	56.0 ± 7.5
2	4	3/1	1/3	50.0 ± 9.5
3	2	2/0	2/0	38.7 ± 19.1

B. QSAT Platform

A new platform called as Quantitative Spasticity Assessment Technology (QSAT) has been developed based on the Mechanomyography (MMG) technique to overcome the inconsistency measurement of spasticity as depicted in Fig. 1. The platform incorporates two primary sensors: an accelerometer Mechanomyography (ACC-MMG), which measures muscle vibrations in the biceps and triceps, and a potentiometer, which assesses the angular position of the upper limb during flexion and extension movements. Through the measurement of patients' biological signals, the extracted features have been examined for their correlation with MAS using machine learning. The utilization of platform measurements mapped to MAS levels enhances the evaluation of spasticity and streamlines the clinical workflows of therapists.

Fig. 1. QSAT System with labels.

C. Data Acquisition and Experimental Setup

In this study, a commercial biological signal acquisition system (Raspberry Pi Pico) was used to record ACC-MMG signals (ADXL345, Digital Devices, full-scale range = ± 2 g to ± 16 g; typical frequency responses = 0.1 to 3200 Hz; sensitivity = 3.9 mg/LSB; size = 3 mm x 5 mm x 1 mm) and potentiometer

data, both sampled at a rate of 166.7 Hz. Each muscle group, including the biceps and triceps, was equipped with a tri-axial ACC-MMG accelerometer and a potentiometer, which were integrated within an elbow brace arm. This configuration enabled single-channel potentiometer recording alongside simultaneous two-channel ACC-MMG recording. The ACC-MMG signal, captured three-dimensionally by the accelerometers, included three distinct sub-signals corresponding to the x, y, and z axes. Consequently, one channel was designated for potentiometer data, while two channels were dedicated to ACC-MMG signal acquisition, with all data recorded concurrently. The ACC-MMG signals along the muscle axes were captured using three distinct tri-axial accelerometers. These accelerometers were oriented along the x, y, and z axes, corresponding to the longitudinal, lateral, and transverse orientations relative to the muscle fibers, respectively, as illustrated in Fig. 2.

Fig. 2. ACC-MMG Sensor placement: (a) On the Biceps and (b) On the triceps.

The experimental protocol began with each subject directed to lie down in the supine position with their arm positioned alongside their body. This evaluation was carried out using the Modified Ashworth Scale (MAS) as the clinical tool for assessment. During the implementation of the MAS, the therapist performs passive movements and assigns spasticity grades to the corresponding joints depending on the level of muscular resistance observed during passive stretching. After the session, the ACC-MMG signal of biceps and triceps was recorded. The sensors were affixed to the skin in a secure manner through the utilization of double-sided tape. "Sensor 1"

was placed on the biceps muscle's belly, while "Sensor 2" was positioned on the triceps muscle's belly. The sensor's x-axis was aligned with the direction of muscle fiber contraction while z-axis was touched directly to the skin surface. At the same time, the potentiometer with elbow brace arm support was attached to the elbow joint. The QSAT experiment began by assessing the subject's arm through the placement of one therapist's hand beneath the lower arm in proximity to the wrist, while the other hand gave stability to the upper arm near the shoulder, as illustrated in Fig. 3. The subject's arm underwent three repetitions of a movement, transitioning from full extension (0°) to full flexion (135°) for a duration of two seconds each time. All results have been recorded and organized in an Excel datasheet.

Fig. 3. Setup of QSAT Platform measures for upper limb.

D. Data Analysis and Feature Extraction

Signal preprocessing was conducted using MATLAB R2023a software (MathWorks Inc.). The ACC-MMG and potentiometer data collected throughout the experiments underwent initial preprocessing to ensure precision and reliability. Based on the analysis of the raw data, the signals exhibited minimal noise interference, indicating that filtering was unnecessary. The continuous data was then divided into epochs corresponding to each movement cycle, ranging from full extension (0°) to complete flexion (135°) of the elbow. The potentiometer data provided distinct markers indicating the beginning and end of each movement cycle. Fig. 4 shows a graph that presents the time-series plots of the ACC-MMG signals along the x_1, y_1, z_1 axes (for the biceps) and the x_2, y_2, z_2 axes (for the triceps), together with the potentiometer readings. The resulting graph visually represents the patterns of muscle fibres vibration along all three spatial directions and joint motions during flexion. The ACC-MMG signals had distinct amplitude and frequency characteristics for each axis, aligning with the longitudinal, lateral, and transverse orientations of muscle fibres. Significant differences in muscle activity patterns can be observed when comparing the ACC-MMG signals of the biceps and triceps while the potentiometer readings, indicating joint angles, align with the ACC-MMG signals, validating the observed movement cycles.

Fig. 4. Muscle vibrations of the biceps (a, b, c) and triceps (d, e, f), and the angular position (g) during flexion for patient 30.

A specialised algorithm was developed to extract significant features from the ACC-MMG signals. The features selected for analysis included Root Mean Square (RMS), Peak to Peak Amplitude (PTP), Max, Min, Mean Average Value (MAV), Standard Deviation (SD), Skewness (S), and Kurtosis (K). During the feature extraction stage, time-domain features were extracted for the x_1, y_1, z_1 axes (for the biceps) and the x_2, y_2, z_2 axes (for the triceps), corresponding to the longitudinal, lateral, and transverse orientations relative to the muscle fibers. The obtained features were tabulated into a dataset. The equation that determines each extracted feature are as follows:

$$RMS = \sqrt{\frac{1}{n} \sum_i x_i^2} \quad (1)$$

$$PTP = Max - Min \quad (2)$$

$$Max = \text{maximum of the terms} \quad (3)$$

$$Min = \text{minimum of the terms} \quad (4)$$

$$MAV = \frac{\text{sum of the terms}}{\text{number of terms}} \quad (5)$$

$$SD = \frac{\sum (x_i - MAV)^2}{n} \quad (6)$$

$$S = \frac{\sum_i^n (x_i - MAV)^3}{(n-1) SD^3} \quad (7)$$

$$K = \frac{n(n+1)}{(n-1)(n-2)(n-3)} \times \sum \left(\frac{x_i - MAV}{SD} \right)^4 - \frac{3(n-1)^2}{(n-2)(n-3)} \quad (8)$$

The RMS is a metric that quantifies the amplitude of a signal, serving as an indicator of the intensity of muscular contractions or tension of the upper limbs [2], [35]. MAV of MMG signals serves as an indicator of the muscular strength and endurance of the specific muscle in concern [36]. It symbolizes the power, and the energy generated by the muscle. SD were computed for the ACC-MMG signals in the x, y, and z axes, providing insights into the average muscle activity and its variability. Complementing these metrics, the PTP value measures the extent of a signal by determining the disparity between its

highest positive peak and its lowest negative peak of vibration amplitude during a specific timeframe, thereby representing the magnitude spectrum of muscular oscillations or motions within the ACC-MMG signals. Additionally, skewness and kurtosis were calculated to offer a deeper understanding of the properties of muscle signal distributions, thus enhancing the comprehension of muscle activity and its variability.

For this study, a total of 90 datasets were collected from 30 subjects in order to train the muscular spasticity classifier. The one-way MANOVA test was utilised with SPSS 27.0.1 (IBM Inc.) to minimise dependent and redundant features through significant feature analysis. The statistical test selected was a one-way MANOVA due to the presence of multiple continuous dependent variables in independent groups [37]. The features were testing using the technique to examine the significant difference in mean value between the groups. The results from the one-way MANOVA test, including significant values and corresponding p-values, are presented in Table II. A rejection threshold was set at $p < 0.05$ to identify significant differences in the dependent variables. The null hypothesis for ANOVA posited that no difference existed in mean values among the groups. As the p-values of the features listed in Table II were less than 0.05, the null hypothesis was effectively rejected. Consequently, these twenty-five optimal features were selected to train the classifiers for classifying the level of muscle spasticity.

E. Machine Learning Algorithm

Machine-learning classifiers were utilised to automatically infer a prediction function from labelled data derived from inertial signals obtained during passive stretching. The therapist provided MAS ratings to annotate these inertial signals, thus structuring the task as a supervised learning problem. Most offline approaches rely on supervised Machine Learning (ML) models for activity recognition, such as Support Vector Machine (SVM), Decision Trees (DTs), K-Nearest Neighbors (KNN) and Linear Discriminant Analysis (LDA) [31], [38]. Supervised machine-learning algorithms have the benefit over unsupervised methods of being able to assign appropriate labels to training data based on preset classes, thereby avoiding the need to create "artificial" groups [39].

SVM known as a collection of supervised learning techniques employed for the purposes of classification and regression [40], [41]. For a classification problem, SVM seeks to identify the separating hyperplanes that maximize the margin between sets of data points in an n-dimensional space, where each data point belongs to one of the available classes. This will guarantee a strong ability to make accurate predictions in various situations, assuming that the target function remains stable between the training and testing data. SVM are primarily used when the data cannot be separated by a straight line in their current domain [42]. SVM applies a transformation to the input data points, mapping them to a feature space where they can be separated by a linear boundary. Essentially, it separates the classes by incorporating support vectors to optimize the separation between samples belonging to distinct classes. Therefore, it is also known as large-margin categorization.

DTs is a structured representation of a decision-making process used to determine the class of a given instance [43]. Every node in the tree represents either a class label or a particular test that divides the instance space according to the potential results of that test. Every subset of partitions corresponds to a subproblem of classification, which is then resolved by a subtree. The terminal nodes of the decision tree include the class labels. To categorize an instance, one must follow a path from the starting point of the tree to one of its end nodes, taking into account the results of the tests at each step of the process.

KNN classifier is a method used to categorise unlabelled data by assigning them to the class of the most comparable labelled samples. Observational characteristics are gathered for both the training and test datasets [44]. The intuition behind Nearest Neighbor Classification is straightforward. It often proves beneficial to consider multiple neighbors, leading to the more commonly utilized K-Nearest Neighbor (KNN) Classification, where the class of an instance is determined based on the k nearest neighbors [45]. Besides that, LDA is also highly popular technique used to extract distinctive features for the purpose of pattern classification [46]. Linear Discriminant Analysis (LDA) leverages label information to acquire a discriminant projection that effectively increases the separation between different classes and decreases the distance within each class, hence enhancing the accuracy of classification. Several extensions of LDA have been established to improve performance and efficiency. The traditional Linear Discriminant Analysis (LDA) model typically assigns a Gaussian density to

each class, assuming that all classes have an identical covariance matrix [47]. LDA is closely associated with ANOVA (analysis of variance) and regression analysis, since each attempt to represent a dependent variable as a linear combination of other traits or data.

Two dataset has been prepared and structured for muscle spasticity model development. The first data utilized all available features, while the second dataset incorporated only the significant features identified through a one-way MANOVA test. Each dataset datasets were divided into training and testing sets with ratios of 90/10, 80/20, and 70/30. In the 90/10 split, 90% of the data was used for training the model while the remaining 10% was reserved for testing. Similar procedures were followed for the 80/20 and 70/30 splits. These different partitions were used to evaluate the models' robustness and generalization capabilities. The optimal algorithm underwent k-fold cross-validation, where it was trained and tested with k values of 5, 10 and 15 to evaluate the stability of the models across different partitioning schemes. The performance of the machine learning algorithms was assessed using confusion matrices, accuracy, and training length. The percentage of correctly predicted samples to the total number of samples represents the definition of accuracy. A True Positive (TP) outcome occurs when the model accurately predicts the positive class while a True Negative (TN) refers to an outcome where the model accurately predicts the negative class. likewise, a False Positive (FP) occurs when the model wrongly predicts the positive class, whereas a False Negative (FN) occurs when the model incorrectly predicts the negative class. Equation 9 can be used to compute the accuracy by considering the values of TP (true positive), TN (true negative), FN (false negative), and FP (false positive) [48].

$$Accuracy = \frac{T_p + T_N}{T_p + T_N + FP + FN} \quad (9)$$

A confusion matrix comprises a square matrix displaying the general classification model performance. The rows of the confusion matrix show actual instances of class labels, whereas the columns show instances of predicted class labels. For each trial, the diagonal components of this matrix will indicate how many times the predicted label matches the actual label. For assessing how effectively the model classified data, the confusion matrix acts as a useful indicator.

V. RESULTS AND DISCUSSION

The accuracy performance of the algorithms influenced by different training and testing splits which presented in Table III. It also compares the accuracy based on features selected for training and testing, yielding varying results. Dataset with all features and significant features for the 90/10 split showed highest accuracy compared to other data ratios. However, most researchers recommend using a 70/30 split for smaller datasets [49]. Dataset with all features shown that KNN algorithm achieved an accuracy of 83.95%, outperforms the others algorithm. Notably, the KNN algorithm demonstrated an even higher accuracy of 90.12% when using significant features, indicating that the use of significant features enhances the model's performance.

TABLE III. PERCENTAGE OF DATA SET AND ACCURACY WITH ALL FEATURES AND SIGNIFICANT FEATURES

Algorithm	Training and Testing Split Percentage of Accuracy					
	All Features			Significant Features		
	90-10	80-20	70-30	90-10	80-20	70-30
DT	64.20	65.28	55.56	65.43	63.89	65.08
LDA	69.14	59.72	46.03	76.54	70.83	66.67
SVM	65.43	69.44	60.32	72.84	68.06	69.84
KNN	83.95	80.56	66.67	90.12	86.11	84.13

The confusion matrix findings shows that the accuracy of KNN algorithm for all features and significant features which presented in Fig. 5 and Fig. 6. The True Positive Rate (TPR) and the False Negative Rate (FNR) are shown in a confusion matrix in KNN algorithms. The rows and columns of the matrix represent the predicted and actual classes for the MAS levels 0, 1, 1.5 (1+), 2, and 3, respectively. Comparing the accuracy of the KNN classifier using all features and significant features reveals important insights. KNN algorithm with all features achieves an overall accuracy of 83.95%, demonstrating superior performance, particularly in correctly identifying the extreme classes (0 and 3) and maintaining high true positive rates across most classes. However, when using the dataset with significant features, the KNN algorithm's overall accuracy increases to 90.12%. This improvement is evident in its enhanced ability to correctly identify not only the extreme classes (0 and 3) but also intermediate classes 1. It also showed increase in true positive rates across classes 1.5 compared to KNN algorithm using all features. This comparison highlights the effectiveness of using significant features in improving the classification accuracy of the KNN model. Furthermore, comparing with both dataset, significant features proving to be most optimum accuracy.

Fig. 5. Confusion matrix for KNN using all features.

Table IV presents the training durations for several machine learning algorithms, illustrating that the use of significant features consistently reduces training time compared to using all features. Specifically, the training time for the Decision Trees (DTs) algorithm decreased from 4.27 seconds to 3.24 seconds. The Linear Discriminant Analysis (LDA) algorithm's training

time was reduced from 1.13 seconds to 0.91 seconds. The Support Vector Machine (SVM) algorithm showed a reduction in training time from 4.35 seconds to 3.75 seconds. Similarly, the K-Nearest Neighbors (KNN) algorithm experienced a decrease in training time from 3.03 seconds to 2.46 seconds. Among the algorithms evaluated, the Decision Trees (DTs) algorithm exhibited the most significant reduction in training time based on the percentage difference with 24.12% due to algorithm structured. The notable decrease in training time emphasises the efficiency improvements obtained by prioritising the most pertinent features, thereby illustrating the advantages of feature selection in machine learning models. Moreover, utilising crucial features simplifies the training process by decreasing the complexity and size of the dataset, enabling machine learning algorithms to function more effectively and attain quicker convergence [47].

Fig. 6. Confusion matrix for KNN using significant features.

TABLE IV. TRAINING TIME OF ALL ALGORITHM WITH ALL FEATURES AND SIGNIFICANT FEATURES

Table Head	Training Time (seconds)		Percentage Difference (%)
	All Features	Significant Features	
DT	4.27	3.24	24.12
LDA	1.13	0.91	19.47
SVM	4.35	3.75	13.79
KNN	3.03	2.46	18.81

Machine learning models trained on datasets with significant features identified through a one-way MANOVA test consistently showed higher accuracy across all data split tests compared to those using all available features. This underscores the impact of feature selection on model performance, demonstrating that models trained on statistically significant features often outperform those using all features. This highlights the importance of feature selection in enhancing model accuracy and efficiency. Furthermore, the efficacy and efficiency of a machine learning solution are contingent upon the inherent qualities and attributes of the data, as well as the proficiency of the learning algorithms [47]. Among the algorithms, KNN exhibited the highest accuracy across all

datasets. The KNN classifier proves to be the optimal method for classifying biomechanical parameter features, particularly in scenarios with limited datasets and low dimensionality [50], [51].

A. Comparative Performance Analysis of Classifier Algorithms

The KNN algorithm using significant features was evaluated and compared in a 90/10 split using k-fold cross-validation with k values of 5, 10, and 15. This methodology enabled a thorough evaluation of the performance of KNN algorithm by dividing the dataset into k subsets, or folds, in a systematic manner. The algorithm underwent k-fold cross-validation, where it was trained and tested k times. In each iteration, a different fold was used as the validation set, while the remaining k-1 folds were utilised for training. Varying the value of k allowed for an examination of the models' stability and robustness across different partitioning schemes, providing a thorough evaluation of their predictive capabilities and overall performance in diverse scenarios. Table V illustrates the comprehensive comparison of accuracy in classifying various levels of spasticity, based on the output of MAS levels. The accuracy of KNN algorithm showed a decreased when the number of folds increased from 5 to 10. However, KNN algorithm demonstrates optimum accuracy with k= 15 at 91.29%.

Based on the result, there is no direct correlation between adjusting the value of K in k-fold cross-validation and the accuracy of machine learning algorithms [52]. Hence, while choosing the value of k, it is important to exercise caution as a lower k value entails decreased computing cost, reduced variance, but increased bias. Conversely, a larger value of k is more computationally demanding but exhibits greater variability and reduced bias. Therefore, the value of k must be chosen such that the size of each validation set is sufficient to ensure a reliable assessment of the model's performance. In conclusion, the KNN algorithm with significant features demonstrated superior performance in objectively evaluating the level of muscle spasticity.

TABLE V. PERFORMANCE OF KNN ALGORITHM WITH DIFFERENT VALUE OF K-FOLDS

k-folds	Percentage of Accuracy
5	90.12
10	88.89
15	91.29

B. Clinical Implementation and Integration

A systematic approach would be beneficial for the successful incorporation of mechanomyography (MMG) technology into current spasticity management treatments. MMG evaluations can serve as an addition to older methods like the Modified Ashworth Scale (MAS) and the Australian Spasticity Assessment Scale (ASAS). MMG can enhance the reliability and consistency of spasticity level evaluations by offering unbiased data that can validate and improve the subjective assessments currently employed.

As trust in the technology increases, MMG might be progressively integrated as a principal evaluation tool. This

would require the development of standardised protocols that integrate MMG measurements into clinical decision-making processes. For instance, MMG data can be utilised to modify treatment strategies, track the development of spasticity over a period, and assess the efficacy of therapies. Integrating MMG with current electronic health record (EHR) systems could enhance efficiency by enabling doctors to conveniently access and analyse MMG data in conjunction with other patient information.

Comprehensive training for therapists is crucial for ensuring the effective utilisation of MMG technology in clinical contexts. This training should include both the technical aspects of utilising MMG devices, and the analysis of data produced by the machine learning models. It is important for therapists to receive training to comprehend the importance of MMG signals, specifically the time and frequency domain characteristics considered essential for precise assessment of spasticity.

Furthermore, therapists must acquire knowledge of the machine learning algorithms employed to analyse MMG data. This entails comprehending the mechanisms by which these models generate predictions, interpreting the significance of the primary output metrics, and incorporating these insights into clinical practice. Hands-on training, supported by user-friendly software interfaces, will further enhance therapists' proficiency in utilizing MMG technology effectively.

C. Limitation of Study

While this study demonstrates the potential of mechanomyography (MMG) in assessing muscle spasticity, several limitations should be considered. Initially, while MMG is proficient in assessing muscle vibrations within the frequency range of 2 to 100 Hz, enhancing the sampling rate could enhance the precision of the data. Increasing the sampling rates can catch finer details of the muscle signals, perhaps improving the accuracy of the assessments and offering a more thorough comprehension of muscle spasticity.

Moreover, the study primarily utilises time domain variables for analysis. Although these features provide information, it may not comprehensively capture all the complexities that comprise MMG signals. In contrast, frequency domain features may identify additional patterns and behaviours that are not evident in the temporal domain. By including frequency domain analysis, a more comprehensive and precise depiction of muscle vibrations can be achieved. This has the potential to enhance the performance of models and enable more dependable evaluations of spasticity.

D. Future Research

A precise assessment of muscle spasticity is essential for the effective treatment and control of neurological diseases in patients. Although mechanomyography (MMG) has potential as a technique for assessing spasticity, its present uses mostly rely on extracting time-domain characteristics from MMG data. To completely maximise the potential of MMG and enhance its practical application in clinical settings, future research should prioritise several crucial areas of development.

Exploring advanced optimisation approaches and ensemble methods can greatly improve the accuracy and reliability of predictive models used in spasticity assessment. Techniques

such as hyperparameter tuning, ensemble learning, and deep learning approaches could offer significant improvements in interpreting MMG data and assessing spasticity levels. Besides that, the exploration of ensemble methods offers another promising avenue for improving model performance. By combining the predictions of multiple algorithms, ensemble techniques such as bagging, boosting, or stacking could reduce variance, mitigate overfitting, and increase the overall predictive power of the models. These methods could enhance the model's ability to generalize across different patient populations and clinical settings, thereby improving the robustness of spasticity predictions.

Moreover, the integration of advanced deep learning techniques, such as convolutional neural networks (CNNs) or recurrent neural networks (RNNs), could enhance the automated extraction of detailed and significant characteristics from the MMG signals. These models have demonstrated considerable efficacy in various biomedical signal processing contexts, as they are adept at identifying intricate patterns and relationships within the data that might be overlooked by traditional feature extraction methods. While this study primarily utilizes time domain features extracted from MMG signals, there remains significant potential to enhance model performance through more sophisticated feature engineering approaches. For instance, increasing the sampling rate of MMG data could capture finer details of the signal, thereby enabling the application of frequency domain extraction methods. Such techniques would provide a more nuanced analysis of the MMG signals, potentially uncovering features that are not detectable in the time domain alone.

By integrating these advanced techniques, the precision and robustness of spasticity assessments could be substantially improved, leading to more accurate and reliable predictions. Future research should investigate these avenues to further enhance the clinical utility of MMG in the objective assessment of muscle spasticity.

VI. CONCLUSION

Essentially, the purpose of this study was to address the problem of subjective and inconsistent evaluation of muscle spasticity in patients with neurological diseases. The objective was to validate MMG as a reliable signal by comparing the accuracy of various machine learning algorithms and demonstrate its clinical applicability in objective measurement. The study demonstrated the efficacy of employing different machine learning algorithms, such as Decision Trees (DTs), Support Vector Machines (SVM), and K-Nearest Neighbours (KNN), for accurately predicting degrees of spasticity. The KNN algorithm, using both all features and significant features, achieved optimal accuracy in the 90/10 split. Specifically, KNN with significant features demonstrated the highest accuracy at 91.29% with $k=15$, outperforming the use of all features, highlighting its effectiveness in categorizing biomechanical parameters. This technological development has the potential to greatly improve rehabilitation processes by offering more accurate and unbiased evaluations of spasticity. Moreover, it has the potential to decrease related expenses and time, ultimately resulting in an enhancement in the standard of treatment for impacted patients.

ACKNOWLEDGMENT

The research was conducted in the Biomechanics Research Laboratory at the International Islamic University Malaysia. The author wishes to gratefully acknowledge the Ministry of Education (MOE) through Fundamental Research Grant Scheme (FRGS/1/2022/TK07/UIAM/02/6).

Abstract—To achieve user interactive color design, this study takes furniture color interactive design as an example, introduces artificial intelligence and augmented reality virtual implantation technology, allowing users to design furniture colors and styles according to their own ideas. By improving cyclic consistency to generate adversarial networks, furniture image style transfer is carried out, and indoor feature point classification and virtual model registration are carried out through density based spatial clustering and other methods to design an unlabeled augmented reality furniture system. The results showed that compared to other methods, the improved cyclic consistency generation adversarial network had a higher structural similarity value. In the zebra to horse image, the structural similarity value was 0.987, which was 0.018 higher than the algorithm before improvement. The registration effect of density-based spatial clustering algorithm was good, with a shorter time consumption in different scenarios, and a maximum time consumption of 0.308 seconds in occluded composite scenes. The performance of the drawing component is good, with each process of tracking threads taking less than 20ms. The research method not only satisfies users in designing furniture colors and styles, but also enhances their experience.

Keywords—Artificial intelligence; AR virtual implantation technology; color; style transfer; furniture

I. INTRODUCTION

The rapid development of information technology has advanced the field of human-computer interaction (HCI) research and enhanced the user experience. However, in the home furnishing industry, there are still shortcomings in the development of human-machine interaction. Users have not been able to achieve interactive design for furniture colors and styles according to their own needs, resulting in furniture colors and other aspects that do not match the home environment [1-3]. Augmented reality (AR) virtual implantation technology (AR-VIT) can solve this problem, providing users with a better interactive experience and significantly improving their sense of participation [4-6]. The emergence of artificial intelligence (AI) technology has driven the development of image style transfer (IST), enabling personalized design to be realized. When designing indoor furniture, choosing this technology is beneficial for real-time migration and adjustment of furniture style, allowing users to adjust colors, textures, and other conditions according to their preferences to meet their needs. In this regard, in furniture color design, to achieve user interaction, this study introduces AR-VIT and uses Cycle-Consistent

generative adversarial networks (CycleGAN) to transfer home style to meet the needs of user interactive color design and improve user experience. The study is divided into five sections. Section II is a literature review that introduces the research status of domestic and foreign scholars on furniture design, CycleGAN algorithm, and AR-VIT. Section III involves IST, virtual model registration, fusion of 3D reconstruction algorithms, and virtual real fusion of furniture models. Section IV conducts result analysis to study the image clustering effect and the application of AR-VIT. Section V summarizes the research methods, pointing out shortcomings and future research directions. The contributions of the research are as follows: (1) the study introduced artificial intelligence and augmented reality virtual implantation technology, enabling users to interactively design furniture colors and styles based on personalized needs. (2) By optimizing loop consistency, the improved network proposed in this study exhibits higher structural similarity values in furniture image style transfer. (3) We have researched, designed, and implemented a label free augmented reality furniture system that can integrate user designed furniture styles into the actual environment in real-time, enhancing the user experience. The abbreviation table used in the study is shown in Table I.

TABLE I. RELATED TIME CONSUMPTION

Full name	Abbreviation
Human-computer interaction	HCI
Augmented reality	AR
Augmented reality virtual implantation technology	AR-VIT
Artificial intelligence	AI
Image style transfer	IST
Cycle-Consistent generative adversarial networks	CycleGAN
Features from accelerated segment test	FAST
Random sample consensus	RANSAC
Parallel tracking and mapping	PTAM
Bundle adjustment	BA
Sum of squared differences	SSD
Multi-modal unsupervised image to image translation	MUNIT
Peak signal-to-noise ratio	PSNR
Structural similarity	SSIM
Inception score	IS
Normalized mutual information	NMI

II. RELATED WORK

In the field of HCI, color interactive design is a part of it. However, in the field of furniture design, the user experience in furniture color and other aspects still needs to be improved. Ge S et al. conducted research on digital design methods for furniture cultural tourism exhibition platforms to improve their design level, based on multimedia networks. They collected and summarized data on Jinzuo furniture from different platforms, and divided furniture genres. After analysis, it was found that design methods can promote the improvement of platform design level [7]. Jiang L et al. studied adolescents and children to understand whether they were influenced by their own color preferences when choosing furniture. They analyzed the color preferences of different functional furniture at different ages. Tests have found that their color preferences can affect the selection of different types of furniture [8]. In the process of designing living room furniture, Nasir EB conducted a specific analysis of the application of design thinking in the design of living room furniture for students. The results showed that under the influence of design thinking, it was beneficial to understand the vague needs of users and had a positive promoting effect on design practice [9]. In the process of studying library furniture, Parvez M S et al. faced the problem of matching its size with student body measurements, conducted experimental settings, collected relevant data on students and home design, and compared them. The mismatch between these two types of data was more pronounced, which would be detrimental to the growth and development of students [10]. Lee I J et al. introduced AR technology and conducted comparative experiments to promote the understanding of 3D space for novice carpenters. With the help of AR, novice carpenters could better understand 3D space and have a higher level of mastery of complex mortise and tenon structures [11].

Liu X et al. designed and optimized the CycleGAN algorithm for unsupervised training in image dehazing, based on the relevant generator. Comparative analysis showed that this method had a better visual effect on image processing [12]. Chen et al. introduced the CycleGAN algorithm in spatio-

temporal image fusion to address the issue of insufficient spatial information in images, and based on this, proposed a corresponding fusion framework. This model simulated the generation and processing of images, and input them into the constructed framework. After verification, the application effect of the proposed method was good [13]. In the process of studying Earth observation applications, Soto P J et al., faced with insufficient training data, chose the CycleGAN algorithm and improved the adaptability of the research object through nonlinear mapping functions. The proposed method could effectively solve the domain transfer problem in remote sensing applications [14]. Angrini L M and others faced the problem of poor mathematical thinking among students and conducted experiments on flat shape design using AR technology based on Unity 3D software. It randomly selected students for testing and interviews, and conducted result analysis. With the assistance of AR, students' mathematical and computational abilities had been significantly improved [15]. Ahmad H et al. focused on consumers and selected respondents to analyze their potential travel destinations during the pandemic, collecting their views on the impact of AR on tourism behavior. Statistical data showed that AR technology had a certain degree of impact on the travel intentions of consumers [16].

In summary, in the design of furniture styles and other aspects, most of them tend to focus on the specific design situation of furniture, with less emphasis on combining AI and AR-VIT, and there has been no research on user interaction color design. The CycleGAN algorithm has shown good performance in IST, which helps users design furniture styles. In addition, AR-VIT can overlay virtual objects into the actual environment, which is beneficial for furniture display. Therefore, to achieve interactive design of furniture styles such as color and texture for users, this study cites the CycleGAN algorithm and AR-VIT for furniture interactive design. Compared to previous research, this study has developed an unlabeled augmented reality system, overcoming the limitations of using artificial markers and applying it to the furniture field. The advantages and disadvantages analysis of different methods are shown in Table II.

TABLE II. ANALYSIS OF ADVANTAGES AND DISADVANTAGES OF DIFFERENT METHODS

Author	Technique/Method	Advantages	Disadvantages
Ge et al.	Digital Design	Enhances platform design	Limited application in interactive design
Jiang et al.	Color Preference Study	Identifies impact of color preferences	Limited generalizability
Nasir EB	Design Thinking Application	Positively promotes design practice	Lacks technical application details
Parvez et al.	Furniture Size Matching	Highlights mismatch issues beneficial for student development	Restricted to specific settings
Lee et al.	AR Technology Application	Improves mastery of complex structures	Limited to novice carpenters
Liu et al.	CycleGAN Optimization	Better visual effects in image processing	Application scenarios not detailed
Chen et al.	CycleGAN in Image Fusion	Proposes a fusion framework with good application effects	Performance in practical scenarios not specified
Soto et al.	CycleGAN in Remote Sensing	Solves domain transfer issues effectively	Limited to remote sensing domain
Angrini et al.	AR for Computational Thinking	Significantly enhances students' abilities	Limited scope and generalizability
Ahmad et al.	Impact of AR on Tourism Behavior	Shows impact of AR on travel intentions	Limited to pandemic context

III. INTERACTIVE DESIGN BASED ON AI AND AR-VIT

To achieve interactive design of furniture styles such as color and texture, this study improves the CycleGAN algorithm to assist users in personalized design of furniture styles. Using AR-VIT, indoor feature point classification and virtual model registration are carried out through density-based spatial clustering of applications with noise DBSCAN and other methods, and an unlabeled augmented reality furniture system design is carried out.

A. IST based on Improved CycleGAN Algorithm

The development of the real estate market has led to the rapid prosperity of the furniture industry, but users still choose furniture using traditional methods. When users are not satisfied with the color, texture, etc. of furniture, it often means that the product transaction has failed, or when the purchased furniture arrives at home, there is a situation where it does not meet the expected effect. Therefore, to achieve interactive design of furniture color among users, this study conducts furniture IST based on user needs to change furniture color. The CycleGAN algorithm is introduced in this study, and its generator structure is Fig. 1.

In Fig. 1, for the CycleGAN algorithm generator, its transformation network contains six residual blocks, and its encoding network has three convolutional layers. Due to the incomplete style transfer and other issues in generating furniture images using this algorithm, this study improves the algorithm by optimizing its generator, discriminator, and loss function. The main architecture of the improved algorithm is the U-Net network, and nine residual blocks are added to the bottom of the network to promote sufficient transformation of

image style. In improving the CycleGAN algorithm, its discriminative network has two discriminators. Different discriminators discriminate from different receptive fields to achieve higher network discrimination performance. In the improvement of the loss function, the L1 norm of the identity loss function is added, and the Wasserstein distance with gradient penalty term is introduced to rewrite the original adversarial loss function and improve the performance of the algorithm. The overall architecture of the improved CycleGAN algorithm is Fig. 2.

In Fig. 2, X and Y represent two different domains, with X being the content domain and Y being the style domain. Sample x in X and sample y in Y . x obtains sample \hat{y} through the generator. D_y is a discriminative network for Y , used to distinguish between y and \hat{y} and determine the probability value of the true sample. F represents the generator from Y to X . \hat{y} generates sample \hat{x} through F . D_x represents the discriminative network of X , and x and \hat{x} can be distinguished through D_x . To maintain the relative balance between the generator and the discriminative network, it is necessary to alternate training between the two, with the images being trained from X to Y and then to X , thus forming a loop. Specifically, to design two generators to improve the CycleGAN algorithm, with the same structure. By adopting this symmetrical structure, feature maps that are completely aligned with the content domain and style domain can be obtained. Overall, the structure of the generator is Fig. 3.

Fig. 1. Related structures.

Fig. 2. The overall architecture of the algorithm.

Fig. 3. Encoding network and decoding network.

In Fig. 3, the encoding network and decoding network represent the contraction path and expansion path of the U-Net network, respectively. In an encoding network, the size of the input image is $3 * 256 * 256$, and the output is a feature map with a size of $1024 * 30 * 30$. The sliding step size of the convolutional layer is set to 1, its filling amplitude is 1, and its convolution kernel is $3 * 3$. Under the influence of this convolutional layer, the input image is processed into a feature map of $64 * 256 * 256$. Due to the fact that selecting either the maximum pooling layer or the average pooling layer during down-sampling can result in significant loss of feature information. In the face of this problem, this study sets the convolution kernel to a size of $4 * 4$, with a sliding step size of 2 and a filling amplitude of 1, respectively. In this case, it can be ensured that the number of output channels remains unchanged and the feature map size is halved. To encode and process images according to the two designed convolution kernels. The convolutional kernel size of the last down-sampling convolutional layer is $5 * 5$, with a sliding step size and filling amplitude of 1 to obtain the final feature map. The image serves as the input of the transformation network, and the final output feature map size remains unchanged. Among them, in the residual block, a mirror is filled with a filling amplitude of 1, and the edge information of the feature map is saved as much as possible, making the feature map size $1024 * 32 * 32$. Under the influence of a convolutional layer containing $3 * 3$ convolution kernels, the size of the feature map changes to $1024 * 30 * 30$. Repeating the image filling and convolutional layer processing, with the same parameter settings, to make the feature map size $1024 * 30 * 30$ again. Using ReLU activation function and instance normalization layer to input the obtained feature map into the decoding network. Its output is the image after style transfer. During this period, feature maps and two different sizes of convolutional layers are concatenated using skip connections, ultimately enabling image reconstruction. The sizes of these two types of convolutional layers are $5 * 5$ and $3 * 3$, respectively.

Design of discriminator: It involves adding discriminator D_1 to the original discriminator PatchGAN D_2 . The two discriminators have the same structure, but there is a difference in their input feature sizes. The former is $3 * 256 * 256$, while the latter is $3 * 128 * 128$. Calculating the mean probability value of two discriminators, and the result obtained is the final output probability value. To design the loss function, and the loss function L_{GAN} from X to Y is Eq. (1).

$$L_{GAN}(G, D_Y, X, Y) = E_{x \sim P_G} [D_Y(x)] - E_{x \sim P_{data}} [D_Y(y)] + \lambda E_{\hat{x} \sim P_{\hat{x}}} [(\|\nabla_{\hat{x}} D_Y(\hat{x})\|_2 - 1)^2] \quad (1)$$

In Eq. (1), the distribution of X and Y is set to $x \sim P_{data}$ and $y \sim P_{data}$, respectively. P represents the smallest rectangular plane of the feature points, which belongs to the initial plane. After passing G , the potential distribution $y \sim P_G$ of X 's image can be obtained. $E_{\hat{x} \sim P_{\hat{x}}}$ represents the gradient penalty term. Constraining the gradient around 1 to satisfy the Lipschitz condition for the discriminator. The penalty coefficient is set to λ , and the corresponding distribution $\hat{x} \sim P_{data}$ can be obtained through $x \sim P_{data}$ and $y \sim P_{data}$.

$$L_{GAN}(G, D_X, Y, X) = E_{y \sim P_G} [D_X(y)] - E_{y \sim P_{data}} [D_X(x)] + \lambda E_{\hat{y} \sim P_{\hat{y}}} [(\|\nabla_{\hat{y}} D_X(\hat{y})\|_2 - 1)^2] \quad (2)$$

Eq. (2) is the adversarial loss function from Y to X .

$$L_{identity}(G, F) = E_{y \sim P_{data}} [\|G(y) - y\|_1] + E_{x \sim P_{data}} [\|F(x) - x\|_1] \quad (3)$$

In Eq. (3), $L_{identity}(G, F)$ represents the identity loss function.

$$L(G, F_x, D_X, D_Y) = L_{GAN}(G, D_Y, X, Y) + L_{GAN}(F, D_X, Y, X) + \lambda L_{identity} + \lambda_c L_{cyc}(G, F) \quad (4)$$

In Eq. (4), $L(G, F_x, D_x, D_y)$ is the total loss function. $L_{cyc}(G, F)$ represents the cyclic consistency loss function. λ_i and λ_c are hyper-parameters. Adjusting the proportion of the loss function to the total loss function through these parameters.

B. Furniture System Based on DBSCAN Algorithm and AR-VIT

After completing the furniture style design, AR-VIT is introduced to conduct research on furniture stacking in actual environments. The first step is to register the virtual model, as shown in Fig. 4.

Fig. 4. Registration process.

In Fig. 4, the camera captures the video stream and performs pyramid layering on it. Different image layers correspond to different scales. The Features from accelerated segment test (FAST) algorithm has been selected to detect layered image features. Definition of corner: If the difference between a pixel and a large number of neighboring pixels exceeds a predetermined threshold, there is a certain probability that the pixel belongs to the corner. The relevant formula is Eq. (5).

$$N = \sum_{x' \in \text{circle}(p)} |I(x') - I(p)| > \varepsilon_d \quad (5)$$

In Eq. (5), x' represents the pixels on the circumference, and $I(x')$ represents the grayscale value of x' . The center point is P and the radius is r . The threshold for grayscale difference is set to ε_d , the adjustable parameter for the algorithm is set to N , and N is set to 10. When there is more than one feature point in the region, to delete the feature points with smaller response values. Calculating the feature point score S : In the feature point set V , assuming the existence of point c , its score is S_c . At point c , there is a neighborhood with a size of $s * s$. There is an arbitrary feature point l in this region, and if S_l exceeds S_c , point l is treated as a local maximum. Iterating other feature points in V in this way. The selection of the area with the densest indoor feature points is carried out by constructing a virtual object display main plane in that area, and then classifying feature points using the DBSCAN algorithm. To achieve higher operational efficiency, the size of the clustering dataset is reduced by setting its feature point data to 500. Datasets with a scale less than 500 are directly clustered, otherwise the score of feature points is calculated using the Shi-Thomas algorithm.

According to the order of scores from high to low, the top 500 points are selected for clustering. During the operation of the DBSCAN algorithm, all sample points are scanned first. If the number of points within the threshold Eps radius range of a certain sample point exceeds the threshold $MinPts$ of the number of samples in the region centered on that point with a radius of Eps , then that point is selected into the core point list. Summarizing the points with the highest density to obtain the corresponding temporary cluster. Merging all temporary clusters to determine the final cluster. In the dataset, filtering out error points and treating them as noise points to avoid their impact on clustering results. After the feature point clustering is completed, the main plane of the virtual object is established for display.

$$q = \begin{cases} \text{reserve, if } q \in C_{\max} \\ \text{delete, otherwise} \end{cases} \quad (6)$$

In Eq. (6), q represents the feature points, and the cluster with the highest number of feature points after clustering is set to C_{\max} . At the location of C_{\max} , to establish the main plane using random sample consensus (RANSAC), which is a rectangle. Choosing the parallel tracking and mapping (PTAM) algorithm to ensure real-time tracking of virtual objects under changing indoor environments. Before this, camera calibration is performed. This study selects a pinhole camera imaging model and calibrates the camera using the Zhang calibration method to obtain the internal and external parameters of the camera. The calibration template is in black and white chessboard format. During the calibration process, 4 frames of images need to be collected from different angles. The main module of PTAM consists of two parts: drawing thread and tracking thread. The drawing thread process is Fig. 5.

Fig. 5. Drawing thread process.

In Fig. 5, the first step is to manually set two keyframes and initialize them. When the camera deviates from the initial pose, the camera determines the current keyframe. It needs to have good tracking performance, contain a large number of feature points, and have sufficient duration. The interval between the image frame and the previous keyframe should be greater than 20 frames. In addition, the current frame should have sufficient distance in spatial position. When a keyframe is determined, the map information is updated based on the world points in that frame, combined with the original world points. Conversely, the map information is optimized using the bundle adjustment (BA) method. In local BA optimization, only the newly added last 5 keyframes and their world points are considered. The constraint is that other keyframes that can observe the world point are not optimized. In global BA optimization, all keyframes and their map points are optimized. During idle time, the drawing thread optimizes the map through old keyframes. To process outliers, treating them as new world points when they can be observed and converge, and adding them to the map. Through this approach, it is possible to prevent the loss of virtual furniture tracking and improve system accuracy. The process of tracking threads is Fig. 6.

In Fig. 6, the input image is layered into four pyramid layers, and the feature points of each layer are extracted using the FAST algorithm. The DBSCAN algorithm is used to cluster the

feature points. After initializing the map, based on the initial two keyframes determined, feature points are selected through sum of squared differences (SSD) block matching (two frame images). Calculating the homography matrix between two frames, decomposing it into a rotation translation matrix, and treating it as the initial pose.

$$SSD(u, v) = \text{Sum} \{ [\text{left}(u, v) - \text{right}(u, v)]^2 \} \quad (7)$$

In Eq. (7), u and v represent the u -axis and v -axis of the pixel coordinate system, respectively. These two coordinate axes are parallel to the x'' -axis and y'' -axis of the image's physical coordinate system, respectively. The smallest difference in this equation is the best matching block. The normalized coordinates of the feature points in the initial two frames are set to x_1 and x_2 , and the formulas involved in these two coordinates are shown in Eq. (8).

$$s_1 x_1^* = s_2 R x_2^* + t^* \quad (8)$$

In Eq. (8), s_1 and s_2 represent the parameters of x_1^* and x_2^* , respectively. R and t^* are the rotation translation matrix.

$$s_1 \hat{x}_1^* x_1^* = s_2 \hat{x}_2^* R x_2^* + x_1^* t^* \quad (9)$$

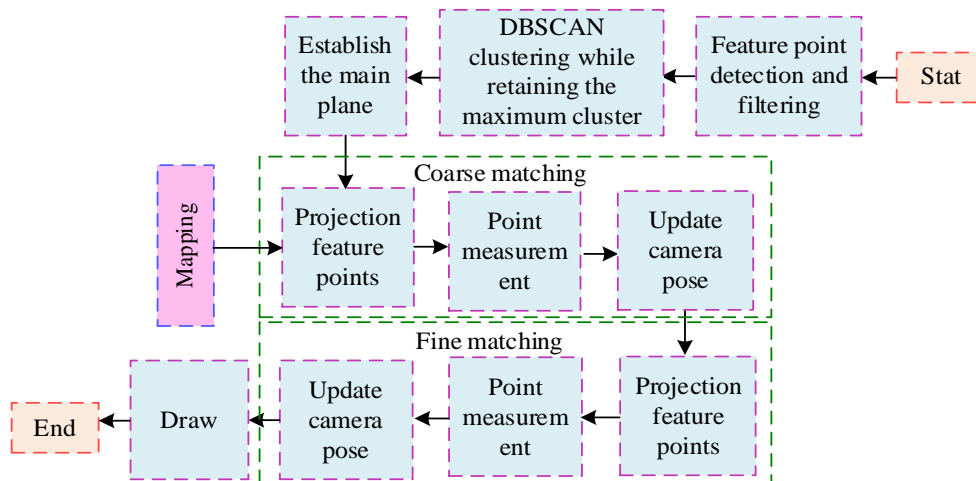

Fig. 6. Track the process of threads.

On the left side of Eq. (9), the equal sign is 0, and s_2 can be directly obtained. Based on this, s_1 can be calculated. Due to the influence of noise, R and t^* may not accurately make the left side of the equation equal to 0, so optimization is carried out through BA. The minimum objective function for local BA optimization is Eq. (10).

$$\{\{\mu_x \in X'\} \{p'_z \in Z\}\} = \arg \min_{\{\{\mu\} \{p\}\}} \sum_{i \in X' \cup Y'} \sum_{j \in Z \cup S_i} Obj(i, j) \quad (10)$$

In Eq. (10), set X' consists of the current frame and its closest 4 other keyframes. In these keyframes, the observable world points are set as set Z . p'_z belongs to the world point in Z . The set of keyframes with observable world points in Z is represented as Y' . i and j are the serial number. μ_x represents the element in X' . Local BA only optimizes elements in Z and X' . Calculating the initial pose of the camera. After obtaining the coordinates of the world point through triangulation, establishing the display main plane. 30-60 points in the top layer of the image pyramid are selected for coarse matching, and the world points based on the camera's pose are mapped. It is projected into the current frame to calculate the error with the current feature point. Based on the obtained results, an error optimization function is established and the camera pose is calculated. Based on the updated camera pose, to re select image points with a quantity of around 1000. Performing pose detection: The process is the same as coarse matching. Optimizing the pose by combining all points. The

PTAM component completes the 3D registration of virtual furniture models to the real environment's 3D coordinate system and real-time tracking through the above process. Virtual real fusion uses user input to paste stylized images onto the surface of the constructed virtual furniture 3D model, and obtains the correct occlusion relationship. This can minimize the number of model vertices and patches, and reduce scene drawing calls, thereby achieving system performance optimization.

IV. APPLICATION ANALYSIS OF FURNITURE SYSTEMS BASED ON IST AND AR-VIT

To analyze the effectiveness of IST and improve the performance of the CycleGAN algorithm, this study compared multiple algorithms with CycleGAN. By analyzing the performance of DBSCAN and PTAM algorithms, the application of the system could be evaluated.

A. Analysis of IST Results

To verify the performance of the improved CycleGAN algorithm, the Ubuntu operating system was selected with a learning rate of 0.0002. The experiment used the Horse2Zebra public dataset, $\lambda_c = 10$, $\lambda = 10$, and $\lambda_i = 1$. The comparative algorithms were the CycleGAN algorithm and the multi-modal unsupervised image to image translation (MUNIT) algorithm. The evaluation indicators were peak signal-to-noise ratio (PSNR), structural similarity (SSIM), and inception score (IS). The style transfer effect of the algorithm under different iterations analyzed is Fig. 7.

Fig. 7. Style transfer effect.

In Fig. 7 (a), as the number of iterations increased, the SSIM value of the iterative feature effect map also increased, and the quality of the iterative map obtained by the research method was better. When the number of iterations was 35, the SSIM value of the research method was 0.547, which was 0.135 higher than the MUNIT algorithm, while the SSIM value of the CycleGAN algorithm was the smallest. When the iteration was 75, the SSIM values of the research method and MUNIT algorithm were 0.805 and 0.679, respectively. In Fig. 7 (b), the line where the research method was located was above the line where other algorithms were located. When the iteration was 45, the PSNR value of the research method was 16.201dB, which was 6.204dB higher than the CycleGAN algorithm. The

results of analyzing the conversion effect between horse and zebra images are shown in Fig. 8.

In Fig. 8 (a), compared to methods such as the CycleGAN algorithm, the PSNR, SSIM, and IS of the research method were all larger. The IS value of the research method was 3.242, which was 1.635 higher than CycleGAN and 0.949 higher than MUNIT. In Fig. 8 (b), the SSIM values of the research method, CycleGAN, and MUNIT were 0.987, 0.969, and 0.955, respectively, indicating that the research method had the highest SSIM value. Therefore, the research method generated images with good quality.

Fig. 8. Related comparison results.

B. Application Analysis of Unlabeled AR Furniture System Based on DBSCAN Algorithm

When conducting application analysis, select representative furniture design cases and demonstrate how to use artificial intelligence and augmented reality technology to customize furniture colors and styles based on personalized user needs. Collecting users' furniture design preferences, including color, style, etc., through style transfer, feature point classification and model registration, and the integration of virtual and reality, users can intuitively see the designed furniture in their living space through augmented reality technology. To analyze the performance of DBSCAN algorithm, the comparison method was K-means algorithm, and the dataset was UCI dataset. The evaluation indicators were normalized mutual information (NMI) and accuracy, and the comparison results are shown in Fig. 9.

In Fig. 9 (a), due to different datasets, there were differences in the accuracy of the same algorithm. In the glass_5 dataset, the accuracy of the DBSCAN algorithm was 0.784, which was 0.187 higher than the K-means algorithm. The maximum accuracy on other datasets was 0.854, which was also higher than the K-means algorithm. In Fig. 9 (b), overall, compared to the K-means algorithm, the DBSCAN algorithm had a larger NMI value. In the Dermatology dataset, the NMI values of DBSCAN algorithm and K-means algorithm were 0.345 and 0.082, respectively. Therefore, the DBSCAN algorithm had a good clustering effect and performance. This study analyzed the registration effect of the DBSCAN algorithm by constructing corresponding main planes at chessboard positions obstructed by objects such as packaging boxes and brochures. Table III shows the display effect.

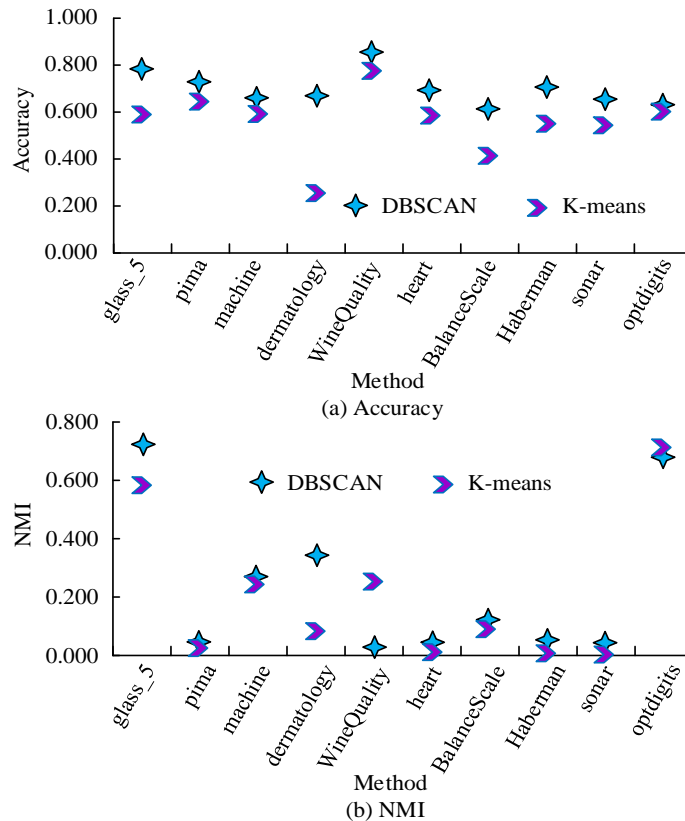

Fig. 9. Clustering results of different algorithms.

TABLE III. REGISTRATION EFFECT OF THE ALGORITHM

Scene	Number of environmental characteristic points/piece	Maximum number of points in the cluster/number	Time consumption/s
Black and white chessboard	119	106	0.156
Packaging box	158	95	0.180
Occlusion composite scene	251	169	0.308
Brochure	108	80	0.090

In Table III, the time consumption of algorithms varied depending on the scenario. Compared to other scenes, occluding composite scenes took up to 0.308 seconds, which was 0.218 seconds more than brochure scenes. Therefore, the real-time performance of the virtual object registration module was good. Table IV shows the time consumption of the drawing and tracking threads in the PTAM component.

In Table IV, when the number of keyframes was less than 50, local BA optimization and global BA optimization took less time, which were 170ms and 381ms, respectively. As the number of keyframes increased, the drawing thread's time consumption increased. When the key frame rate was between 100 and 149 frames, the global BA optimization took 6900ms. Overall, compared to other processes, the feature point measurement process took more time. When in the living room,

projecting feature points took 3.5ms, which was 6.3ms less than the feature point measurement process in the same environment. Overall, each process of tracking threads took less than 20ms. Overall, the performance of PTAM components was good. Twenty users were randomly selected and rated on a scale of 1-5. The satisfaction evaluation data of the system application was collected through a survey questionnaire, as shown in Fig. 10.

In Fig. 10, compared to before system optimization, the optimized user satisfaction was higher. Overall, the user satisfaction score ranged from 3.50 to 5.00. Among them, after system optimization, the average user satisfaction score was 4.43 points, which was 0.30 points higher than before system optimization. Therefore, the application effect of the constructed AR system was outstanding.

TABLE IV. RELATED TIME CONSUMPTION

Stage	Keyframes/Frame		Local BA optimization/ms	Global BA optimization/ms
Drawing Thread	2-49		170	381
	50-99		277	1700
	100-149		445	6900
Tracking threads	Flow	Living room/ms	Bedroom 1/ms	Kitchen/ms
	Projection feature points	3.5	2.6	3.0
	Update camera pose	3.5	2.9	2.8
	Get keyframes	2.3	3.1	2.9
	Measurement of feature points	9.8	8.4	9.5

Fig. 10. User satisfaction with the system before and after optimization.

V. CONCLUSION

To achieve color interactive design for users, enhance their sense of participation and experience, this study used IST and AR-VIT to design furniture styles, achieving the goal of user color interactive design for furniture. Firstly, the CycleGAN algorithm was introduced for IST, and the overall performance of the algorithm was improved through identity loss functions and other means, making it convenient for users to design personalized furniture colors and styles. Subsequently, AR-VIT was introduced, and virtual model registration was performed using the DBSCAN algorithm, followed by the design of an unlabeled AR furniture system. The results showed that the improved CycleGAN algorithm performed better. When the number of iterations was 35, the SSIM value of the research method was 0.547, which was 0.135 higher than the MUNIT algorithm, while the SSIM value of the CycleGAN algorithm was the smallest. The IS value of the research method was 3.242, which was 1.635 higher than the CycleGAN algorithm. Compared to K-means, DBSCAN algorithm had higher accuracy and NMI. In the glass_5 dataset, the maximum accuracy of the DBSCAN was 0.854, which was higher than the K-means. In the PTAM component, the tracking thread took less time. When in the living room, the projection of feature points took 3.5ms, which was 6.3ms less than the feature point measurement process in the same environment. The user satisfaction after system optimization was relatively high, with an average satisfaction score of 4.43. Overall, the application effect of the research method is good. At present, the research method only considers the design content of color design in furniture design, and has not yet conducted targeted design for furniture appearance, structure, and material design, and cannot participate in the complete furniture design process. Subsequent research will focus on designing other aspects involved in furniture design, and integrate existing processes with other aspects to design furniture design methods that can meet more design needs and expand the scope of research methods.

Faculty of Computer Science and Information Technology, Universiti Malaysia Sarawak, Sarawak, Malaysia¹

Abstract—The potential of Internet-of-Things (IoT) in healthcare is evident in its ability to connect medical equipment, sensors, and healthcare personnel to provide high-quality medical expertise in remote locations. The constraints faced by these devices such as limited storage, power, and energy resources necessitate the need for a lightweight authentication mechanism that is both efficient and secure. This study contributes by exploring challenges and lightweight authentication advancement, focusing on their efficiency on the Internet-of-Medical-Things (IoMT). A review of recent literature reveals ongoing issues such as the high complexity of cryptographic operations, scalability challenges, and security vulnerabilities in the proposed authentication systems. These findings lead to the need for multi-factor authentication with a simplified cryptographic process and more efficient aggregated management practices tailored to the constraints of IoMT environments. This study also introduces an extended taxonomy, namely, Lightweight Aggregated Authentication Solutions (LAAS), a lightweight efficiency approach that includes a streamlined authentication process and aggregated authentication, providing an understanding of lightweight authentication approaches. By identifying critical research gaps and future research directions, this study aims to provide a secure authentication protocol for IoMT and similar resource-constraint domains.

Keywords—Lightweight authentication; Aggregated Authentication; Multi-Factor Authentication (MFA); Internet-of-Medical Things (IoMT)

I. INTRODUCTION

In the age of the Internet of Things (IoT), the integration of devices and networks has spread to the healthcare industry, resulting in the Internet of Medical Things (IoMT). These networks comprise interconnected medical equipment, sensors, and systems that allow for real-time observation, data collection, and analysis, improving patient care and healthcare delivery efficiency [1]. However, the use of IoT devices in medical settings raises concerns about security and privacy. Unauthorized access to these networks can result in data breaches, and exposing sensitive patient information necessitates robust security measures, particularly in the realm of authentication. It is critical to safeguard against unauthorized access and other cyber threats to ensure a secure and trustworthy authentication mechanism in IoMT environments.

Authentication as described by NIST, is the legitimacy of one's identity and an authenticator [2]. In general, authentication is the process of verifying the identity of a user, entity, or device attempting to access a network or system. Authentication is essential to all facets of private access, including access control to data and resources that are only available to specific entities. These processes include verifying credentials like passwords, digital certificates, or biometric information against a known set of registered identities in an authentication server or directory.

Authentication in IoMT is a multifaceted challenge due to the diverse range of devices, communication protocols, and the stringent requirements for data integrity and privacy. Traditional authentication methods, such as password-based schemes, are often inadequate in this context due to their susceptibility to various attacks, including replay attacks, man-in-the-middle (MITM) attacks, and impersonation attacks. Consequently, there has been a significant shift towards adopting more sophisticated authentication mechanisms, such as token-based, biometric, and multi-factor authentication (MFA) protocols. Despite these advancements, existing authentication protocols in IoMT still face several limitations. Many protocols are either too complex, resulting in increased computational overhead which is unfit for resource-constraint devices, or weak cryptographic techniques that are insufficiently secure against emerging threats. Thus, the development of lightweight authentication schemes, especially for IoMT, has been the subject of several studies to cater to resource limitations while providing secure communication and data exchange within the medical network.

This study aims to look further into lightweight approaches using various authentication credentials and their efficiency. Thus, this review attempts to evaluate the lightweightness approaches used and the limitation of existing authentication mechanisms in IoMT to give healthcare providers insight into best practices for securing these networks. This study also presents the background study of authentication solutions using a lightweight approach. Furthermore, current literature that employed a lightweight approach for IoMT is reviewed to obtain a better understanding of the requirements for healthcare settings. Thus, this study presented two contributions which are an extended authentication taxonomy, emphasizing lightweight approaches and multi-factor authentication solutions based on the existing work by Alsaeed and Nadeem [3], and a review of

recent existing works on authentication mechanisms using a lightweight approach that is particularly suited for IoMT environments. By categorizing and analyzing these protocols, this study seeks to highlight existing gaps and suggest potential areas for further research and development.

The remainder of this study is organized as follows. Section II illustrates the background study of the multi-factor authentication mechanism focusing on lightweight approaches. The extended authentication taxonomy is introduced in Section III with two lightweight authentication efficiency approaches: streamlined authentication process and aggregated authentications. Section IV presents a review of recent (2020-2024) related works on existing authentication mechanisms in IoMT. A discussion of the review is presented in Section V with identified research gaps and future works. Finally, the conclusion is included in Section VI.

II. BACKGROUND STUDY

The healthcare industry has undergone a significant transformation with the advent of the Internet of Medical Things (IoMT). IoMT refers to the interconnected system of medical devices and applications that communicate through networking technologies to collect, analyze, and transmit health data [4]. This interconnected network allows for continuous, real-time monitoring of patients, leading to improved healthcare delivery, personalized treatment plans, and enhanced patient outcomes [5]. The integration of IoMT in healthcare has revolutionized traditional practices, making remote monitoring, telemedicine, and mobile health (mHealth) increasingly viable and effective.

With the increasing deployment of IoMT devices, ensuring the security and privacy of sensitive medical data has become a paramount concern [6]. Authentication is the first security layer and a critical security mechanism that verifies the identity of users and devices, ensuring that only authorized entities can access the system to protect from malicious security threats and data breaches [7]. Given the sensitive nature of medical data, any compromise can have severe implications, including incorrect diagnosis, treatment errors, and potential harm to patients.

As depicted in Fig. 1, a typical access system within an IoMT environment to ensure secure and efficient access control and data integrity across interconnected medical devices adopted from Anca et al. [8]. Access control has two important counterparts: the authentication and authorization processes, to enforce permissions for legitimate users or devices. Various factors such as passwords, biometrics, tokens, and multi-factor authentication are used when a user or a device wishes to attempt the system and the authentication mechanism will verify these credentials against stored data or through real-time verification. The author incorporates a lightweight mechanism into the authentication process model to ensure that the authentication process is efficient and uses minimal computational resources. On the other hand, the authorization database plays an important role in storing relevant credentials and permissions, in which the system administrator manages to maintain system integrity. Putting all together, this highlights

the importance of integrating lightweight solutions to handle the difficulties presented by the heterogeneous and resource-constraint in IoMT ecosystem without sacrificing scalability or performance.

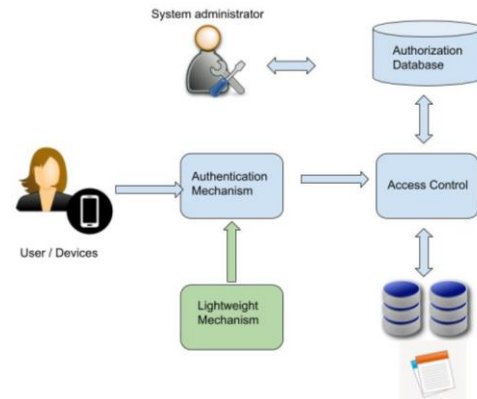

Fig. 1. Typical access system integrating lightweight mechanism in the authentication process (adopted from Anca et al. [8]).

Additionally, the diversity of devices and communication protocols used in IoMT environments necessitates adaptable and interoperable authentication solutions. As of March 2020, IEEE has published a new architectural standard for IoT, in response to the numerous unstandardized frameworks of IoT that have been proposed by researchers and industry. The goal of this standard is clear, to facilitate heterogeneous interaction, system interoperability, and the industry's continued development and scalability. According to one of the two standards, the P2413.1 RASC - Standard for a Reference Architecture for Smart City, defines a Reference Architecture with a four-layer architecture: device layer, communication network layer, IoT platform layer, and application layer [9]. Fig. 2 is the potential design used to develop IoMT authentication-role-specific architecture with reference to the P2413.1 RASC architecture.

In Fig. 2, the architecture of IoMT typically involves multiple layers: the device layer, communication layer, IoT platform layer, and application layer. Each layer faces unique security threats, and robust authentication mechanisms are essential to safeguard the entire IoMT ecosystem. The device layer comprises numerous wearable devices and medical sensors that collect medical information [10, 52]. This layer initiates the authentication process with basic verification of devices and initial user authentication, ensuring that data collected from legitimate sources is securely transmitted. Next is the network layer, which uses technologies such as Wi-Fi, Bluetooth, and cellular networks for secure data transmission and network authentication to healthcare providers and cloud services to prevent unauthorized access [11]. Moving up, at the IoT platform layer, intermediate authentication mechanisms are implemented to verify the integrity of data and devices before further processing or transmission to the cloud. Finally, the application layer encompasses comprehensive authentication and authorization processes, ensuring that only verified users and devices can access sensitive medical data and analytics services.

Fig. 2. IoMT authentication-role-specific architecture.

Further discussion on authentication is not complete without a reference to the four levels of security assurance. According to NIST, there are four levels of security assurance for authentication processes [12]. This structured framework provides specific requirements for identity proofing, authentication methods, and threat resistance vary depending on the level as depicted in Fig. 3.

There are several authentication levels and processes involved in authentication for IoMT. A typical usually involves 1) device registration, 2) user registration-this process verifies the identity of the users accessing the IoMT system, and 3) data access control, which ensures that only authorized users can access sensitive medical data. Each stage requires a robust authentication mechanism (in Fig. 2) to ensure the integrity and confidentiality of the transmitted health information At Level 1, device registration. In this stage, medical devices are registered with the healthcare network, often involving the generation and exchange of cryptographic keys. Basic verification using a simple authentication mechanism might be used at the device layer, suitable for initial health data collection. Moving up to Level 2, a more robust identity verification and single-factor authentication would be applied at the communication layer, to resist security attacks such as replay and eavesdropping for secure data preprocessing and transmission. Level 3 and Level 4 are essential in the cloud layer, where multi-factor authentication and strong encryption methods are used to safeguard information during data analysis and long-term storage. This setup offers protection against cyber-attacks like MITM attacks ensuring that only authorized users and devices can access important medical data. This hierarchical application of assurance levels provides as a basis across the IoMT architecture to ensure a thorough security approach is established, tailored to the needs and capabilities of each layer.

However, the unique characteristics and distributed nature of IoMT devices present several challenges for a robust authentication mechanism making it challenging to implement complex and computationally intensive authentication protocols. Moreover, limited processing power and memory in many resource constraints IoMT devices pose challenges for deploying strong authentication mechanisms like multi-factor

authentication (MFA) or cryptographic techniques. These constraints necessitate the development of lightweight, yet secure authentication solutions tailored to the capabilities of IoMT devices. Thus, it is imperative to have an authentication mechanism that can minimize computational and communication overhead as well as energy consumption while maintaining robust security measures. There are a few possible existing authentication approaches in the IoMT system which include approaches like lightweight cryptography, lightweight multi-factor authentication, and lightweight hybrid anomaly detection [5]. For instance, lightweight cryptographic algorithms such as elliptic curve cryptography (ECC) and physically unclonable functions (PUFs), offer strong security with reduced resource requirements [13], [14], [15], [16]. In general, the characteristics of any lightweight algorithms can be defined as follows:

- 1) *Low computational complexity:* Algorithms that require fewer computational cycles to execute [17].
- 2) *Minimal memory usage:* Less memory is used for both code and authentication data [18].
- 3) *Energy efficiency:* Optimized for low power consumption, crucial for battery-operated devices [19].
- 4) *Small key sizes:* Use of smaller cryptographic keys to reduce processing overhead while maintaining security [20].

Fig. 3. Four security assurance levels by NIST.

Researchers focusing on developing authentication solutions strive to find a balance between security and resource efficiency to address security risks in IoMT environments. Efforts in lightweight authentication research often concentrate on creating solutions to meet this need. Many studies have investigated aspects of lightweight cryptography and

authentication schemes in the wider IoT context, but a focused look within the specific IoMT realm is lacking. Research efforts have mostly focused on cryptographic techniques, with varying attention to the details of data transmission and authentication within IoMT. The works of Sallam and Beheshti [21] have added a lot to understanding the applicability of lightweight cryptography and studies ongoing developments in the realm of IoT, but there's a gap in having a thorough streamlined authentication approach specific to IoMT is still lacking. As the number of connected medical devices and the complexity of IoMT environments grow, ensuring efficient authentication at scale becomes increasingly crucial to meet the healthcare industry's demands. Moreover, while some studies have talked about potential attacks on lightweight cryptography, there's not much literature systematically analyzing the aggregated authentication mechanism necessary in IoMT. The authors aim to fill these gaps by putting together and critically looking at the existing knowledge, and finding areas where more investigation is needed. Through this, the authors hope to offer an updated and consolidated understanding of lightweight cryptography and authentication in IoMT, pushing forward improvements in the security of healthcare IoT systems. Nonetheless, despite these limitations and challenges, continued research and development in lightweight authentication mechanisms are necessary to enhance security efficiency, particularly in healthcare settings.

III. EXTENDED AUTHENTICATION TAXONOMY

A well-defined taxonomy for authentication on the Internet of Medical Things (IoMT) is essential to enhance the understanding of this complex topic and address the interrelationships among various elements within IoMT systems. In recent years, numerous security solutions have been created and put forth. However, it remains considerably challenging to produce a competent solution for authentication in a resource-constrained network. One of the main challenges is to provide a lightweight authentication solution, tamper-proof to security threats for IoT applications specifically in the field of medical IoT. The extended taxonomy is built upon an existing authentication taxonomy by Alsaeed and Nadeem [3]. There are seven main perspectives in Alsaeed and Nadeem's taxonomy. The taxonomy is further categorized by the authors according to the following axes:

- Authentication Factors comprised of Type of Credentials, Authentication Levels, and Authentication Procedure. This study will focus on the type of credentials used in the authentication processes in recent literature as different types of credentials have varied impacts on the lightweightness of an authentication process. Authentication Procedures consist of One-way authentication verifies one entity to another, two-way (mutual) authentication verifies both entities to each other, and three-way authentication involves a third trusted entity in the process. The selection of credentials should align with the specific limitations and needs of the IoMT environment, ensuring a balance between lightweightness and security.
- Authentication Schemes which refer to authentication architectures and authentication categories.

Authentication architectures include both centralized and decentralized architectures, which are further divided into flat and multi-level approaches. Authentication categories differentiate between static and continuous authentication.

- Authentication attacks, address various authentication attacks and the measures taken to prevent them, such as resistance to guessing, impersonation, man-in-the-middle attacks, etc.
- The fourth axe is on the authentication solutions which include basic authentication methods, key-agreement used in authentication, cryptography-based and certificate-based schemes. And finally, the extended taxonomy on lightweight authentication mechanisms. The lightweight mechanism includes streamlined authentication processes and aggregated authentication which include approaches designed to optimize performance by reducing computational and communication overhead, resource usage, and response time, which are key attributes of efficiency in authentication protocols.

Furthermore, several key aspects must also be considered when designing a lightweight authentication mechanism for IoMT to ensure that the system is secure, efficient, and compatible with resource-constrained devices such as medical devices. These aspects can be categorized into four aspects: Security robustness, Lightweight Efficiency approach, Compatibility approach, and Usability approach. This study explores two areas in terms of multi-criteria authentication taxonomy based on the work of Alsaeed and Nadeem [3] and Agrawal and Ahlawat [22].

1) *Security robustness*: Firstly, the security mechanism must be robust. The security approach primarily focuses on the authentication strength such as using strong cryptographic methods and multi-factor authentication[23], [24], [25], [26]. One of the challenges is that implementing robust encryption without significantly impacting device performance can be difficult.

2) *Lightweight efficiency approach*: The efficiency for authentication should cover the key design considerations such as the low computational overhead that can adapt to IoMT devices with limited processing power by employing lightweight cryptographic algorithms [27], [28]. Recent advancements in lightweight cryptographic algorithms have shown significant potential in improving the efficiency of IoMT authentication processes. Using lightweight cryptographic primitives such as Elliptic Curve Cryptography (ECC) and hash functions provides strong security with minimal computational resources [15], [29]. Thus, selecting the right cryptographic primitives in the authentication process is crucial. For instance, the work of Chatterjee et al. [29] demonstrated the effectiveness of ECC and hash-based schemes in IoT security, highlighting their suitability for resource-constrained devices. Furthermore, the integration of aggregated authentication techniques such as batch processing and shared key generation, streamlines the authentication process, reduces communication overhead, and

improves scalability, making them suitable for dynamic IoMT environments where devices frequently join and leave the network.

3) *Compatibility approach*: Some of the well-known standard protocols such as OAuth 2.0 or FIDO are required to ensure the authentication mechanism is interoperable with a wide range of IoMT devices and platforms. Scalability remains the biggest hurdle within the IoMT ecosystem due to the growing number of devices and diverse platforms.

4) *Usability approach*: The usability approach centers around the authentication process that should never be overlooked. The authentication factors should be user-friendly employing methods such as biometric authentication for ease of use [30]. Challenges include designing authentication mechanisms that are both user-friendly and secure can be conflicting goals.

This study will further investigate lightweight efficiency approaches to fulfill the study goal. To identify the best authentication efficiency approaches for lightweight mechanisms were studied through existing recent literature. In a survey by El-hajj et al. [31], the author provides a comprehensive review of lightweight authenticated encryption for IoT devices, using a multi-criteria classification approach. The authors evaluate various aspects of authentication methods to assess their strengths and weaknesses, including security robustness, computational efficiency, scalability, simplicity of implementation, resilience to attacks, compatibility with existing systems, and usability. By considering these evaluation parameters, the authors compare the efficiency of different authentication techniques in IoT applications. The assessment of lightweight design, multi-factor authentication, and encryption technique usage provides insights into the efficiency and effectiveness of authentication methods in securing IoT devices while optimizing resource utilization.

In another survey done by Agrawal and Ahlawat [22], they review the authentication schemes based on three different parameters which are lightweight, multi-factor authentication, efficient, and encryption technique usage. According to the

authors, these three classifications based on their reviews are important considerations in determining authentication efficiency. They also compared the efficiency of different authentication techniques in IoT applications and assessed whether any of the criteria used are preferred to ensure efficient operation in resource-constraint IoMT environments. The authentication protocols can be designed according to various factors. Two-factor authentication consists of utilizing user identification and biometric data to grant access to the IoMT system [32]. On the other hand, multi-factor authentication is the combining different elements such as user possession, inheritance and knowledge credentials to increase security [33], [34]. Many authentication approaches rely on multi-factors to enhance security and provide more resilient authentication solutions to protect from any adversary breach [26]. Thus, the presence of multi-factor authentication needs to be considered in the comparison to determine the efficiency of the authentication method [19].

On the other hand, the authors Samal et al. [35], classified authentication protocols into five different domains which are mutual authentication, one-time password, public key cryptography, zero-knowledge proof, and digital signature. They further classified three different categories for cryptographic algorithms such as 1) Encryption algorithms, 2) Signature algorithms, and 3) Hashing algorithms. These cryptographic techniques should be implemented efficiently to avoid the excessive computational burden of IoMT devices [35].

Thus, taking into account the analysis from the previous section, this study provides the extended version (Lightweight Aggregated Authentication Solutions, LAAS) of the authentication solutions taxonomy by Alsaeed and Nadeem [3] by adding in another authentication solution, namely under the lightweight approach, with its two methods; streamlined authentication process and aggregated authentication, as shown in Fig. 4 (illustrated in dashed rectangle box) to be well-suited for a resource-constraint environment such as IoMT. The details of these two methods are discussed in the next subsections.

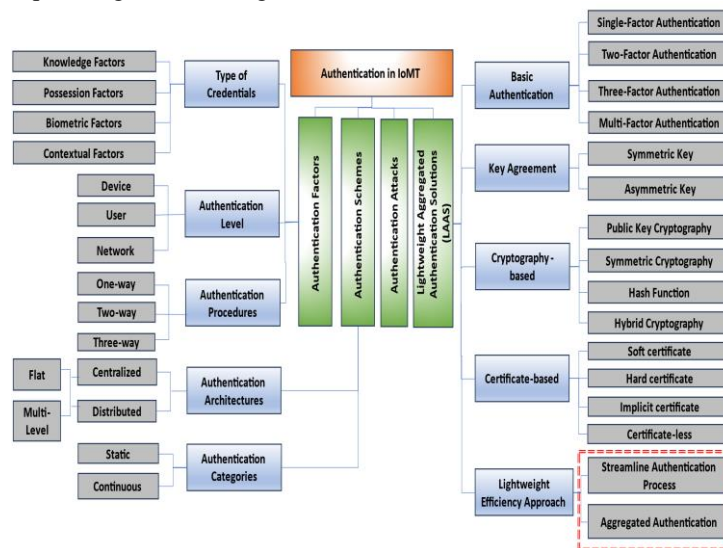

Fig. 4. Extended taxonomy for authentication in IoMT.

B. Lightweight Efficiency Approaches

1) *Streamlined authentication process*: It has been observed in recent years that lightweight authentication schemes were being proposed by numerous researchers at different times to increase system efficiency. According to Alsaeed and Nadeem [3], the number of exchanged messages during authentication processes will immediately affect the authentication scheme performance. Reducing the number of messages in an authentication protocol can be a strategy to make the algorithm lightweight, but it is not the sole criterion. As depicted in Fig. 4, the authors used an extended term to refer to this lightweight approach in authentication which is a streamlined authentication process that refers to the reduction in the complexity and number of steps involved in the authentication process. These lightweight authentication algorithms typically involve based on the usage of multiple factors such as 1) Symmetric key lightweight protocols, a lightweight algorithm that is being used during the pre-shared key exchanges, secure and shorter key sizes for encryption and decryption operations. 2) Hardware-assisted lightweight solutions such as PUF-based authentication 3) Biometric-based authentication like fingerprint recognition or 4) Simplified cryptography primitives, such as XOR, concatenation, and hash operations to support processing capabilities of IoT devices. Current literature agrees that streamlined authentication processes in authentication are the key essential in any lightweight solutions to enhance security while minimizing resource scarcity and computational complexity [3], [13], [36], [37]. Often, simpler cryptographic operations are used such as using only hashing and XOR to minimize the overhead complexity so that it is lightweight enough for a resource-constrained environment [38], [39], [40], [41]. Therefore, all the above factors are vital aspects of streamlined authentication, enhancing the practicality and performance of security mechanisms in real-time, high-frequency authentication scenarios in IoMT and similar applications. However, the challenge is to streamline the authentication process and keep a high level of security. In the context of the IoMT environment, this is crucial as we are dealing with time-sensitive healthcare applications, thus a high level of security is the utmost priority.

2) *Aggregated authentication*: Implementing a robust authentication mechanism in IoMT poses several challenges. As pointed out in the previous section, resource constraints in IoMT devices are the main challenge as these devices often have limited computational and energy resources, and the possible authentication solution is to make them lightweight. Apart from these main challenges, scalability issues are nothing new in IoMT environments. Handling the growing number of connected devices and users with one-to-one communication is inefficient for the massive communication required by today's IoMT-based applications.

Aggregated authentication in IoMT refers to combining authentication processes into a single operation, enhancing efficiency and reducing communication overhead [42]. Several

techniques are involved such as aggregating multiple authentication requests into a single process (batch processing) [43] and hierarchical aggregation which typically involves multi-level aggregation where data is aggregated at local/edge nodes before being sent to central servers [44]. These approaches are tailored to address the unique constraints of IoMT environments, ensuring that authentication processes are both secure and efficient.

This approach is particularly beneficial in environments where numerous small transactions occur frequently, as it can significantly reduce overhead, improve processing efficiency, and enhance overall system performance. In the context of lightweight authentication, aggregated authentication can be leveraged to streamline authentication processes, especially in systems like the IoMT where multiple authentication requests might occur simultaneously from various medical devices and sensors. By bundling these requests, the system can handle them more efficiently, minimizing computational load and reducing latency. This method aligns well with the principles of lightweight authentication, which aim to provide secure, efficient, and low-overhead authentication mechanisms suitable for resource-constrained environments. Therefore, incorporating aggregated authentication into lightweight authentication schemes can further enhance their efficiency and effectiveness, making them an attractive solution for real-time, high-frequency authentication scenarios in IoMT and other similar applications.

IV. RELATED WORKS

To address the need for lightweight multifactor authentication schemes, several research works have been conducted in recent years. In [45], they proposed a lightweight multifactor authentication [51] scheme for cellular networks, exclusively 5G, and a trust-based blockchain architecture for VANET to mitigate major communication attacks using blockchain technology. In a subsequent paper, they extended this work to propose a lightweight multifactor authentication security scheme for a multi-hop scenario using timestamping, one-way hash function, Blind-Fold Challenge scheme with public key infrastructure with reduced authentication overhead, computation cost, and communication cost [23]. They also contributed to this area by proposing a lightweight multifactor authentication protocol for multi-gateway WSNs using hash functions and XOR operations. Additionally, Xue et al. [41] used lightweight cryptographic primitives to propose a lightweight three-factor anonymous authentication approach in multi-gateway WSNs using hash functions and XOR operations. These works collectively demonstrate the ongoing efforts to develop efficient and secure lightweight multifactor authentication schemes for various network scenarios, including cellular networks, WSNs, and healthcare applications.

In another research effort, Atiewi et al. [46] introduced a lightweight multifactor secured smart card-based user authentication for cloud-IoT applications, emphasizing the importance of scalability and security in big data IoT systems. To tackle the resource-constraint issues in the IoMT, it is significant to use lightweight multi-factor cryptographic algorithms, such as block ciphers and hash functions to enhance

data confidentiality, integrity, and secure authentication [28]. Hash functions and block ciphers are a few examples of lightweight cryptographic algorithms that can be applied in IoT devices to achieve strong protection against unauthorized access and data breaches. These cryptographic primitives, which offer effective encryption, safe authentication methods, and data integrity verification are necessary to guarantee the security of the system.

On the other hand, Gumis et al. [24], proposed a biometric blockchain-based multifactor privacy-preserving authentication scheme for Vehicular Ad Hoc Networks (VANETs). The scheme employs Physical Unclonable Functions (PUF) and one-time dynamic pseudo-identities as authentication factors, providing lightweight and privacy-preserving authentication for VANETs. PUFs have gained widespread use in user authentication protocols, leveraging a device's distinct physical characteristics for authentication rather than easily replicable passwords and secret keys [47], [48].

In a related study, Malik et al. [49] proposed a lightweight certificate-based authentication scheme for IoT devices and networks, introducing L-ECQV, a lightweight certificate profile of ECQV implicit certificates, and suggesting the inclusion of PUFs for multi-factor authentication. The study provides insights into certificates and PUFs in lightweight authentication protocols, contributing to the development of an enhanced two-factor authentication protocol. Additionally, the work by Ebrahimabadi et al. [50] addressed the threat of PUF modeling by employing multifactor authentication, including a shared cryptographic key alongside the Challenge Response Pair (CRP), to enhance the resilience of authentication protocols for IoT devices. This illustrates ongoing efforts to counter specific security threats through multifactor authentication, contributing to the advancement of lightweight authentication mechanisms for IoT environments.

Other related work includes researchers working on the same authentication area using the blockchain model proposing various approaches and evaluating their work against various security threats using formal or informal security analysis on the Internet of Medical Things. The work of [39], [44], and [45] proposed that apart from using multifactor authentication and lightweight cryptography to enhance security and optimize efficiency, it is essential to integrate blockchain technology between IoT and cloud environments that could provide an additional layer of security and transparency, ensuring the integrity of data and transactions. Thus, it is crucial to have a balance of security and efficiency for resource-constrained WSN nodes, considering factors such as energy consumption and computational overhead.

Therefore, the comparison of several recent related works on authentication is selected and discussed in Table I. These fourteen related works (2020-2024) on multi-factor authentication are selected in the domain of Internet-of-Medical-Things (IoMT) and Blockchain. The reviews are done based on the authors' contributions and summarize the findings reflecting on the extended authentication taxonomy (as depicted in Fig. 4). The results are shown in Table I.

V. DISCUSSION

As shown in Table I, there's a variety of authentication methods that have been employed in recent works, particularly within the context of IoMT. The first column insights are on the type of credentials. The most widely used model in the authentication process is often based on a combination of user identity, passwords, and biometric information. These multi-factor authentications are used in more recent studies to enhance security further. Using only single-factor authentication schemes, such as device information, pseudo-identities, and user tokens, is less prevalent compared to multi-factor authentication solutions. The reviewed articles show various lightweight authentication approaches suitable for resource-constrained environments such as in IoMT. Many of the proposed solutions emphasize a lightweight approach which is critical for resource-constraint IoMT devices. Common ones include the use of lightweight cryptographic algorithms (e.g., ECC), physically unclonable functions (PUFs), and lightweight cryptographic primitives such as XOR and hash functions are common. Most of the existing works implement a combination of asymmetric and symmetric cryptography, including Rivest-Shamir-Adleman (RSA) and secure hash algorithms. Some authentication solutions avoid the complexity of traditional certificate management by implementing implicit or soft certificates. Schemes like group authentication techniques based on Shamir's Secret Sharing (SSS) algorithm are employed to streamline the authentication process by reducing the number of blockchain transactions. Alsaed et al. [53] proposed work, distribute authentication credentials among multiple entities (e.g., fog nodes), and combine only a sufficient number as part of streamlining the authentication process to help reduce computational and communication overhead. It can be seen that some of the recent works proposed lightweight authentication schemes, utilizing solutions such as PUFs or blockchain technology, but they often still encounter significant increases in their computational overhead and complexity. Apart from that, not every proposed work addressed scalability issues, particularly concerning the computational overhead, resource utilization, and the management of key and authentication data. This is highlighted in protocols that rely heavily on blockchain technology or those with complex key management schemes. The limitations of each reviewed work are also presented in Table I in the last column.

In addition to reviewing the recent related works on authentication (as shown in Table I), a conceptual validation of the established benchmarks in the field is conducted against the proposed lightweight authentication approach. This validation focuses on varying levels of computational efficiency, security robustness, and scalability comparing them against the proposed method to illustrate its advantages and identify potential areas for further improvement. The conceptual validation table is presented in Table II.

As depicted in Fig. 4, the Lightweight Efficiency approach is a crucial authentication solution in IoMT environments, where resource constraints such as limited processing power are common. The techniques reviewed in Table II demonstrate varying degrees of efficiency, from high efficiency to medium, and low efficiency. High efficiency depicts those methods that involve low computational overhead, fast processing times, or

require minimal resources, making them suitable for resource-constrained environments. Existing methods that struggle with low scalability suffer performance degradation as the system

grows. Medium security is for methods that provide adequate security but may have vulnerabilities that could be exploited under certain conditions.

TABLE I. REVIEW OF RECENT RELATED WORKS

Related Works (2020-2024)	Authentication Factors	Authentication Solutions						Limitations
	Type of Credentials	Lightweight Approach		Basic Authentication	Key Agreement	Cryptography-based	Certificate-based	
		Streamline Authentication Process	Aggregated Authentication					
Edge IoT authentication protocol [54]	Pseudo-identity	No	No, single process	Single-Factor	Symmetric	Asymmetric ECC	Certificate-less	Computational Overhead Potential to replay attacks.
A Lightweight and Robust Secure Key Establishment Protocol for Internet of Medical Things in COVID-19 Patients Care [18]	Password and Device Authentication	Yes, PUF-based, Simplified cryptography primitives	No, single process	Multi-Factor	Symmetric key generation	Hash function	No	The reliance on device authentication can be a limitation if the device is stolen, as it could potentially be used to gain unauthorized access. Potential to side-channel attacks.
A Lightweight and Secure Authentication Scheme for Remote Monitoring of Patients in IoT [34]	User Identity, Biometrics, and Password	Yes, lightweight	No, single process	Multi-Factor	Symmetric and Asymmetric key generation	Hash function XOR operation Asymmetric ECC	No	Implementation Complexity
A framework introduces a group authentication technique [53]	Authentication Token	Yes, non-interactive and efficient	Yes, group key agreement reduces blockchain transactions. Hierarchical aggregation	Single-Factor	Group Authentication - Shamir's Secret Sharing (SSS) algorithm.	Asymmetric ECC Hash function	No	Implementation Complexity Potential vulnerability if fog node is compromised
Design of a novel lightweight and fast membership authenticated group key agreement scheme for resource-constrained IoT devices [55]	User Tokens	Yes, non-interactive and efficient, Simplified cryptography primitives	Yes, group key agreement combines processes	Single-Factor	Binary symmetric polynomials	XOR operation		Potential vulnerability if the Membership Registration Center (MRC) is compromised Complexity issues
Development of a Privacy-Protection Authentication Management Protocol [56]	User ID, Password and Biometric Information	No	No	Multi-Factor	Symmetric	Hash function	No	Computational overhead. Scalability concern.
Proposal of a lightweight anonymous authentication scheme based on consortium blockchain in the IoT [57]	User ID, Password and Biometric	Yes, lightweight	No	Multi-Factor	Pre-shared, Symmetric	Hash function XOR operation	Soft Implicit and Certificates	High complexity High computational cost

Develop a blockchain-based security system with light cryptography for user authentication security [58]	Biometric, Password	Yes, lightweight Biometric-based authentication	No	Multi-Factor		Symmetric Secure hash algorithm 256 (SHA-256) Shift-AES	Soft and Implicit Certificates	Computational overhead Scalability challenges The scheme may be prone to Biometric Spoofing.
Develop a framework that utilizes fog node computing in a Blockchain-based IoMT framework [59]	Device Information	Yes	No	Multi-Factor	Elliptic Curve, Digital Signature Algorithm (ECDSA), Diffie-Helman	Hash function	-	Complexity in implementation due to the integration of multiple technologies.
Design a blockchain-based secure authentication system to safeguard Electronic Health Record (EHR) data transferred over open channels. [60]	User identity, password, and Biometric information	Yes, lightweight Biometric-based authentication	No	Multi-Factor	RSA	Hash function XOR operation Symmetric AES	-	High computational cost due to the complexity of the authentication process
A novel approach to authentication using mobile agents, elliptic curve cryptography, and a challenge/response mechanism in IoT-based healthcare systems [61]	Challenge/response system with a secret commitment key	Yes	No	Multi-Factor	Public-key cryptography	Hash function XOR operation Asymmetric ECC	No	High complexity Adoption and integration challenges
A lightweight authentication protocol that uses Physically Unclonable Functions (PUFs) to establish a connection between a fog node and a smart device [62]	Physical Unclonable Function (PUFs)	Yes, Implicit Certificates	No	Multi-Factor	Asymmetric	Asymmetric ECC	Implicit Certificates	High complexity Key management issues
An improved three-factor-based data authentication scheme (TDTAS) [63]	Smart card, password, and biometric information	Yes, lightweight	No (Individual Device Authentication)	Multi-Factor	Asymmetric	Asymmetric ECC Hash function XOR	Hard Certificates	High computational cost Scalability concern Lack of formal verification
A novel blockchain-based authentication and key agreement protocol tailored for secure health data sharing within a cooperative hospital network [64]	User's identity, password, and Biometric information	Yes	No	Multi-Factor	Asymmetric	Asymmetric ECC	Soft and Implicit Certificates	Scalability issues Computational overhead for storing and managing authentication data

TABLE II. CONCEPTUAL EVALUATION OF THE RECENT RELATED WORKS

Ref	Efficiency	Security Robustness	Scalability	Advantages
[54]	High	Medium	Medium	Efficient ECC-based authentication. Privacy-preserving pseudo-identity. Robust against various attacks.
[18]	High	Medium	Medium	Efficient authentication using lightweight cryptography. Anonymity and privacy preservation. Robust against replay, MITM, and impersonation attacks.
[34]	High	High	Medium	Lightweight authentication for remote monitoring applications.
[53]	Medium	Medium	High	Supports scalability by allowing many devices to be authenticated efficiently.

[55]	High	Medium	High	Lightweight and efficient with XOR operations. Scalable. Robust against various attacks with forward and backward secrecy.
[56]	Medium	High	Medium	Strong security with blockchain and Chebyshev chaotic maps. Privacy-preserving with user anonymity. Comprehensive security analysis.
[57]	Medium	High	Medium	Lightweight and efficient with XOR and hash functions. Scalable with consortium blockchain. Robust security with anonymity protection.
[58]	Medium	Medium	Medium	Lightweight cryptography with Shift-AES. Achieve security with blockchain integration. Privacy-preserving hybrid authentication
[59]	Medium	High	Medium	Comparable efficiency with fog computing. Scalability through decentralized blockchain and IPFS. Robust security with ECDSA
[60]	Medium	High	Medium	Robust security with blockchain and RSA. Comprehensive security analysis. Privacy-preserving multi-factor authentication.
[61]	Medium	High	Medium	Robust security with ECC and blockchain. Distributed processing with mobile agents. Anonymity and privacy preservation.
[62]	Medium	High	Medium	Ensure user anonymity, cross-fog authentication, and efficiency without the need for a trusted third party.
[63]	Medium	Medium	Medium	Strong security with ECC and multi-factor authentication. User anonymity and privacy protection
[64]	Medium	Medium	Low	Removed the dependency on centralized storage.

From Table II, the work of Soleymani et al. [54] demonstrates high efficiency, and medium scalability with modest security, making it suitable for moderately sized IoMT deployments where security is paramount, but resource constraints are a high priority. They prioritize efficiency using pseudo-identities. However, this approach often involves trade-offs, such as reduced security robustness in the case of replay attacks where an attacker captures and reuses valid pseudo-identity credentials to gain unauthorized access in subsequent sessions. The proposed method builds on these approaches by employing streamlined cryptographic operations that incorporate nonces or timestamps into the authentication process to ensure that each session or transaction is unique minimizing computational overhead while maintaining a robust security profile, thus offering a more balanced solution for resource-constrained environments.

For many existing IoMT authentication techniques, scalability continues to be a major concern. The work of [53] and [55] demonstrates high scalability as both introduce group-based authentication to reduce the computational load associated with individual transactions. While these solutions attempt to streamline the authentication process via blockchain and group key agreement, they often introduce additional complexity. The proposed approach, however, addresses these challenges by aggregating authentication tasks using only simple cryptographic operations such as XOR or lightweight block ciphers and consolidating multiple authentication steps into fewer, more efficient processes. This approach reduces the complexity typically associated with group authentication and ensures that the proposed method can effectively scale to meet the increasing demands of IoMT networks without compromising performance or security.

Furthermore, the work of Rani and Tripathi [64] in their "Blockchain-Based Authentication and Key Agreement Protocol" is evaluated as having medium efficiency and security with low scalability indicating its limitations in large-scale, resource-constrained IoMT networks. The proposed method addresses these challenges by enhancing efficiency through lightweight cryptographic algorithms that are

specifically designed for resource-constraint environments such as ECC over RSA for key agreement, using batch processing to authenticate multiple individual transactions, and minimizing the overall computational and communication overhead. This comparative evaluation helps to identify which methods are best suited for specific applications, particularly where the balance between these critical factors is essential.

In summary, the following research gaps are identified:

- Complexity and scalability of lightweight authentication algorithms. Despite several efforts made by the researchers to streamline authentication processes, many lightweight protocols still exhibit significant complexity. This complexity results from an authentication scheme that involves multiple steps, interactions, credentials (biometric authentication, fuzzy extraction, blockchain), key management, and integration of advanced cryptographic algorithms, which could limit the efficiency and scalability that is needed for a bigger-scale implementation in the IoMT ecosystem.
- Insufficient focus on Aggregated Authentication. Although some works streamline the authentication process by introducing aggregated authentication approaches such as group key agreements, these solutions are not widely adopted. Moreover, they introduce new vulnerabilities, particularly if key components are compromised. It is important to develop a robust security mechanism for aggregated authentication systems.

Thus, based on the identified research gaps in recent related works, this study intends to make recommendations for future work that addresses these issues. Consequently, the following are recommended for this study's future efforts.

- To design simplified cryptographic protocols that are lightweight and scalable. This involves streamlining cryptographic operations within the authentication processes with efficient key management techniques while maintaining robust security. For instance, further

exploration of lightweight block ciphers offering lower computational overhead could be beneficial.

- One of the key challenges in IoMT is minimizing the communication overhead associated with the authentication process. Future work should explore methods for reducing the number of authentication messages exchanged between entities, thereby creating a low communication overhead. This could involve designing protocols that aggregate or combine authentication messages without compromising security. Streamlining the communication flow is essential for ensuring the efficiency and scalability of authentication protocols in large, distributed IoMT networks.
- To develop adaptive group aggregation authentication techniques to address scalability issues in large-scale IoMT setups. Innovations in group key management might include the use of hierarchical key distribution schemes or dynamic rekeying methods that can adjust key distribution processes based on network demands and usage patterns, thereby enhancing both security and scalability.
- To identify necessary requirements for designing authentication algorithms that can mitigate majority security attacks in communication. This includes addressing vulnerabilities that arise from multi-factor authentication, group authentication schemes, and the use of lightweight cryptographic primitives. Future efforts should aim to create comprehensive security frameworks that can pre-emptively address potential attack vectors, ensuring that authentication protocols remain secure as they scale.
- To implement the proposed authentication algorithms and evaluate their performance to ensure robustness.

VI. CONCLUSION

The current research trend in lightweight cryptography and authentication algorithms is developed to provide a secure, efficient, and scalable solution tailored to the unique requirements of the IoMT devices and infrastructure. However, striking a balance between robust security and efficient authentication performance is a significant challenge. Although a great deal of research has been done to guarantee high security in various IoT applications, potential adversary attacks are still valid and exist in our modern days. Hence, the exploration of lightweight authentication methods, decentralized authentication models, and advanced cryptographic techniques is the future research direction in the field of authentication mechanisms in IoMT.

This paper provides a comprehensive analysis of lightweight authentication methods within the context of IoMT. Therefore, two contributions have been proposed in this study, and they are:

- The study contributes to a thorough review of existing works on lightweight efficiency approach, focusing on streamlined authentication processes and aggregated authentication protocols with other current authentication solutions proposed by the authors. This

review also highlighted the limitations of each approach and suggested the current state of lightweight multi-factor authentication approaches that can be used as a basis or guidance for future efforts to develop a more robust, secure, and scalable authentication protocol.

- This study also introduces the development of extended taxonomy (LAAS) for lightweight authentication protocols, emphasizing streamlining the authentication process and managing aggregated authentications. This taxonomy hopes to promote consistency against different authentication studies and contributes to the knowledge base for future researchers to develop more secure and efficient authentication mechanisms for IoMT and other similar environments.

As a conclusion, this study investigates the essential role of lightweight authentication in IoMT (Internet of Medical Things). Ensuring a secure and efficient authentication mechanism is vital to any healthcare system from malicious threats that can compromise sensitive medical data. The study analyzes recent related works on how lightweight approaches, particularly in streamlining authentication processes using various approaches such as multi-factor authentication, and other authentication solutions to identify its significant research gaps such as high computational cost, high complexity, and security vulnerabilities. It suggests that the authentication field requires further exploration to achieve more lightweight, secure, and scalable solutions. The proposed work suggests enhancing these authentication protocols through a streamlined authentication process using a more simplified cryptographic operation, multi-factor authentication, adaptive group management, and a secure encryption technique usage with the integration of advanced technologies like blockchain or AI. In a nutshell, this comprehensive review necessitates continuity for future development and innovations to safeguard the confidentiality, integrity, and functionality of the IoMT system.

ACKNOWLEDGMENT

The researchers express their gratitude to Universiti Teknologi Malaysia and Universiti Malaysia Sarawak for their valuable support in this study.

Dynamic Simulation and Forecasting of Spatial Expansion in Small and Medium-Sized Cities Using ANN-CA-Markov Models

Chengquan Gao

School of Architecture and Urban Planning, Henan University of Urban Construction, Ping'dingshan 467001, China

Abstract—This study utilizes the ANN-CA-Markov (Artificial Neural Network-Cellular Automata-Markov) model to address spatial planning and expansion challenges in China's small and medium-sized cities. With China's urbanization rate reaching 59.58% in 2018 and expected to hit 70% by 2030, the country is entering a mid-stage of urbanization, leading to rapid expansion of megacities and a gradual decline in smaller cities. The study aims to dynamically simulate urban spatiotemporal evolution and predict future land use changes, integrating land use data, DEM elevation, transportation, administrative centers, and ecological information. The model forecasts the ecological spatial layout of Wanzhou District by 2025, with results indicating a slight decrease in ecological space and an increase in construction land. This suggests a need to balance urban development with ecological sustainability amidst rapid urbanization. The study demonstrates the high accuracy of the ANN-CA-Markov model in predicting land use changes and provides valuable insights for urban planners in making informed land use decisions.

Keywords—ANN-CA; Markov; small and medium-sized cities; spatial; planning

I. INTRODUCTION

In 2018, China's urbanization rate reached 59.58%, and it is expected to hit 70% by 2030, marking the country's entry into the middle stage of urbanization [1-3]. Since 2011, China has been systematically revising its traditional urbanization approach, leading to the rapid expansion of megacities and the gradual decline of many small and medium-sized cities and towns. With the central government's strategic decisions to "establish a scientifically and reasonably structured urban pattern, where large, medium, and small cities and towns, as well as city clusters, are well-organized," new opportunities and broad prospects have emerged for the development of small and medium-sized towns. The healthy urbanization of these smaller cities requires more scientific planning and development of urban land resources by administrators [4, 5].

Scientifically defining urban development boundaries not only enables the intensive use of spatial resources and controls the disorderly sprawl of cities but also supports the sustainable socio-economic development of cities while protecting the natural ecological environment [6-9]. However, one of the major challenges in urban planning is accurately predicting the spatial and temporal evolution of land use, particularly in small and medium-sized cities where data may be less comprehensive, and urbanization patterns are more complex.

In recent years, numerous scholars have utilized the ANN-CA (artificial neural network-cellular automata) coupled model to dynamically simulate the temporal and spatial evolution of cities and predict future land use changes, assisting in urban land use simulation, urban development boundaries, and ecological redline protection in urban planning, achieving many meaningful results [10-12]. For instance, Xu et al. [13] integrated Artificial Neural Networks (ANN), Cellular Automata (CA), and Markov Chain (MC) to simulate urban expansion in rapidly urbanizing areas, revealing the nonlinear relationship between the expansion process and its drivers. Similarly, Zhao et al. [14] studied land-use changes in Yucheng District, Ya'an City, China using an ANN-CA model, emphasizing the improvement of simulation accuracy through appropriate thresholds and random variable parameters. Additionally, Asanza et al. [15] explored the integration of ANN and CA models for spatial-temporal land use forecasting, highlighting the enhanced forecasting accuracy through temporality and geospatial data analytics.

Despite these advances, challenges remain in effectively modeling and predicting land use changes in regions where data availability is limited or where the urbanization process involves complex interactions among multiple factors. The current study addresses these challenges by developing an enhanced ANN-CA-Markov coupled model that incorporates more comprehensive datasets and refined transition rules to achieve higher simulation precision. Specifically, this study leverages Wanzhou District's land use cover data, DEM elevation data, road traffic data, administrative center data, river data, ecological protection redline data, and natural conservation area data from 2000, 2006, 2012, and 2018. By integrating these data with the ANN-CA-Markov coupled model, we aim to predict the ecological spatial layout of Wanzhou District by 2025 more accurately.

The novel contribution of this work lies in overcoming the difficulties associated with limited data availability and complex urbanization processes by enhancing the precision of the ANN-CA-Markov model. This is achieved through the integration of additional data sources and the refinement of transition rules, offering a more comprehensive approach to modeling and predicting spatial changes. This study, therefore, represents a significant advancement in the field, particularly in the context of small and medium-sized cities where such challenges are most pronounced.

II. METHOD

A. ANN-CA Model

The ANN-CA model, short for Artificial Neural Network - Cellular Automata model, is a discrete time, space, and state grid dynamic model where spatial interactions and temporal causal relations are local. It enables the bottom-up simulation of the spatiotemporal evolution of complex systems. The state of each cell is determined by the states of its neighboring cells, and upon establishing transition rules, all cells can evolve autonomously following these rules, highlighting the core essence of transition rules. Artificial neural networks possess self-learning and associative capabilities, allowing for the rapid identification of optimized solutions [16-18]. By learning the rules of land use data changes through the neural network model and applying these extracted rules to the grid data of the starting year, simulation predictions can be completed within the cellular automata. The core principle involves training neurons with land use data from different periods, then determining the transition probabilities for each land use type based on the characteristics of influencing factors, culminating in the simulated prediction of land use planning. To ensure the model's accuracy, the input parameters were rigorously selected and optimized. The primary inputs include land use types, digital elevation model (DEM), neighborhood development density, and transition suitability. These parameters were chosen based on the terrain characteristics of the study area, the diversity of land use, and the complexity of its spatial distribution.

Extensive experiments were conducted to evaluate the impact of different parameter combinations on the model's predictive outcomes. Specifically, different neighborhood window sizes, DEM resolutions, and land use classification standards were tested. Sensitivity analysis revealed that the size of the neighborhood window significantly affects the model's spatial resolution and computational efficiency, while variations in DEM resolution notably influence the prediction accuracy. Ultimately, a 5×5 Moore neighborhood window and a 30-meter resolution DEM were selected as they offered the best balance between computational efficiency and prediction accuracy.

Additionally, the selection of transition suitability parameters was explored. These parameters primarily represent the likelihood of transitions between different land use types. During the parameter adjustment process, a stochastic disturbance factor was introduced to simulate unforeseen changes in real-world conditions. The final selection of these parameters was made based on a comparative analysis of multiple simulation results, tailored to the specific conditions of the study area. The mathematical expression is as follows:

$$P(k, t, l) = (1 + (-\ln \gamma)^\alpha) \times P_{ann}(k, t, l) \times \Omega_k^t \times \cos(S_k^t) \quad (1)$$

In this expression, it mainly expresses the transition probability P of a cell k at time t to the l -th type of land use as a function of random factors, artificial neural network calculated probabilities, neighborhood development density, and transition suitability. $(-\ln \gamma)^\alpha$ represents the random factor; $P_{ann}(k, t, l)$ is the transition probability of a certain land type calculated by the trained artificial neural network; Ω_k^t represents the urban land

density within the defined neighborhood window, i.e., the total number of urban land cells divided by the total number of grid cells in the neighborhood window; $\cos(S_k^t)$ represents the transition suitability between two land types, generally indicated by 0 or 1, mainly to signify whether a transition is possible.

B. Markov Model

The Markov model (Markov), based on a type of stochastic process is a mathematical method used to predict the prior probabilities and conditional probabilities of events [14-16]. Its changes over time are continuous, and when the process parameters take discrete time values, it is referred to as a Markov sequence. The primary feature of the Markov sequence is its Markov property, not time series property, meaning when the state of the process (system) at time t_0 is known, the state of the process (system) at time t ($t > t_0$) is independent of the state at time t_0 . The Markov model is an extremely important predictive model in geographic forecasting research. In constructing the Markov model, we meticulously adjusted the state transition probability matrix. The state transition probabilities primarily reflect the likelihood of transitions between different land use types within a specific time sequence. To ensure the accuracy of this probability matrix, we conducted several experiments to test the impact of different initial conditions and transition probabilities on the final predictive outcomes. Sensitivity analysis indicated that certain key parameters in the state transition probability matrix significantly influence the spatial distribution of the model's predictions. For instance, increasing the probability of converting arable land to construction land by 10% substantially increases the predicted area of construction land while decreasing the areas of forest land and water bodies. This highlights the need to adjust transition probabilities in accordance with real-world conditions. The Markov model mainly consists of states, state transition processes, state transition probabilities, and state transition matrices, detailed as follows:

- 1) *State*: Represents an outcome, indicating the result appearing at a specific point in time.
- 2) *State transition process*: The relationship between the state change of an event and time.
- 3) *State transition probability*: Refers to the likelihood of an event's state changing to another state, expressed mathematically as follows:

$$P_{ij} = P(E_i \rightarrow E_j) = P(E_j / E_i) \quad (2)$$

In the formula, P_{ij} and $P(E_i \rightarrow E_j)$ both represent the probability of the state transition of the event, $P(E_j / E_i)$ represents the conditional probability, and E_i and E_j respectively represent the state at moments i and j .

- 4) *State transition probability matrix*: If a specific event has n possible states, then the state transition probability from state E_i to state E_j is denoted as p_{ij} and expressed through a matrix as follows:

$$p = \begin{pmatrix} p_{11} & \dots & p_{1n} \\ \vdots & \ddots & \vdots \\ p_{n1} & \dots & p_{nn} \end{pmatrix} \quad (0 \leq p_{ij} < 1) \quad (3)$$

In the above expression, p represents the state transition probability matrix.

C. Construction of the ANN-CA-Markov Model

To simulate and predict the ecological space pattern of Wanzhou District, this study employs the CA-Markov model,

which combines the transition prediction capability of the Markov model with the spatial distribution simulation of cellular automata [17-19]. Traditional CA-Markov models face challenges in handling nonlinear relationships, so an artificial neural network (ANN) model is introduced to learn and establish more accurate transition rules. The process is divided into two stages: training and simulation. The operational logic of the model is illustrated in Fig. 1.

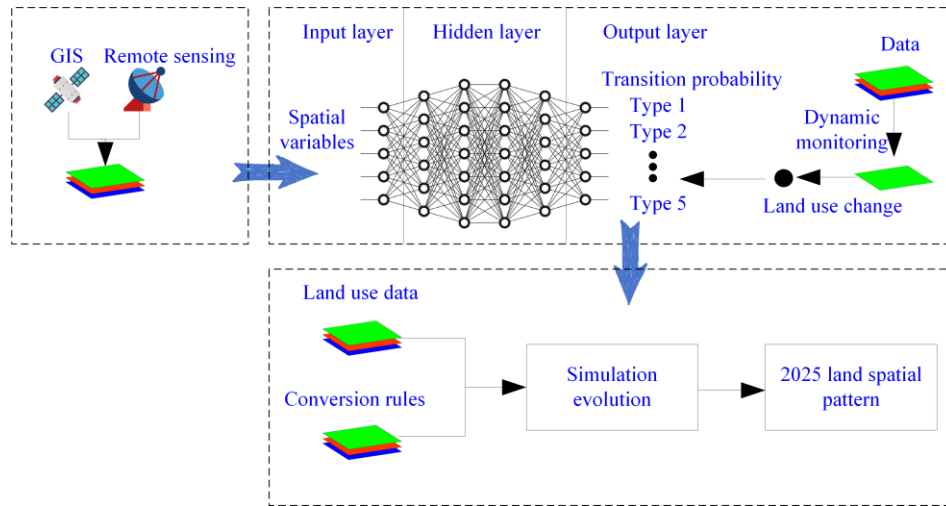

Fig. 1. Technical route map.

III. RESEARCH AREA AND DATA PROCESSING

A. Geographic Overview

Wanzhou District is located on the eastern edge of the Sichuan Basin, in the northeastern part of Chongqing. The Yangtze River flows into Wanzhou from the southwest, traverses northeastward, and then flows into Yunyang. Wanzhou District is situated between 107°55'22"E to 108°53'25"E and 30°24'00"N to 31°14'58"N. Lichuan and Shizhu are located to the south of Wanzhou District, Yunyang to the east, Liangping and Zhong County to the west, and Kaizhou District and Kaijiang to the north. The straight-line distance from Wanzhou District to Chongqing is 228 kilometers. Fig. 2 shows the location map of Wanzhou District.

Fig. 2. Location map of wanzhou district.

B. Data Sources

This study employed Landsat TM/ETM imagery for Wanzhou District from 2000, 2006, 2012, and 2018. The 2000, 2006, and 2012 data were sourced from Landsat-5 TM, while 2018 data came from Landsat-8, all acquired via the Geospatial Data Cloud (Table I). The imagery has a 30m×30m resolution, and the data were projected using the Albers projection. Additional data included 30m GDEM elevation data, OSM road, river, and administrative boundaries, and population data from the Chongqing Statistical Yearbook.

TABLE I. CLASSIFICATION STANDARDS FOR LAND USE TYPES IN WANZHOU DISTRICT

Land Category Code	Land Category Type	Detailed Types
1	Cultivated Land	Paddy fields, dry land
2	Forest Land	Forested land, shrub land, sparse forest, and other forest lands
3	Grassland	High, medium, and low coverage grasslands
4	Water Bodies	Rivers, lakes, reservoirs, ponds, tidal flats
5	Constructed Land	Urban areas, rural settlements, industrial and mining areas, transportation land
6	Unused Land	Bare land, sandy land, other types of unused land

C. Data Preprocessing

The study highlighted remote sensing image preprocessing importance using ERDAS 9.1 for band synthesis, geometric correction, and image cropping, enhancing data quality for

Wanzhou District. Band synthesis integrated different bands to improve image classification accuracy. Geometric corrections were applied using a third-order polynomial method to ensure pixel accuracy, while image cropping maintained research area consistency. The analysis involved visual and computer processing, adhering to “Current Land Use Classification” standards and incorporating field data and professional verification to achieve over 85% interpretation accuracy. These processed images provide a reliable basis for further analysis.

IV. ANALYSIS OF ECOLOGICAL SPACE CHANGE CHARACTERISTICS

A. Dynamic Degree and Transfer Rate

In studying the characteristics of ecological space change, the dynamic degree and transfer rate are mainly used to examine the changes in the quantity of ecological spaces within the study area. The formula for calculating the transfer rate of ecological space types is as follows:

$$K = \frac{u_b - u_a}{u_a} \times \frac{1}{T} \times 100\% \quad (4)$$

K represents the transfer rate of a certain ecological space type; u_a represents the quantity of a certain ecological space type at the beginning of the study; u_b represents the quantity of the same ecological space type at the end of the study; T represents the time span of the study period. The formula for calculating the overall dynamic degree of ecological space in the study area is:

$$Lc = \left(\frac{\sum_{i=1}^n \Delta Lu_{i-j}}{2 \sum_{i=1}^n Lu_i} \right) \times T^{-1} \times 100\% \quad (5)$$

Lu_i represents the quantity of the i th ecological space type at the beginning of the study; ΔLu_{i-j} represents the absolute value of the quantity of the i th ecological space type transformed into the non- i th ecological space type during the study period; T represents the time span of the study period, Lc represents the comprehensive dynamic degree of ecological space.

B. Transition Matrix

In the land-use transition matrix, the rows and columns represent the ecological space types at the beginning and end of a certain time sequence unit, respectively. Therefore, using the transition matrix to study ecological space types can reveal the changes in the area of each ecological space type from the beginning to the end of the period, as well as the transition situations of ecological space types. The formula for calculating the transition matrix is as follows:

$$S_{ij} = \begin{bmatrix} S_{11} & \cdots & S_{1n} \\ \vdots & \ddots & \vdots \\ S_{n1} & \cdots & S_{nn} \end{bmatrix} \quad (6)$$

In the formula, S represents the area of ecological space types within the time sequence unit, n is the total number of ecological space types within the time sequence unit, i represents the index of ecological space types at the beginning of the time

sequence unit; j represents the index of ecological space types at the end of the time sequence unit.

C. Landscape Pattern Indices

The spatial change characteristics of ecological spaces are mainly analyzed through the landscape pattern indices and classified landscape pattern indices of the study area. The analysis of these indices quantitatively describes the structure and distribution characteristics of the landscape itself. This paper selects the patch area, patch number, patch density, largest patch index, splitting index, and Shannon’s diversity index to analyze the landscape pattern indices and classified landscape pattern indices, thereby analyzing the spatial change characteristics of ecological spaces.

1) *Patch area (CA)*: The patch area (CA) represents the total area of a specific landscape type, and its calculation formula is as follows:

$$CA = \sum_{j=1}^n a_{ij} \times (1/10000) \quad (7)$$

In the formula, a_{ij} represents the area of patch i_j in a landscape type, n is the total number of all landscape types in the study area.

2) *Patch Number (NP)*: The patch number (NP) reflects the spatial pattern of the landscape. The larger the value of NP, the higher the degree of fragmentation in space, and vice versa. The spatial distribution characteristics of various landscape types can be determined to some extent by the patch number (NP), and its calculation formula is as follows:

$$NP = m(m \geq 1) \quad (8)$$

In the formula, m represents the number of patches of a certain ecological space type.

3) *Patch Density (PD)*: Represents the number of patches per unit area of the entire ecological space or a certain ecological space type. The larger the value of PD, the greater the separation among individual patches; conversely, the closer the patches are to each other. The calculation method is as follows:

$$PD = N / A \quad (9)$$

In the formula, N represents the number of patches of the ecological space type, A is the area of the study region.

4) *Largest Patch Index (LPI)*: The largest patch index represents the ratio of the largest patch of an ecological space type to the total area of the study region. The larger the LPI value, the higher the connectivity among patches of ecological space types, and vice versa. The calculation method is as follows:

$$LPI = \frac{Maxa_{ij}}{A} \times 100 \quad (10)$$

In the formula, LPI represents the value of the largest patch index, a_{ij} is the area of patch i_j of the ecological space type, A is the total landscape area of the entire study region.

5) *Splitting Index (SPLIT)*: Used to indicate the degree of fragmentation of a landscape type. The larger the value of SPLIT, the higher the degree of fragmentation of the landscape type, and vice versa. The calculation method is as follows:

$$SPLIT = \frac{A^2}{\sum_{i=1}^m \sum_{j=1}^n a_{ij}^2} \quad (11)$$

In the formula, SPLIT represents the value of the splitting index, a_{ij} is the area of patch ij in a landscape type, A is the total landscape area of the study region.

6) *Shannon's Diversity Index (SHDI)*: Indicates the degree of evenness among different ecological space types within the study area. The larger the value of SHDI, the more even the distribution of ecological space type patches, and vice versa. The calculation method is as follows:

$$SHDI = -\sum_{i=1}^m p_i \quad (12)$$

In the formula, m represents the number of ecological space types, p_i is the proportion of ecological space type i in the area of the study region.

D. Analysis of Ecological Space Structure Type Change Characteristics

The ecological space structure types in Wanzhou District mainly include cultivated land, forest land, grassland, water bodies, and unused land. Using the land use type data of Wanzhou District from 2000, 2006, 2012, and 2018, the software ArcGIS 10.1 was used to analyze the changes in the area of ecological spaces in Wanzhou District.

Using ArcGIS 10.1's mapping features, land use type maps of Wanzhou District from 2000 to 2018 were created, as shown in Fig. 3. Additionally, ArcGIS's statistical tools were employed to compile data on ecological spaces and land use areas in Wanzhou District from 2000 to 2018, as presented in Table II.

Table II highlights that Wanzhou District's ecological spaces are predominantly woodland (over 50%) and arable land (over 44%), with water bodies and grassland as secondary types. Unused land is minimal. Transition matrices for 2000–2006, 2006–2012, 2012–2018, and 2000–2018, generated using ArcGIS and Excel, are shown in Tables III to VI.

As shown in Table III, during 2000–2006, the main ecological space type conversions were from arable land and woodland to water bodies and built-up land, primarily due to the water storage of the Three Gorges Reservoir Area and rapid urbanization.

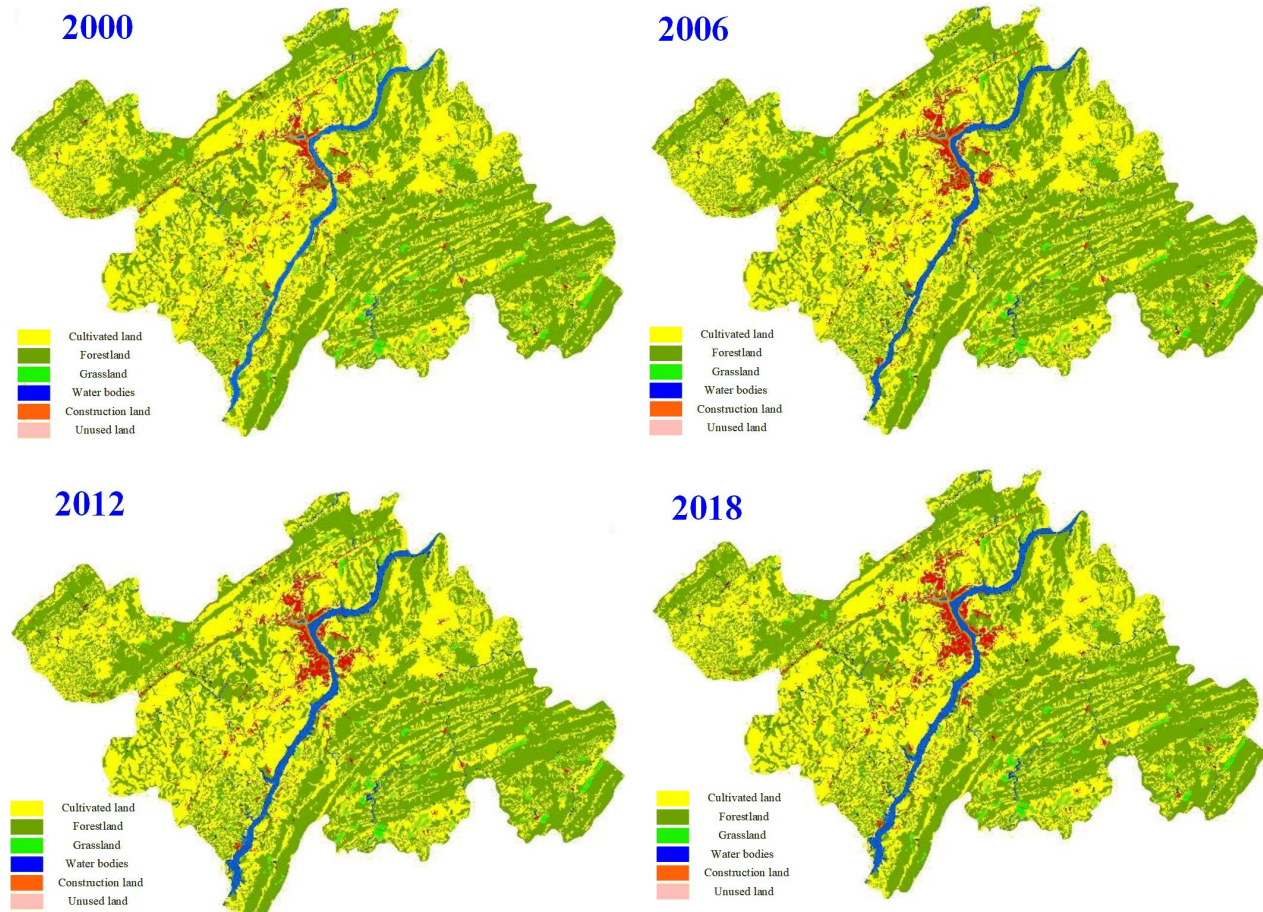

Fig. 3. Distribution map of ecological space structure types in wanzhou district from 2000 to 2018.

TABLE II. AREA STATISTICS OF ECOLOGICAL SPACE STRUCTURE TYPES IN WANZHOU DISTRICT FROM 2000 TO 2018

Type	2000		2006		2012		2018	
	Area (hm ²)	Percentage (%)	Area (hm ²)	Percentage (%)	Area (hm ²)	Percentage (%)	Area (hm ²)	Percentage (%)
Ecological Space	337826.13	98.33%	336026.89	97.80%	334956.05	97.49%	334279.17	97.29%
Arable Land	152779.02	44.47%	150913.92	43.92%	149056.68	43.38%	148385.62	43.19%
Woodland	169647.69	49.38%	169140.76	49.23%	168503.00	49.04%	168417.14	49.02%
Grassland	5906.24	1.72%	5826.97	1.70%	5754.00	1.67%	5848.84	1.70%
Water Bodies	9461.36	2.75%	10138.51	2.95%	11637.71	3.39%	11618.41	3.38%
Unused Land	31.82	0.01%	6.73	0.00%	4.66	0.00%	9.17	0.00%
Developed Land	5748.00	1.67%	7547.25	2.20%	8618.08	2.51%	9294.97	2.71%

Based on the 2006–2012 land use transition matrix (Table IV) for Wanzhou District, the conversion of arable land to built-up land significantly decreased compared to the period 2000–2006.

According to Table V, arable land no longer converts to forestland but solely transitions from arable land to forestland, with a conversion area of 19.57 hm². This indicates that during the 2012–2018 period, the policy of converting farmland back to forestland was strongly implemented in Wanzhou District. During this time, the primary land use transitions were from arable land and forestland to grassland and built-up land. The most significant conversion was from arable land to built-up land, with an area of 612.62 hm², followed by the conversion from forestland to built-up land, with an area of 64.27 hm².

According to Table VI, during the period from 2000 to 2018, the primary transition for arable land was towards built-up land, with a conversion area of 2885.10 hm², followed by transition to water bodies, totaling 1455.37 hm². Similarly, forestland mainly converted to built-up land, with an area of 654.03 hm², and secondarily to water bodies, with 643.38 hm². Grassland predominantly transformed into built-up land (57.50 hm²) and forestland (42.93 hm²). Water bodies mainly converted to arable land (27.03 hm²) and built-up land. Built-up land primarily transitioned to water bodies, with an area of 63.22 hm². Unused land primarily transformed into arable land (11.42 hm²) and built-up land (7.86 hm²).

Developed Land	-1.19	-2.46	0.03
Unused Land	13.14	5.12	-16.11
Comprehensive Dynamic Degree	0.08	0.10	0.05

E. Analysis of Ecological Space Dynamics

When studying the evolution characteristics of ecological space, it is necessary to examine the transfer rate and the activity level of the ecological space. Therefore, based on the area statistics table of Wanzhou District’s ecological space types from 2000 to 2018, the transfer rate and comprehensive dynamic degree of Wanzhou District’s ecological space from 2000 to 2018 are calculated, with the results shown in Table VII.

F. Influencing Factors

The changes in the ecological space layout of Wanzhou District are a complex process, influenced by a combination of various natural and human factors. Based on extensive literature review and adhering to the four principles of factor selection mentioned earlier, the preliminary selected influencing factors

include: elevation factor, slope factor, road traffic factor, administrative center factor, river factor, and policy control factor. The specific factors of elevation, slope, road traffic, administrative center, river, and policy control are illustrated in Fig. 4.

After the preliminary selection of influencing factors such as elevation, slope, road traffic, administrative center, river, and policy control factors, the Empirical Likelihood method is used to further select and analyze the elevation, slope, road traffic, administrative center, and river factors. The results are shown in Fig. 5. The reason for not applying the Empirical Likelihood method to further verify and select the policy control factor is that it serves as a constraint, significantly impacting the ecological space layout changes.

Fig. 4. Wanzhou district influencing factors map.

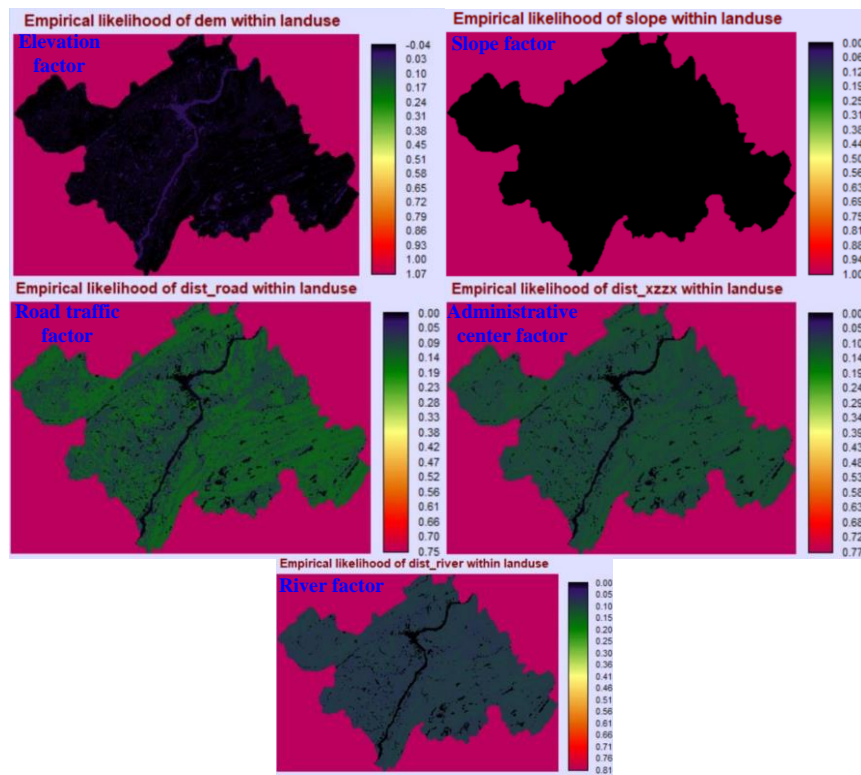

Fig. 5. Wanzhou district influencing factors impact map.

Based on Fig. 5, the final selected influencing factors are elevation, road traffic, administrative center, and policy control factors.

V. SIMULATION OF ECOLOGICAL SPACE LAYOUT IN WANZHOU DISTRICT BASED ON THE ANN-CA-MARKOV MODEL

A. ANN-CA-Markov

The Ann-CA-Markov model, aimed at simulating Wanzhou District's ecological space pattern, is constructed as follows: (1) Cells are defined as 30m×30m grids based on TM image data, mirroring the district's ecological structure. (2) Cellular space consists of these grids. (3) Cell states represent ecological and non-ecological spaces, categorized into types like cultivated land, forest, grassland, water bodies, and construction land. (4) The neighborhood is defined using a 5×5 extended Moore setup, where 24 adjacent cells affect the central one. The choice of a 5×5 neighborhood window balances computational efficiency with spatial accuracy. This window size was selected based on sensitivity analysis, which demonstrated that smaller windows (e.g., 3×3) provided insufficient spatial context, while larger windows (e.g., 7×7) added unnecessary complexity without significantly improving model precision. (5) Transition rules are established using spatial and quantitative methods, with the former calculated via the MLP_ANN model and the latter through Markov model-derived transition probability matrices between space types. (6) Transition probabilities are calculated for 2000—2006, 2006—2012, and 2012—2018 using IDRISI software, aiding in predicting land use changes, shown in Tables VIII, IX, and X, respectively.

After selecting spatial variables and influencing factors, the MLP_ANN tool was utilized to construct the transition rules for

the cellular automaton model (Fig. 6). The MLP_ANN comprises a three-layer network structure, including an input layer, a hidden layer, and an output layer. In this study's MLP_ANN, the input layer consists of 15 neurons, corresponding to the 15 influencing factors identified earlier. The number of neurons in the hidden layer, representing the number of input samples, should be at least two-thirds of the number of input layer neurons, hence 11 neurons were set for the hidden layer. The output layer contains 6 neurons, each corresponding to the transition probabilities for Wanzhou District's five ecological space types and one non-ecological space type. However, due to the negligible area of unused land in the study area, the actual number of neurons in the output layer used is five, representing the transition probabilities for farmland, woodland, grassland, water bodies, and construction land.

Following the computation of transition probability maps for various land use types, including farmland, woodland, grassland, water bodies, and construction land, using the MLP_ANN model, the results were refined to reflect both the prevailing policies and the real-world conditions of the study area. To ensure that the study's outcomes were consistent with local land use regulations, specific constraints were applied. These constraints mandated that construction land and water bodies could not change, while ecological spaces and non-ecological areas within designated protected zones—such as ecological protection red lines, forest parks, nature reserves, geological parks, and scenic areas—were preserved from any transitions. As the ANN-CA-Markov model is built on the principles of cellular automata (CA), the refined transition rules, now represented as probability maps for each land use type,

were standardized to a 0–255 scale. The standardized transition probability maps for the respective land types are presented in Fig. 7. In the final step, these maps were integrated into a

comprehensive suitability mapset using the Collection Editor tool within the IDRISI software suite.

B. Determining the Number of Iterations and the Forecast Year

After setting the iteration interval to 6 years, based on the base data and calculated transition probability matrices, the ecological space evolution in the study area for 2012 is simulated and predicted based on the 2000 and 2006 data. Then, the ecological space evolution in 2018 is simulated and predicted based on the 2006 and 2012 data. After verifying the accuracy of the simulated ecological space for 2012 and 2018 with the ANN-CA-Markov coupled model and meeting the accuracy requirements, the ecological space evolution in 2025 is simulated and predicted. Thus, in the ANN-CA-Markov coupled model, 2012, 2018, and 2025 are determined as the forecast years.

C. ANN-CA-Markov Coupled Model Accuracy Verification

After constructing the ANN-CA-Markov coupled model, the ecological space distribution in Wanzhou District for the years 2012 and 2018 is simulated based on the data from 2000 to 2006 and 2006 to 2012, respectively. The simulation results are shown in Fig. 8 and 9.

After completing the simulation maps of the ecological space structure types in Wanzhou District for 2012 and 2018, it is necessary to verify the simulation accuracy of the ANN-CA-Markov coupled model. This is done by comparing the simulation results for 2012 with the actual data for 2012, and the simulation results for 2018 with the actual data for 2018, to validate the simulation accuracy of the ANN-CA-Markov coupled model.

First, a quantitative verification is performed by comparing the simulated results for 2012 and 2018 with the actual data for those years. The specific quantitative verification results are shown in Tables XI and XII.

Based on Tables XI and XII, except for unused land, the simulation results for other ecological space types (cultivated land, forest land, grassland, water bodies) and non-ecological space type (construction land) show high accuracy rates. The lower accuracy for unused land is due to its minimal grid cell count, which does not reach 0.01% of the total grid cell count in the study area. Overall, the ANN-CA-Markov coupled model demonstrates high simulation accuracy in terms of quantity.

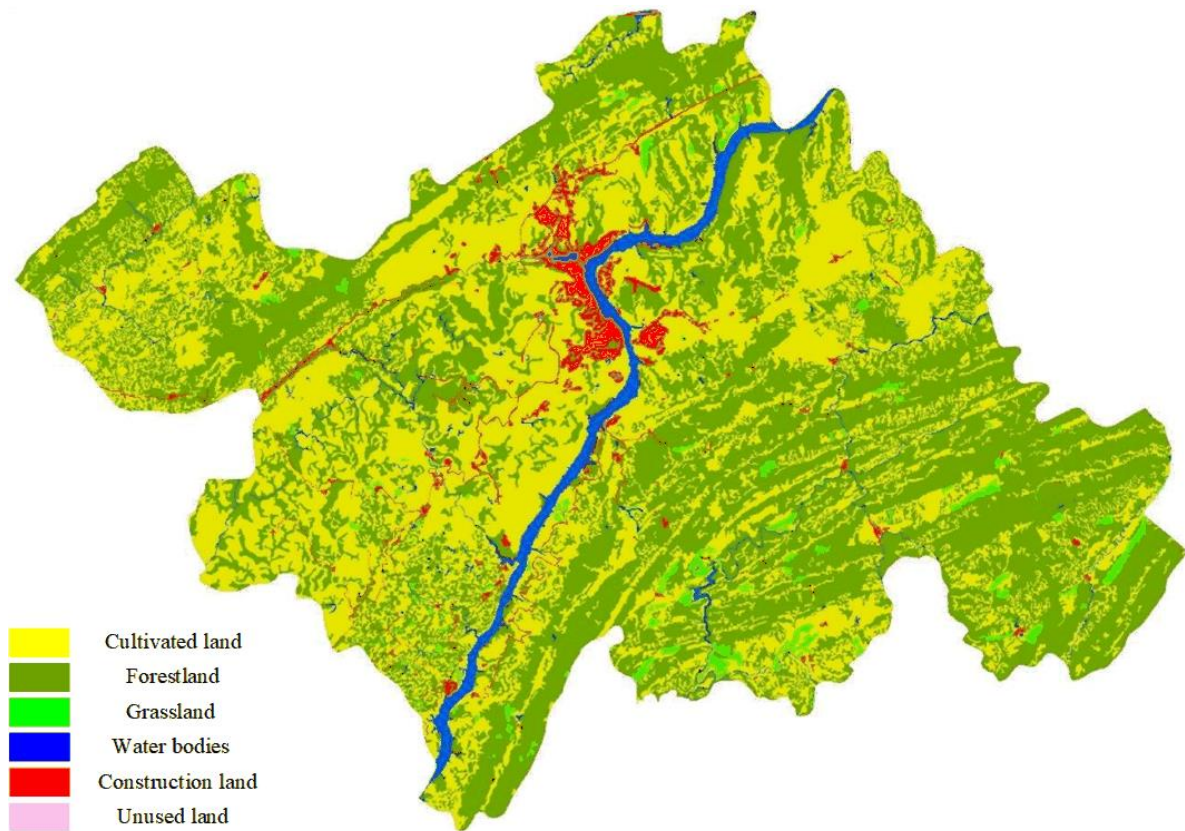

Fig. 8. Simulation map of the ecological space structure types in Wanzhou District for the year 2012.

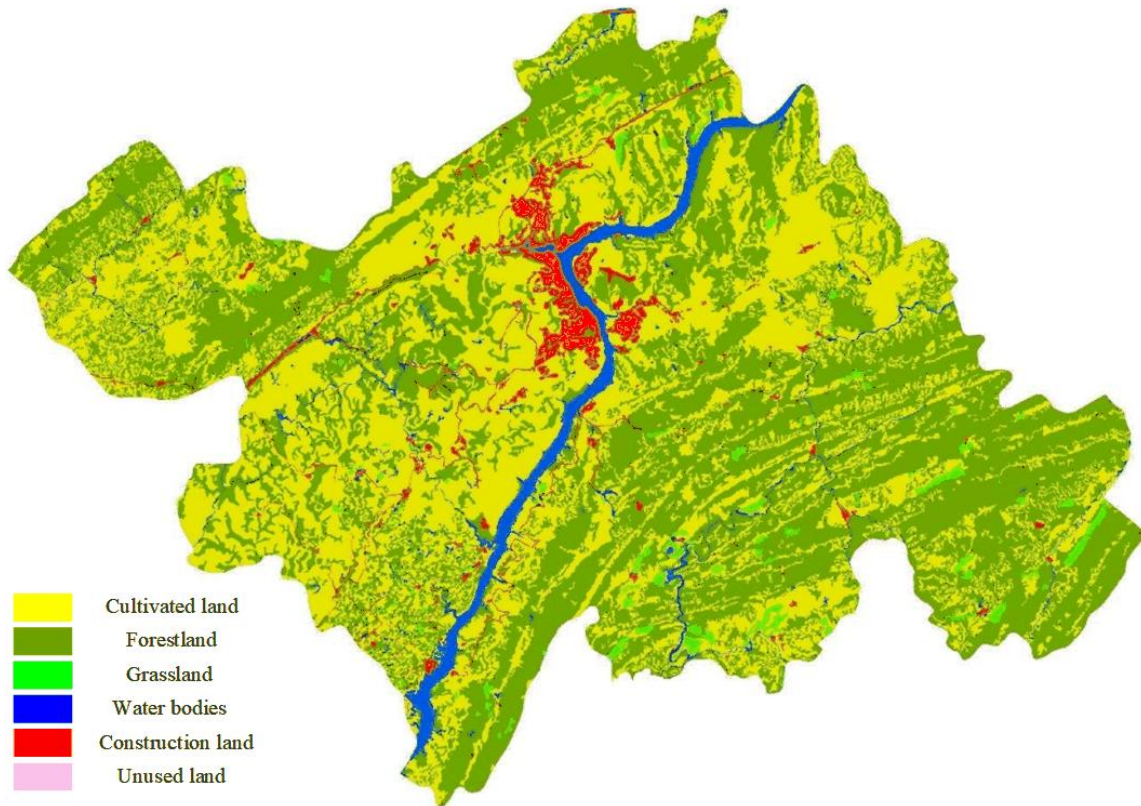

Fig. 9. Simulation map of the ecological space structure types in Wanzhou District for the year 2018.

TABLE XI. VERIFICATION OF THE SIMULATED AND ACTUAL NUMBER OF GRIDS FOR 2012

Land Type	Actual Number of Grids (2012)	Simulated Number of Grids (2012)	Accuracy (%)
Cultivated Land	1,655,590	1,672,030	99.01
Forest Land	1,870,820	1,873,846	99.84
Grassland	63,945	65,175	98.08
Water Area	129,273	113,517	87.81
Unused Land	55	73	67.27
Construction Land	95,783	90,825	94.82

Land Type	Actual Number of Grids (2018)	Simulated Number of Grids (2018)	Accuracy (%)
Cultivated Land	1,648,162	1,661,779	99.17
Forest Land	1,869,859	1,870,178	99.98
Grassland	64,994	55,553	85.47
Water Area	129,054	128,992	99.95
Unused Land	107	55	51.40
Construction Land	103,290	98,909	95.76

D. Simulation and Result Analysis of Ecological Space Layout in the Study Area for 2025

After validating the Ann-CA-Markov model’s high accuracy, it was applied to project Wanzhou District’s 2025 ecological space. For the 2025 simulation, the model used 2018 data for neighboring variables and current space types, adjusted conversion probability maps, and derived the transition matrix from 2012 and 2018 data. These modifications enabled the projection of the district’s 2025 ecological layout, depicted in Fig. 10. A corresponding map illustrating the predicted ecological space distribution for 2025 is shown in Fig. 11.

Based on the simulation results for Wanzhou District in 2025 (Fig. 10 and 11) and the actual data from 2018, the areas of

ecological spaces in Wanzhou District were calculated and summarized, as shown in Table XIII.

In 2025, ecological space in Wanzhou District is projected to cover 334,022.95 hectares (97.28%), dominated by cultivated land (147,743.20 hectares) and forest land (168,944.40 hectares). Grassland (5,698.71 hectares) and water bodies (11,627.26 hectares) contribute smaller portions, while unused land remains negligible. Constructed land expands to 9,349.42 hectares (2.72%). From 2018 to 2025, the ecological space decreased slightly by 81.02 hectares, as cultivated land and grassland declined, while forest land and water bodies saw modest increases. The transfer matrix in Table XIV highlights the shifts between these land types during the period.

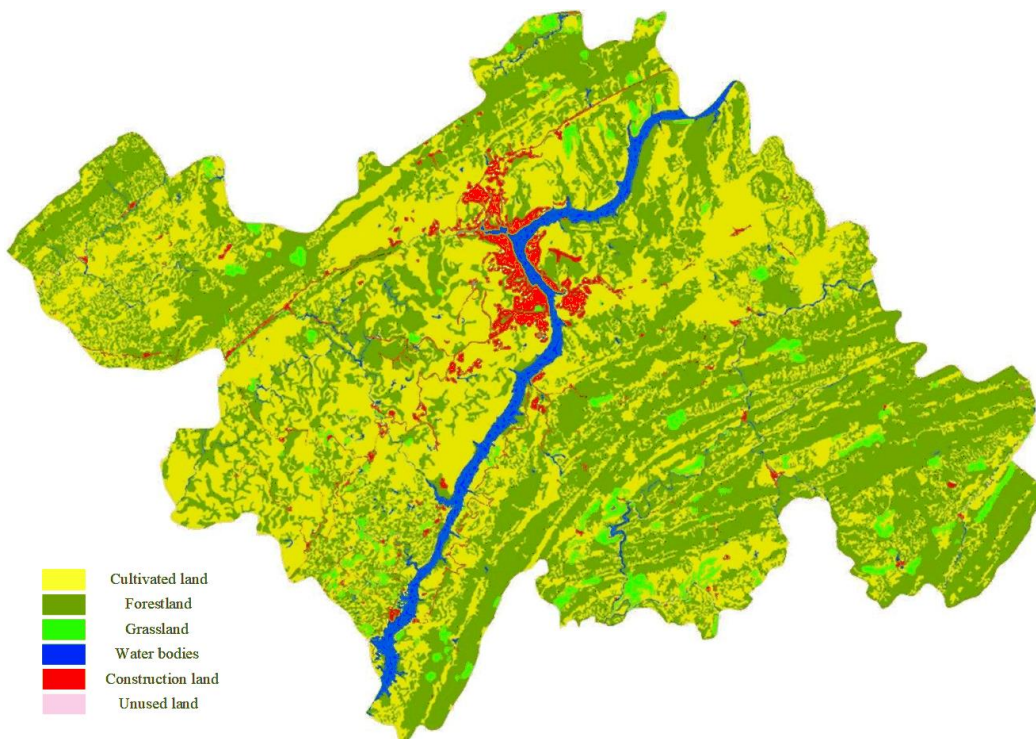

Fig. 10. Simulated distribution map of ecological space structure types in wanzhou district for 2025.

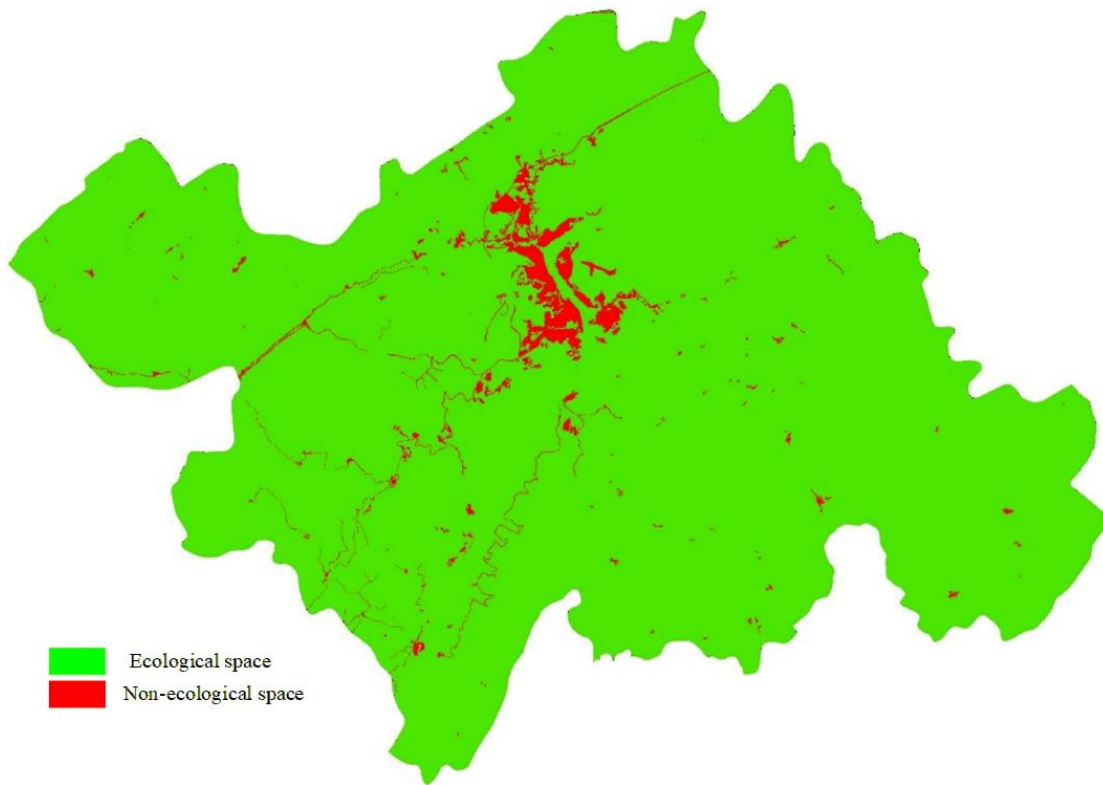

Fig. 11. Simulated ecological space distribution map in wanzhou district for 2025.

TABLE XIII. SIMULATED RESULTS OF ECOLOGICAL SPACE IN WANZHOU DISTRICT FOR 2025

Type	2018		2025	
	Area (hm ²)	Proportion(%)	Area (hm ²)	Proportion(%)
Ecological Space	334103.97	97.30	334022.95	97.28
Cultivated Land	148328.32	43.20	147743.20	43.03
Forest Land	168317.33	49.02	168944.40	49.20
Grassland	5843.57	1.70	5698.71	1.66
Water Body	11605.37	3.38	11627.26	3.39
Unused Land	9.37	0.00	9.37	0.00
Constructed Land	9268.41	2.70	9349.42	2.72

TABLE XIV. TRANSFER MATRIX OF ECOLOGICAL SPACE STRUCTURE TYPES IN WANZHOU DISTRICT FOR 2018-2025 (HM²)

2018	2025					
	Arable Land	Woodland	Grassland	Water Bodies	Developed Land	Unused Land
Arable Land	147528.64	742.57	9.07	4.20	43.85	0.00
Woodland	88.62	168128.55	23.34	11.90	64.93	0.00
Grassland	48.58	60.61	5653.00	34.73	46.64	0.00
Water Bodies	3.25	8.61	8.30	11572.30	12.90	0.00
Developed Land	74.11	4.06	5.00	4.13	9181.11	0.00
Unused Land	0.00	0.00	0.00	0.00	0.00	9.37

According to Table XIV, during the period from 2018 to 2025, the area of cultivated land mainly transferred to forest land and constructed land, with transfer areas of 742.57 hm² and 43.85 hm², respectively. The primary transfers from forest land were to cultivated land and constructed land, with transfer areas of 88.62 hm² and 64.93 hm², respectively. Grassland transfers were relatively balanced among various types, with transfer

areas to cultivated land, forest land, water bodies, and constructed land being 48.58 hm², 60.61 hm², 34.73 hm², and 46.64 hm², respectively. Water bodies had smaller transfer areas to other types, with the largest being the transfer to constructed land, at 12.90 hm². Constructed land primarily transferred to cultivated land, with a transfer area of 74.11 hm². Unused land did not undergo any transfers.

VI. CONCLUSION

The deployment of the ANN-CA-Markov model in this study provides a detailed and forward-looking analysis of the expected land use changes in Wanzhou District by the year 2025. The results of the analysis suggest that ecological spaces will remain predominant, accounting for 97.28% of the district's total land area. However, a minor reduction in ecological spaces is forecasted, accompanied by a corresponding increase in construction land, indicating the growing impact of urbanization on the region's ecological zones. Specifically, the study anticipates a decline in arable land and grassland areas, while forested regions and water bodies are projected to expand. This shift may reflect the influence of regional policies and planning initiatives aimed at conserving forests and water resources. Although the increase in construction land is relatively small, it nonetheless reflects the broader trend of intensified land use and development driven by urbanization pressures. Furthermore, an examination of the transition dynamics between various land use categories reveals a pattern where arable land is increasingly converted to forested areas and construction sites, while transitions involving forest land typically lead to its conversion into arable land or construction areas. These land use transformations are likely driven by a combination of policy enforcement, economic development, and resource management practices.

Advanced IoT-Enabled Indoor Thermal Comfort Prediction Using SVM and Random Forest Models

Nurtileu Assymkhan, Amandyk Kartbayev

School of Information Technology and Engineering, Kazakh-British Technical University, Almaty, Kazakhstan

Abstract—Predicting thermal comfort within indoor environments is essential for enhancing human health, productivity, and well-being. This study uses interdisciplinary approaches, integrating insights from engineering, psychology, and data science to develop sophisticated machine learning models that predict thermal comfort. Traditional methods often depend on subjective human input and can be inefficient. In contrast, this research applies Support Vector Machines (SVM) and Random Forest algorithms, celebrated for their precision and speed in handling complex datasets. The advent of the Internet of Things (IoT) further revolutionizes building management systems by introducing adaptive control algorithms and enabling smarter, IoT-driven architectures. We focus on the comparative analysis of SVM and Random Forest in predicting indoor thermal comfort, discussing their respective advantages and limitations under various environmental conditions and building designs. The dataset we used included comprehensive thermal comfort data, which underwent rigorous preprocessing to enhance model training and testing—80% of the data was used for training and the remaining 20% for testing. The models were evaluated based on their ability to accurately mirror complex interactions between environmental factors and occupant comfort levels. The results indicated that while both models performed robustly, Random Forest demonstrated greater stability and slightly higher accuracy in most scenarios. The paper proposes potential strategies for incorporating additional predictive features to further refine the accuracy of these models, emphasizing the promise of machine learning in advancing indoor comfort optimization.

Keywords—Heating; building energy management; thermal comfort; IoT; Support Vector Machine; Random Forest

I. INTRODUCTION

Optimizing built environments for human habitation crucially involves predicting thermal comfort, a significant challenge intensified by climate change. As climate change escalates, extreme weather events become more frequent and severe, heightening the need for effective management of indoor thermal conditions. The importance of accurately predicting thermal comfort is underscored by its substantial impact on human health, productivity, and overall well-being. Inadequate thermal environments, characterized by excessive heat or cold, can result in discomfort, fatigue, and health complications, adversely affecting an individual's quality of life and reducing productivity in various environments such as workplaces, educational institutions, and homes.

Moreover, the economic consequences of neglecting thermal comfort are significant. Suboptimal indoor climates lead to heightened energy consumption as occupants frequently

use heating or cooling systems to alleviate discomfort. This increased reliance on HVAC (Heating, Ventilation, & Air Conditioning) systems not only results in higher utility bills but also contributes to environmental strain. Consequently, there is an urgent need to develop reliable predictive models that can accurately forecast occupants' thermal comfort preferences under varying environmental conditions and architectural designs. Such models must incorporate a range of factors, including ambient temperature, humidity levels, clothing insulation, metabolic rates, and individual preferences, to deliver precise assessments of thermal comfort levels.

Addressing this imperative necessitates interdisciplinary collaboration among architects, engineers, psychologists, and data scientists. Integrating insights from environmental science, human physiology, and behavioral psychology is essential for developing effective predictive models. By harnessing advancements in sensor technology, data analytics, and machine learning algorithms, these models can be refined to provide real-time insights into the dynamics of thermal comfort. This enables building managers and occupants to optimize indoor environments, thereby enhancing well-being and promoting sustainable resource utilization.

To further understand the impact of thermal comfort, let's explore a detailed example. Temperature plays a critical role in human well-being, akin to how a rise in body temperature can signal illness, indicating that something is amiss. Similarly, room temperature significantly affects comfort and, consequently, our ability to function optimally.

Consider a scenario on a hot summer day: you begin to prepare for lessons or study in your room. To create a quiet environment, you close the door to block out noise and shut the window to keep out the heat. However, this action inadvertently leads to a reduction in airflow and available space, causing an increase in carbon dioxide levels as it accumulates in the room. This buildup of carbon dioxide decreases the oxygen levels, leading to a rise in room temperature. Consequently, you may start to feel distracted and lethargic, a direct result of the diminished air quality and increased warmth. This situation can be remedied by simply opening the door to improve ventilation. This action helps to balance the air quality and regulate the room's temperature, restoring a more comfortable and conducive environment for studying. This example underscores the importance of managing thermal comfort to maintain productivity and well-being in indoor spaces. The process of predicting thermal comfort involves the analysis of various factors, including temperature, humidity, air velocity, and clothing insulation.

Traditional methods, based on human comfort models, tend to be subjective and time-consuming.

In this paper, we explore the application of Support Vector Machines (SVM) and Random Forest algorithms for predicting thermal comfort in buildings, aiming to assess their effectiveness and compare their performance across different scenarios. The goal is to provide a thorough understanding of how these machine learning algorithms can aid building designers and facility managers in optimizing indoor environments and enhancing occupant comfort. Our research is structured around a series of hypotheses that guide the experimental design:

- **Data Preparation:** We hypothesize that removing NaN values and establishing a threshold for the minimum number of observations per feature will improve model accuracy by ensuring the data quality and relevance of the features used.
- **Feature Encoding:** We will evaluate the suitability of different encoding strategies as OneHotEncoder, LabelEncoder, and Word2Vec, to determine how best to handle categorical variables. The choice of encoder may significantly impact the performance of our models, depending on the nature of the data.
- **Feature Selection:** The SelectKBest model will be utilized to identify the most relevant features for predicting thermal comfort. This method is expected to highlight the variables most closely linked to the outcomes, thereby streamlining the modeling process.
- **Feature Variants:** Post feature selection, we will focus on variants of the filtered features that are closely associated with temperature prediction. This step is crucial for refining the model's focus and enhancing its predictive accuracy regarding thermal comfort.

Through this structured approach, we aim to validate our hypotheses and draw meaningful conclusions about the utility of the algorithms in the context of thermal comfort prediction, potentially offering actionable insights for the design and management of building environments. Both SVM and RF are supervised learning algorithms capable of being trained on datasets consisting of thermal comfort parameters alongside corresponding human feedback.

This paper is structured as follows: Section II provides a literature review, contextualizing our study within existing research. Section III describes the methodology employed, detailing the techniques used to analyze data. Section IV presents the findings of the study, supported by relevant tables and illustrations. Section V discusses the implications of these results. Finally, Section VI offers a conclusion, summarizing the key outcomes and proposing directions for future research.

II. RELATED WORKS

The Internet of Things (IoT) is revolutionizing the building management systems (BMS) industry, with forecasts predicting up to 125 billion connected devices by 2030. Despite these advancements, current BMS solutions often lack flexibility, especially in terms of feedback control options. To fully

leverage the potential of IoT, adaptive control algorithms and modular architectures are being explored. The authors have introduced the "Semantically-Enhanced IoT-enabled Intelligent Control System" (SEMIoTICS) architecture, which enhances control system capabilities through redundancy and automatically adjusts configurations based on quality-of-service criteria [1]. Additionally, Model Predictive Control (MPC) is becoming increasingly popular for optimizing energy efficiency and comfort in HVAC systems. Nonetheless, the use of nonlinear models introduces significant computational challenges. In response, research has shifted towards linear controllers that utilize Jacobian linearization. A notable innovation in this field is a bilinear model for nonlinear MPC, designed to minimize energy costs while maintaining comfort levels. However, the computational intensity of this model poses challenges for its application in real-time control settings [2].

Another articles introduce a cutting-edge reinforcement learning (RL)-based approach for HVAC systems integrated into the Transactive Energy Simulation Platform (TESP). Utilizing the Deep Deterministic Policy Gradients (DDPG) algorithm, this method focuses on intelligent and granular control of HVAC operations by optimizing a cost function that seeks a balance between electricity costs and end-user dissatisfaction. The approach includes a market price prediction model developed using Artificial Neural Networks (ANN), a DDPG-based RL control algorithm, and both implementation and testing phases within the TESP framework [3]. Further the authors present a simulation model that incorporates both high-level and low-level controllers for a passenger car's air conditioning system. This model prioritizes occupant thermal comfort and the precise regulation of the physical system. They also introduce an Eco-Cooling Strategy employing MPC to optimize control inputs. The strategy is designed to achieve efficient cooling, reduce energy consumption, and maintain comfort. The simulation results underscore the critical role of control settings in effective thermal management [4].

Fuzzy logic-based models are increasingly utilized to control air conditioning systems at variable speeds, optimizing energy consumption and enhancing thermal comfort. Implemented in hardware such as microcontrollers, VLSI chips, and EDA tools, these controllers precisely manage temperature and humidity levels, effectively regulating fan and compressor speeds. Integrated with other techniques, they significantly improve energy efficiency and system performance [5]. Ref. [6] explores a range of HVAC control strategies, from classical PID controllers to advanced MPC. They address challenges in system simulation, control implementation, artificial intelligence integration, and energy savings, introducing the LAMDA controller to enhance real-time responsiveness and self-adjustment based on contextual information, further refining control accuracy and efficiency in HVAC systems.

The escalating energy consumption in commercial buildings, particularly through HVAC systems, has spurred increased research into optimizing energy efficiency. Despite advancements in HVAC technologies that have enhanced Demand Response (DR) programs, challenges remain in the

application of model predictive control techniques. Recent studies have utilized machine learning methods, including Reinforcement Learning and Supervised Learning, to improve these systems [7]. Research in BEM has particularly focused on optimizing HVAC operations through various innovative approaches. Key developments include dynamic demand response controllers, mixed-integer nonlinear optimization models, stochastic programs, multi-objective optimization models, occupancy-based controllers, and incentive-based DR controllers. Additional methodologies explored include event-based control, mutual information frameworks, and MPC [8]. Furthermore, this paper [9] introduces a three-layered model designed for optimizing energy consumption in smart homes, incorporating data collection, prediction, and optimization phases. The model employs an Alpha Beta filter for reducing noise, Dynamic Evolving Neural Network (DELM) for dynamic parameter prediction, and fuzzy controllers for making refined control decisions. This integrated approach not only addresses static user parameters but also enhances both comfort and energy efficiency.

One study introduces an innovative model that omits gender and age factors in assessing thermal comfort, focusing instead on six key thermal factors: air temperature, mean radiant temperature, relative humidity, air speed, clothing insulation, and metabolic rate. This model, developed using Supervised Machine Learning, is tailored for application in a commercial building environment [10]. Another study conducted in Bilbao, Spain, at the KUBIK energy efficiency research facility, examines human thermal perception in response to external temperatures to enhance indoor comfort and reduce energy consumption [11]. Further research evaluates indoor thermal comfort using the Fanger method and adhering to ASHRAE Standard 55, emphasizing real-world conditions to promote well-being, productivity, and energy conservation in buildings [12].

Additionally, a study introduces a model based on multiple preferences for predicting group thermal comfort in shared spaces. This model integrates individual preferences and environmental parameters, segments occupants by Body Mass Index (BMI), predicts individual comfort zones, and adjusts settings to achieve group satisfaction [13]. Overall, optimizing thermal comfort in buildings is crucial for enhancing occupant well-being, productivity, and energy efficiency. Effective assessment models take into account variables such as air temperature, humidity, radiant temperature, and air speed, with the ASHRAE 55 standards providing guidelines for acceptable conditions.

Alternative models such as ANN, hybrid ANN-fuzzy systems, SVM, decision trees, and Bayes networks offer enhanced flexibility and accuracy in predicting thermal comfort [14]. Thermal comfort is a key component of indoor environmental quality, which can be categorized into static, adaptive, and data-driven models. Static models, like the Predicted Mean Vote (PMV), incorporate environmental and personal factors but have recognized limitations due to their lack of adaptability to individual responses. Adaptive models account for psychological and behavioral adaptations, enhancing their responsiveness to occupant preferences. Data-driven models leverage real-time data from sensor technologies

for dynamic and responsive assessments of thermal comfort [15].

Further advancements are seen in the development of a building thermal model that utilizes low-resolution data from smart thermostats, improving accuracy and applicability across different seasons. This approach transforms traditional empirical models into a data-driven framework by using surrogate features to approximate internal heat gains. The model's design allows for implementation on either edge devices or cloud infrastructure, facilitating efficient data collection, model learning, and deployment [16].

Research continues to evolve with studies focusing on innovative cooling technologies such as Thermoelectric Air Ducts, with neural network models demonstrating high accuracy in predicting comfort parameters in dynamic settings. Understanding the interplay between climatic variables, occupant comfort, and system performance is fundamental [17]. Overall, the prediction of thermal comfort and optimization of energy use in buildings are critical for ensuring occupant satisfaction and achieving energy efficiency. Key factors influencing comfort include metabolic rate, clothing insulation, and air temperature.

Deep feedforward neural networks and reinforcement learning models are increasingly utilized to predict comfort levels, which is essential for monitoring and optimizing HVAC energy consumption in building operations [18]. A novel methodology employing machine learning, data mining, and statistical techniques has been developed to create predictive models for Combined Heat, Cooling, and Power (CHCP) systems. This methodology encompasses four stages: data preparation, data engineering, model building, and model evaluation. Data preparation includes retrieving failure events, labeling instances, and compiling a comprehensive dataset. Data engineering focuses on improving data representation through feature extraction and selection. The model building phase employs machine learning algorithms for various classification and regression tasks, while model evaluation assesses time to failure and other performance metrics to ensure the model's suitability [19].

Another innovative study explores thermal comfort in indoor environments through a novel approach called Relative Thermal Sensation (RTS). This method views thermal sensation as a continuous function of time, offering a more detailed understanding of human thermal perception. The study introduces a 3-point Relative Thermal Sensation Scale (RTSS) to collect real-time data on thermal sensations, capturing subtle changes that traditional discrete scales might overlook. Additionally, the research integrates RTS data with Absolute Thermal Sensation data from modified versions of the ASHRAE 7-point thermal sensation scale, enhancing the comprehensive understanding of thermal comfort [20].

Interpretable thermal comfort systems are being developed to enhance energy efficiency and occupant satisfaction in smart building environments. Traditional models such as the PMV often lack interpretability, posing challenges for building operators who need to understand the mechanisms influencing thermal comfort. To address this, researchers are integrating

machine learning techniques that promote model transparency, such as Partial Dependence Plots (PDP) and SHAP values.

These tools allow operators to comprehend how environmental conditions affect human comfort and to evaluate the significance of various features under different scenarios. Furthermore, these interpretable machine learning algorithms are also being used to create surrogate models that replicate and potentially improve upon existing thermal comfort models, making them more accessible and actionable for building management [21].

III. METHODOLOGY

A. Dataset

The dataset, sourced from the ASHRAE and available on Kaggle [22], comprises 70 columns and 107,583 rows, containing data collected globally from 1995 to 2015. Initially, an examination of the dataset description led to a filtering process. This revealed that some columns contained sparse data. Consequently, a threshold was set at 60,000 rows; data points below this limit were discarded. Additionally, it was necessary to address missing values. Despite starting with 107,583 rows, the removal of rows with NaN values was essential to ensure data integrity.

Another analytical approach considered was the use of the Interquartile Range (IQR) method to identify and eliminate outliers, further refining the dataset's quality (see Fig.1).

Fig. 1. Data filtering scheme.

Regarding the conversion of text data to numeric form, as shown in Fig. 2, two encoding options were evaluated: LabelEncoder and OneHotEncoder. The decision to proceed with OneHotEncoder was based on its superior performance in preliminary results [23], effectively transforming categorical text data into a usable format for machine learning models.

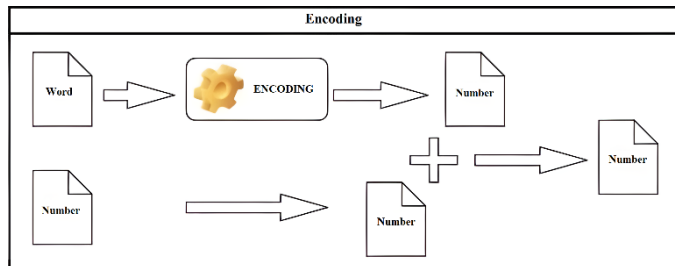

Fig. 2. Encoding scheme for the conversion of text data to numeric form.

In the feature selection process, as shown in Fig. 3, two methods were considered: using the SelectBest library or selecting based on correlation with a predefined threshold. The chosen method was to use correlations, specifically setting a boundary above 50% to determine relevant features. The final set of features selected includes Age, Clothing insulation (Clo), Sex, Metabolic rate (Met), Thermal preference, Year, Season, Köppen climate classification, Cooling strategy at the building level, City, Predicted Percentage of Dissatisfied (PPD), Air temperature (C), Outdoor monthly air temperature (C), Relative humidity (%), and Air velocity (m/s). This selection represents the culmination of extensive testing with various combinations of features, all of which will be detailed in the Experiments section of our study.

Fig. 3. Feature selection.

These features were instrumental in enhancing the predictive accuracy of our models. For the experimental setup, the dataset was divided into 80% for training and 20% for testing. Typically, thermal comfort ratings in the dataset ranged from 1 to 6. Another hypothesis tested was the conversion of these label values into integers. By reducing the range of thermal comfort ratings from six to three distinct categories, we observed a significant improvement in model accuracy. This transformation simplifies the model's classification task, enabling more precise predictions.

B. Inter Quartile Range (IQR)

The Interquartile Range (*IQR*) is a measure of statistical dispersion that is calculated as the difference between the third quartile (*Q3*) and the first quartile (*Q1*) of a dataset. Mathematically, it is defined as:

$$IQR = Q3 - Q1 \tag{1}$$

where *Q1* is the median of the lower half of the dataset and *Q3* is the median of the upper half of the dataset. It is particularly useful in identifying and dealing with outliers, which are data points that significantly differ from the rest of the dataset. Here's how the *IQR* is calculated and how it can be used to remove outliers:

1) Calculation of IQR:

- Firstly, you need to arrange your dataset in ascending order.
- Then, find the median of the dataset, which is the middle value when the data is sorted. If the dataset has an odd number of observations, the median is the middle value. If it has an even number of observations, the median is the average of the two middle values.

- Divide the dataset into two halves at the median. The lower half contains all the values less than or equal to the median, and the upper half contains all the values greater than or equal to the median.
- Find the median of each half. This gives you the first quartile ($Q1$) and the third quartile ($Q3$) of the dataset, respectively.
- The IQR is then calculated as the difference between $Q3$ and $Q1$: $IQR = Q3 - Q1$.

2) Identifying outliers using IQR :

- Outliers can be detected using the IQR method by considering values that lie below $Q1 - 1.5 \times IQR$ or above $Q3 + 1.5 \times IQR$. These values are considered to be significantly different from the rest of the dataset.
- Values below $Q1 - 1.5 \times IQR$ or above $Q3 + 1.5 \times IQR$ are commonly referred to as lower and upper bounds, respectively.
- Any data points falling outside these bounds can be considered outliers.

3) Removing outliers using IQR :

- Once outliers are identified using the IQR method, you can choose to remove them from the dataset to improve the robustness of your analysis or model.
- Outliers can be removed by filtering the dataset to exclude any observations that fall outside the lower and upper bounds defined by $Q1 - 1.5 \times IQR$ and $Q3 + 1.5 \times IQR$, respectively.
- After removing outliers, the dataset may be more representative of the underlying distribution and less influenced by extreme values.

4) Considerations:

- While the IQR method is effective in identifying and removing outliers, it's important to exercise caution and consider the context of the data.
- Outliers may sometimes carry valuable information or be indicative of rare but important events. Therefore, the decision to remove outliers should be made judiciously based on the specific goals of the analysis or model.
- Additionally, the choice of the multiplier (1.5 in the conventional method) used to define the bounds can be adjusted depending on the desired level of sensitivity to outliers.

In summary, the IQR is a useful statistical measure for assessing the spread of a dataset and identifying outliers. By calculating the IQR and defining bounds based on it, outliers can be effectively detected and removed, leading to a more robust analysis or model.

C. Applied Algorithms

SVM is a robust supervised machine learning algorithm well-suited for both classification and regression tasks. In thermal comfort prediction, SVM is employed to delineate the complex interrelationships between various environmental factors—like temperature, humidity, and air velocity—and human thermal comfort responses. The algorithm focuses on maximizing the margin between classes in classification tasks or minimizing the error in regression, all while effectively controlling for overfitting. By training on labeled datasets that encapsulate environmental conditions and corresponding thermal comfort ratings, SVM learns to accurately predict thermal comfort levels based on specific environmental inputs.

Random Forest is another versatile machine-learning algorithm capable of handling both classification and regression challenges. It operates on an ensemble learning principle, utilizing multiple decision trees to construct a more accurate and robust model, as shown in Fig. 4. The process involves extensive data preparation, including cleaning, handling missing values, and appropriate transformations to fit the model. Random Forest uses random sampling to select data subsets for training each tree, employs recursive partitioning for tree creation, and integrates a voting mechanism to aggregate the predictions from various trees. This method is particularly effective in modeling nonlinear relationships and interactions among different environmental variables. Random Forest's ability to generate reliable predictions is enhanced by its ensemble approach, which provides a comprehensive view of thermal comfort across varying conditions.

Fig. 4. Multiple decision trees of the Random Forest algorithm.

Both SVM and Random Forest are adept at capturing the nuanced dynamics between environmental parameters and thermal responses, making them invaluable for predicting thermal comfort in diverse settings. These models stand out for their robustness against overfitting, ensuring consistent reliability across different datasets and environmental scenarios. While SVM offers clear decision boundaries facilitating easier interpretation of the factors influencing thermal comfort, Random Forest provides insights into feature

importance through its aggregated decision trees, although individual tree interpretations are less straightforward.

The flexibility of SVM and Random Forest models allows for the accommodation of various data types, making them ideal for integration with different environmental sensors and monitoring systems in thermal comfort assessment. An innovative approach within this domain is utilizing the 'Thermal preference' column as an alternative predictive variable instead of the conventional 'Thermal comfort' scale, moving away from traditional models that categorize comfort into six distinct levels to a more simplified three-level scale, which could potentially streamline the prediction process and enhance model accuracy.

D. Integration with IoT

The IoT component of the system is integral to enhancing building management by deploying a comprehensive network of sensors throughout the facility. These sensors are designed to monitor a variety of environmental conditions in real-time, including temperature, humidity, CO2 levels, and occupancy rates. The data collected by these IoT sensors is then transmitted to a central server, where it is stored and analyzed. For efficient and reliable data transfer, wireless communication protocols such as Wi-Fi, Bluetooth, or LoRaWAN are utilized.

As part of the system design of the controller, a thorough selection of hardware components and parameters was conducted. The designed printed circuit board (PCB) features include:

- A PCB thickness of 1.5 mm;
- A copper foil thickness of 35 μm ;
- Glass epoxy laminated with foil;
- Epoxy-urethane varnish;
- Minimum conductor width and spacing of 0.3 mm, with a power bus width of 0.4 mm;
- Minimum hole diameter of 0.352 mm, with mounting hole diameter of 2 mm;
- Geometric dimensions of the board: 50.7 mm \times 39.1 mm \times 6.81 mm.

Following the selection of the electronic base and PCB parameters, a Raspberry Pi compatible topology was developed using DipTrace, as shown in Fig. 5. All components were positioned as closely as possible to minimize the board's size. Metallized holes were created in the corners of the board for mounting in the enclosure. The connections for power sources were placed on the left side of the board, and the connection for the battery was located on the right side.

Fig. 5. Schematic of the IoT controller developed using DipTrace software.

The AI models within the system leverage this real-time data to continuously refine their predictions and immediately adjust the building's HVAC system to achieve optimal thermal comfort. A key feature of this setup is its feedback loop mechanism, which plays a critical role in maintaining desired thermal conditions. The AI algorithms actively process the incoming data from the IoT sensors and either make recommendations or directly control the HVAC system's operations, as shown in Fig. 6.

Fig. 6. General design of the system.

The device, powered by a rechargeable battery (referred to as the "slave device" in our model), collects data from sensors and sends this data to the master device. In our case, we use temperature and humidity sensors, which allow for monitoring in the environment to solve specific tasks. The only requirement for using this topology is that all slave devices must be no more than 100 meters away from the master device.

The topology of this model implies that each slave device is only aware of the master device's existence and there is no data transmission between two slave devices. This arrangement eliminates one of the main drawbacks: unreliable communication between two devices. The master device, in turn, is connected to the global network, and therefore, it only structures and redirects the data to the final destination—a database. There is a possibility that the master device may fail. However, nothing prevents connecting two master devices, through which sensor data is transmitted, and writing it into backup databases.

For instance, if the system detects any deviations from set comfort levels, it is programmed to make necessary adjustments to temperature, humidity, or airflow. This dynamic adjustment ensures that thermal comfort is not only achieved but sustained, adapting to both environmental changes and occupancy patterns within the building. A Raspberry Pi connected to a LoRa module serves as the master device. The role of the slave device is performed by a system composed of a microcontroller, a LoRa module, and sensors, all powered by a rechargeable battery. The collection of analog values produced by temperature and humidity sensors is facilitated by an integrated analog-to-digital converter. A fully charged battery can support the operation of the devices for up to 30 days.

The algorithm is implemented on the Raspberry Pi, which emulates the operation of a microcontroller. This device continuously listens on the 866 MHz frequency, which is used for transmitting data from the sensors. Selecting a suitable and efficient microcontroller will be part of future research. Managing comfortable environmental levels can also be controlled through an application as shown in Fig. 7. The interface allows us to easily manage the environment of a room. On the display, it can be seen current room conditions including temperature, humidity, and comfort level. To customize these settings, we can use the "Adjust Settings" section on the right, and the "Apply Settings" button to apply the new conditions.

Fig. 7. GUI of the managing application.

IV. RESULTS

After an initial filtering process, our dataset was reduced from 70 to 21 columns. We continued to refine our feature selection by using correlations and deliberately avoided incorporating Fanger's features. Further filtration using both

correlation analysis and the SelectKbest model, which assists in identifying the most impactful features, led us to define three distinct sets of features:

- First Set (17 features): Age, Sex, Metabolic rate (Met), Thermal preference, Thermal sensation, Clothing insulation (Clo), Subject's height (cm), Subject's weight (kg), Year, Season, Köppen climate classification, Building type, Cooling strategy at building level, Air temperature (C), Outdoor monthly air temperature (C), Relative humidity (%), and Air velocity (m/s).
- Second Set (9 features): Age, Sex, Met, Clo, Year, Season, Air temperature (C), Relative humidity (%), Air velocity (m/s).
- Third Set (15 features): Age, Clo, Sex, Met, Thermal preference, Year, Season, Köppen climate classification, Cooling strategy at building level, City, Predicted Percentage of Dissatisfied (PPD), Air temperature (C), Outdoor monthly air temperature (C), Relative humidity (%), Air velocity (m/s).

Following the feature selection, our dataset consisted of 17 columns and 6,765 rows. In the initial modeling phase, we utilized all 17 features, which yielded unsatisfactory results. Subsequent iterations with 9 and then 15 of the 17 features also failed to significantly improve outcomes. These iterations allowed us to test our hypotheses; notably, the IQR method enhanced model accuracy by approximately 3-4%, and the method of reducing label values improved accuracy by 20-23%.

Adjusting the parameters of our models led to more promising configurations. For the SVM model, optimal settings were identified as a radial basis function (RBF) kernel with gamma set to 0.001 and C set to 3. For the Random Forest model, the best parameters were found to be 300 estimators with a maximum depth of 15. These parameters maximized accuracy.

Additionally, comparing the impact of using LabelEncoder versus OneHotEncoder on the dataset revealed a difference in performance of 2-4%. This discrepancy influenced our decision to favor OneHotEncoder. Our tests on data standardization, using both the StandardScaler and MinMaxScaler, indicated that standardization did not significantly alter the accuracy, which remained relatively stable. Tables I, II, and III below present the initial results of our prediction efforts, illustrating the performance of each feature set and modeling approach:

TABLE I. ITERATION OF 17 FEATURES

Model	Accuracy	Precision	Recall	F1 score
SVM	0.509	0.451	0.509	0.436
RF	0.543	0.505	0.543	0.5

TABLE II. ITERATION OF 9 FEATURES

Model	Accuracy	Precision	Recall	F1 score
SVM	0.507	0.461	0.507	0.438
RF	0.526	0.513	0.526	0.49

TABLE III. ITERATION OF 15 FEATURES

Model	Accuracy	Precision	Recall	F1 score
SVM	0.533	0.448	0.533	0.433
RF	0.54	0.475	0.539	0.482

Based on the initial results, we further pursued enhancing model accuracy by employing the hypotheses formulated earlier in our study. The implementation of the IQR method was a particular focus, aimed at refining the data by removing outliers, which are often a source of prediction error. Tables IV, V, and VI below display the outcomes of applying the IQR method, which has further streamlined the model training process. These tables illustrate the effect of this technique on the overall performance of the models:

TABLE IV. ITERATION OF 17 FEATURES WITH IQR

Model	Accuracy	Precision	Recall	F1 score
SVM	0.522	0.44	0.522	0.441
RF	0.548	0.517	0.548	0.504

TABLE V. ITERATION OF 9 FEATURES WITH IQR

Model	Accuracy	Precision	Recall	F1 score
SVM	0.507	0.44	0.383	0.424
RF	0.52	0.501	0.52	0.479

TABLE VI. ITERATION OF 15 FEATURES WITH IQR

Model	Accuracy	Precision	Recall	F1 score
SVM	0.563	0.539	0.563	0.425
RF	0.57	0.494	0.57	0.5

Building on the improvements, which enhanced model accuracy by approximately 2-5%, our next step involves reducing label values to further increase the accuracy. This simplifies the output space of the model, potentially making it easier for the algorithms to distinguish between different states of thermal comfort. The Tables VII, VIII, IX shows the result of this approach:

TABLE VII. ITERATION OF 17 FEATURES WITH REDUCING LABELS

Model	Accuracy	Precision	Recall	F1 score
SVM	0.715	0.644	0.715	0.614
RF	0.744	0.708	0.744	0.704

TABLE VIII. ITERATION OF 9 FEATURES WITH REDUCING LABELS

Model	Accuracy	Precision	Recall	F1 score
SVM	0.688	0.598	0.688	0.569
RF	0.699	0.657	0.699	0.645

TABLE IX. ITERATION OF 15 FEATURES WITH REDUCING LABELS

Model	Accuracy	Precision	Recall	F1 score
SVM	0.78	0.608	0.78	0.683
RF	0.78	0.719	0.78	0.727

We utilized Random sampling to select subsets of the dataset for training individual decision trees within our Random Forest model. By integrating strategies such as feature reduction, IQR, and Random sampling, we have enhanced the construction and performance of our decision trees. These trees are built using recursive partitioning that methodically splits the data into increasingly specific subsets. This splitting is based on the feature values that most effectively differentiate the categories of the target variable.

The process is further refined through selective feature selection, which concentrates on the most impactful variables. This allows the model to focus on the data elements that are most predictive of the outcomes, significantly enhancing the overall performance of the model. These integrations contribute to a more efficient predictive tool, suitable for complex scenarios in smart building environments. After incorporating the feature-reduced model, further simplifying the feature space, we observed the following results, as in Tables X, XI, XII:

TABLE X. ITERATION OF 17 FEATURE-REDUCED LABELS AND IQR

Model	Accuracy	Precision	Recall	F1 score
SVM	0.726	0.598	0.726	0.621
RF	0.733	0.678	0.733	0.688

TABLE XI. ITERATION OF 9 FEATURE-REDUCED LABELS AND IQR

Model	Accuracy	Precision	Recall	F1 score
SVM	0.706	0.498	0.706	0.584
RF	0.717	0.668	0.717	0.653

TABLE XII. ITERATION OF 15 FEATURE-REDUCED LABELS AND IQR

Model	Accuracy	Precision	Recall	F1 score
SVM	0.835	0.697	0.835	0.76
RF	0.821	0.738	0.821	0.766

The implications of these findings are significant, especially in the context of predictive accuracy in environmental modeling for predicting thermal comfort levels in smart building systems. The Receiver Operating Characteristic (ROC) curves graph, presented in Fig. 8, provide a visual comparison of the performance of two machine learning models: SVM and Random Forest (RF). These curves are essential tools in evaluating the models by plotting the True Positive Rate (sensitivity) against the False Positive Rate (1-specificity) at various threshold settings. The area under the curve (AUC) serves as a summary measure of the model's ability to discriminate between positive and negative classes.

Fig. 8. ROC comparison for both the SVM and RF.

In this analysis, the SVM model demonstrates an AUC of 0.72, while the RF model exhibits a slightly superior AUC of 0.84. This suggests that the RF model has a better overall performance in distinguishing between the classes under study, likely due to its ensemble nature, which typically provides a more robust prediction by averaging multiple decision processes.

The following boxplots, depicted in Fig. 9, below show the distribution of cross-validation accuracy scores for SVM and RF models across various feature sets and conditions. The SVM exhibits a broader range of accuracy variations, especially with the 15-feature set. The increase in accuracy when reducing label values suggests that SVM benefits significantly from a simplified output space, potentially due to reduced complexity in the decision boundary formation. The RF shows tighter accuracy distributions and higher median accuracies across all feature sets, indicating better stability and robustness. The performance improvements with label reduction demonstrate RF's effectiveness in handling more straightforward, cleaner data. Further exploring more sophisticated data preprocessing techniques such as feature scaling, transformation (like log transformation for skewed data), or anomaly detection methods could help to handle outliers more dynamically than just applying IQR.

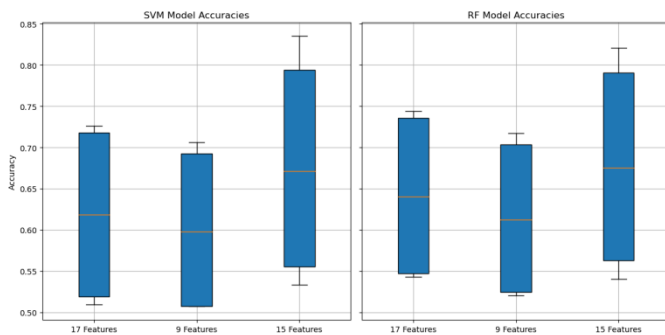

Fig. 9. Boxplots of cross-validation accuracy scores.

The implications of these findings are significant, especially in the context of predictive accuracy in environmental modeling, such as predicting thermal comfort levels in smart buildings. The higher AUC for the RF model indicates a higher likelihood of correctly classifying the thermal comfort levels as satisfactory or unsatisfactory, which

is crucial for developing systems that can dynamically adjust to maintain or achieve desired comfort states. Moreover, the relatively lower performance of the SVM could be attributed to its sensitivity to the choice of kernel and the tuning of its parameters, which might not have been optimal in this scenario. These insights not only aid in selecting the appropriate model for deployment but also highlight the importance of model tuning and feature selection, reinforcing the need for ongoing model adjustment in practical applications to achieve the best outcomes.

V. DISCUSSION

This research assesses the effectiveness of Random Forest and SVM algorithms across different feature sets in predicting thermal comfort and thermal preference. We introduced eight new features in our analysis, while seven features were consistent with those used in prior studies. When comparing the outcomes for guessing Thermal comfort versus Thermal preference, the performance gap between them was relatively narrow, ranging from 1-3%, with Random Forest generally exhibiting greater stability.

Specifically, in the scenarios where we tested sets with 9 and 15 features, alternative versions of our models initially led in performance. However, a significant shift occurred when we simplified the prediction scale from six to three Thermal comfort values, which resulted in our primary model configuration achieving superior results. This simplification appeared to enhance the model's ability to discriminate between different levels of comfort effectively.

Moving forward, we plan to incorporate additional features to refine the models' accuracy further. One promising candidate is Heart Rate Variability (HRV), which has potential implications for assessing physiological responses to thermal environments. Moreover, I am keen to explore the capabilities of neural networks and deep learning techniques, inspired by their success in related fields. My intention is to experiment with various advanced algorithms such as Convolutional Neural Networks (CNNs), Recurrent Neural Networks (RNNs), Long Short-Term Memory (LSTM) networks, Autoencoders, and Deep Belief Networks (DBNs). These methodologies, referenced in papers [18] and [10], will form the basis of future research efforts aimed at enhancing the predictive accuracy of thermal comfort models.

While the reduction of the thermal comfort scale from six levels to three markedly improved the models' discriminative capabilities, some researchers argue that this simplification might obscure subtle nuances in human comfort perception [24]. Critics suggest that while a simpler output space indeed facilitates more accurate classifications by reducing the complexity the model must manage, it potentially oversimplifies human experiences, which could be better captured with a more granular scale [25].

The introduction of the IQR method led to an approximate 3-4% improvement in model accuracy. However, it is essential to note that while IQR can effectively reduce outlier influence, it may bring limitations to valid extreme cases that are crucial for understanding the full spectrum of environmental impacts on thermal comfort [26]. The more substantial impact came

from reducing label values, which boosted accuracy by 20-23%. This dramatic increase underscores the pivotal role of thoughtful statistical techniques in predictive model development. Yet, there remains a debate over whether such methods compromise the depth of data insights for the sake of model performance [27].

The system's architecture, employing a master-slave device setup, has shown efficient data management and transmission capabilities. Slave devices, powered by rechargeable batteries and strategically placed not more than 100 meters from a Raspberry Pi master device, efficiently transmit sensor data. However, some experts raise concerns about the scalability and maintenance of such setups in larger or more complex building environments [28]. Critics also question the reliance on Raspberry Pi for critical real-time data processing, citing potential limitations in processing power and storage compared to more robust computing solutions [29].

The capability for direct user interaction with the building management system through an application is hailed for its user-centered design, merging comfort with energy efficiency. Nevertheless, this approach raises questions about the trade-offs between user control and automated system efficiency, with some arguing that excessive user interaction might lead to less optimal energy use [30].

This study's significant contributions to environmental control and smart building management highlight the intersection of advanced computational techniques with practical IoT implementations. Yet, the ongoing exploration of new features and modeling techniques also points to a field that is constantly evolving, with ongoing debates about the best balance between accuracy, user experience, and system reliability [31]. We hope, these discussions are crucial as they push the boundaries of what smart building systems can achieve, ensuring they meet both current and future demands effectively.

VI. CONCLUSION

This study has explored the application of Random Forest and SVM algorithms to predict thermal comfort and preference, utilizing a refined feature set that integrates both newly introduced variables and established ones from prior research. The performance differential between predicting thermal comfort and thermal preference was relatively minimal, typically within 1-3%, with Random Forest demonstrating superior stability and robustness across varied feature sets. A pivotal enhancement in model performance was observed when the complexity of the thermal comfort scale was reduced from six to three levels, which notably improved the model's ability to discriminate between different comfort states more effectively.

To address the shortcomings in existing research, our paper showcases the advantages of the proposed techniques over traditional methods. For instance, the paper introduces clever adjustments to the thermal comfort prediction models, such as the reduction of the thermal comfort scale from six to three levels, which has shown to improve the accuracy of SVM and Random Forest models. This simplification not only enhances model precision but also makes these models more adaptable to

various data types, which is essential for integrating environmental sensors in building management systems. Additionally, the novel use of the 'Thermal preference' column as a predictive variable instead of the standard 'Thermal comfort' scale offers a more streamlined and effective approach to predicting thermal comfort. By providing a thorough comparative analysis of these modifications against conventional methods, the paper highlights the practical implications in improving thermal comfort assessments.

While the simplification of the thermal comfort scale has yielded significant improvements, it also raises questions about the potential limitations of oversimplifying the nuances of human thermal perception. The use of the IQR method has also shown to improve model accuracy modestly; however, its tendency to remove valid extreme data points could limit understanding the broader impacts of environmental variables on thermal comfort. Moreover, the substantial increase in accuracy from reducing label values underscores the critical role of sophisticated statistical techniques in developing effective predictive models, though this approach has sparked debate regarding the depth and granularity of data interpretation.

The architectural design of our IoT-based system, featuring a master-slave configuration, has proven effective in data management and transmission, albeit with some concerns about scalability and dependency on limited-capability devices like the Raspberry Pi for critical processing tasks. Additionally, the system's design allowing direct user interaction via an application exemplifies a user-centered approach that harmoniously blends comfort with energy efficiency, though it also invites scrutiny over the potential for suboptimal energy usage due to excessive manual interventions.

Future enhancements are planned through the integration of additional predictive variables such as HRV, which holds promise for assessing physiological responses to varying thermal conditions. The potential of neural networks and deep learning will also be explored to leverage their proven capabilities in similar domains. Techniques such as CNNs, LSTM networks, and DBNs will be investigated to further refine the accuracy and efficiency of our models.

The contributions of this research to the fields of environmental control and smart building management are significant, illustrating the powerful synergy between advanced computational methods and practical IoT implementations. The ongoing development and refinement of these models push the boundaries of what smart building systems can achieve, ensuring they not only meet current demands but are also well-prepared for future challenges.

Exploration of Deep Semantic Analysis and Application of Video Images in Visual Communication Design Based on Multimodal Feature Fusion Algorithm

Yanlin Chen, Xiwen Chen*

College of Visual Arts, Hunan Mass Media Vocational and Technical College, Changsha 410000, China

Abstract—Fully utilizing image and video semantic processing techniques can play a more effective role in visual communication design. In order to further explore the application of multimodal feature fusion algorithm (MFF) in video image feature analysis in visual communication design, with the aim of enhancing the depth and breadth of design creation. This article focuses on the application of video semantic understanding technology by combining image and video semantic processing techniques, in order to achieve a comprehensive, three-dimensional, and open expansion of design thinking. The MFF algorithm was proposed and implemented, which innovatively integrates multimodal information such as visual and audio in videos, deeply explores action semantics, and shows significant performance improvements compared to traditional algorithms. Specifically, compared to the other two mainstream algorithms, its performance has improved by 24.33% and 14.58%, respectively. This discovery not only validates the superiority of MFF algorithm in the field of video semantic understanding, but also reveals the profound impact of video semantic understanding technology on visual communication design practice, providing new perspectives and tools for the design industry and promoting innovation and development of design thinking. The novelty of this study lies in its interdisciplinary methodology, which applies advanced algorithm techniques to the field of art and design, and the significant improvement of the proposed MFF algorithm in enhancing design efficiency and creativity.

Keywords—Video semantics; understanding; visual communication; design

I. INTRODUCTION

Under the background of new media, visual communication design has become a comprehensive discipline, which promotes the emergence of new design art forms, and also changes the traditional design concept and thinking mode, which has been widely used in all aspects of life [1]. The video semantic understanding technology is updating day by day, which plays a driving role in the development of visual communication design, and promotes the information design to have different meanings and effects. In varying degrees, it has an impact on visual effects in various fields, becoming a role of visual culture construction, and also a designer of the new era [2]. In the process of visual design, there is an inseparable relationship between the state of graphic design and its aesthetic feeling. From the graphic chronicle in ancient

times to the evolution of graphic symbols and character symbols today, the rule of graphic language has realized a good interaction between simple and complex, and has actually become one of the indispensable decorative languages in people's lives [3]. In a design work, almost all images can appear in the form of points, surfaces, lines, and the comprehensive application of points, lines and surfaces, which is flexible [4]. Moreover, the design should follow such a principle that visual graphics must be clearly identifiable, on the contrary, when a graphic structure is fuzzy, the meaning it conveys must be fuzzy [5]. Graphical symbols of visual design, as well as visual representations such as pattern modeling, pictures, signs, etc. aimed at the design theme, are called graphic information through the content, feelings and visual impact conveyed by these graphics [6]. In the visual design language, the modeling elements are points, lines, surfaces, tones and materials. Any kind of graphic information, such as trademarks, patterns, etc., can be understood as a specific modeling element [7]. Therefore, in visual design, a Fig. 1, a pattern or a style of symbols should be used accurately. Only in this way can they convey the necessary information [8].

With the rapid development of digital media technology, visual communication design is no longer limited to traditional static images and text, but is gradually evolving towards dynamic, multidimensional, and interactive directions. Video, as one of the most expressive and infectious forms of media, plays an increasingly important role in visual communication design. However, current video semantic understanding technology cannot fully meet the needs of visual communication design for accurate and efficient information extraction and expression, especially when dealing with complex scenes and multimodal data, there is a significant research gap. This study aims to fill this research gap by exploring the application of video semantic understanding technology in visual communication design and proposing a new method based on multimodal feature fusion algorithm (MFF). This algorithm aims to integrate multi domain scene information, especially action semantic information, in videos to achieve more accurate and comprehensive video content understanding and analysis. Through this method, we hope to enrich the thinking and expression methods of visual communication design, making design thinking more diverse and extensive, while improving the efficiency of information communication and aesthetic experience of design works. In

*Corresponding Author.

the process of using visual design language to communicate, designers mostly pay attention to and study how to convey "explicit" visual information [9]. In fact, these explicit visual information communications are established on the basis of "known information", and these "known information" are often ignored by designers, let alone effectively used. These "preset information" are just the basis and prerequisite for importing the visual information to be conveyed. Only by effectively combining this implicit known information with the explicit visual information to be conveyed can an effective visual communication process be generated [10]. If the traditional way of communication is adopted, the relevant staff need to fuse images, words, etc. to realize the transmission of visual information [11]. Through dynamic visual transmission, the transmission speed can be improved. At the same time, it allows people to obtain accurate information resources in a short time and observe the way of information transmission, while the dynamic way of transmission requires the assistance of video semantic understanding technology. Under the video semantic understanding technology, through dynamic transmission, the abstract visual works are more vividly presented in the eyes of the audience, so that the audience has a more profound memory [12]. Compared with traditional static images, the dynamic design of visual communication has more advantages to avoid visual fatigue of the audience, increase the sense of interest for the audience, and make the information communication effect good.

Semantic understanding of video is the highest level of research in machine vision. Firstly, video is processed and analyzed, and then the main content of video is described. Different video meanings and tasks require different working situations, and different objects appear. Of course, different visual comprehension algorithms are needed. In a certain period of time, multimedia data such as video frames, audio signals, and transcribed texts may not appear at the same time, and there is an unsynchronized phenomenon, but they all share a semantic meaning and are coupled with each other within the semantic duration [13]. For example, different shots that express the same meaning may look very different visually. Swimming and football, which also represent "sports", are mainly composed of blue swimming pool water and green football field grass. However, text features may express more similarities, thus making up for the weak correlation of other modes [14].

The introduction of this article first emphasizes that in the context of new media, visual communication design has become a comprehensive discipline, which not only promotes the emergence of new design art forms, but also changes traditional design concepts and ways of thinking, and is widely applied in various aspects of life. This clarifies the important position and influence of visual communication design in contemporary society. Furthermore, the introduction points out that the increasingly updated video semantic understanding technology has played an important role in promoting the development of visual communication design, and has facilitated information design to have different meanings and effects. This further emphasizes the positive impact of technological progress on the field of design. The contribution points of research innovation are as follows:

- This study proposes a multimodal feature fusion algorithm (MFF), which demonstrates unique advantages in video semantic understanding. By integrating semantic information of multi domain scene actions in videos, MFF algorithm can comprehensively understand video content, which is an important innovation for traditional video processing algorithms.
- The research has improved the application effect of video semantic understanding technology in visual communication design. The application of MFF algorithm in the field of visual communication design has achieved an organic combination of video semantic understanding technology and design art.
- Compared to the other two mainstream algorithms, the MFF algorithm has improved performance by 24.33% and 14.58%, respectively. This significant improvement not only validates the effectiveness of the MFF algorithm.
- Research the application of video semantic understanding technology in visual communication design from the perspective of semantic analysis. The update of this design concept helps designers better grasp design trends and create more innovative and artistic works.

II. RELATED WORK

Ren believes that visual thinking is based on the information of the objective image itself, and uses visual thinking to capture the characteristics of the shape as a means to connect the abstract shape with the semantics of the concrete objective image [15]. Min, Wang, Rushan emphasized that in visual communication, the meaning of shape is generated, communicated, fed back in the "person shape person" system, and then generated, communicated, and fed back again, and so on [16]. Therefore, in the video semantics, Chang and others believe that visual communication design is not only a simple combination of words, sounds and pictures, but also a combination effect of three or more communication elements. The diversified design helps both the transmission and reception of video news achieve ideal effects [17]. Xue has shown in his research that graphics are one of the important elements in visual communication design, and each designer has different performance for the use of graphic design in visual communication. Because people live in different geographical environments, their cultural cognition is also different. However, through the interpretation of graphics and visual transformation, barriers and barriers in communication can be effectively solved, so that visitors can more accurately understand the design connotation [18]. Ge H regards multi-level semantic concepts as the hidden state of Markov chain, and regards multiple basic visual semantics with time semantic context constraints as the observable symbols corresponding to the hidden semantic state. Under this condition, using hierarchical hidden Markov model, the analysis and extraction process of multi granularity visual semantics can be transformed into the process of analyzing the most likely hidden state of known observable symbols [19]. In

the research of video semantic understanding, features of different modes cannot be directly analyzed and compared in the semantic analysis process. How to mine the complementary association between different modes and extract and construct data information consistent with the semantic content has become a problem to be solved. Bae J proposes an extended direct push support tensor machine, which is used as a semantic classifier to detect the semantic concept of video shots [20]. Xin thinks that video data contains a large amount of valuable information. However, due to semantic barriers, human beings have been unable to make full use of this information. However, the birth of data mining technology can help people make full use of this information [21]. Xiao et al. proposed a feature extraction method (Dense Trajectory, DT) based on dense trajectories. This method samples each frame of video intensively, then tracks the optical flow information of these sampling points, and obtains more accurate feature expression through screening and optimization [22]. Subsequently, Natalia et al. proposed an improved Dense Trajectory (iDT) algorithm, which mainly optimizes optical flow images, and improves the regularization and feature encoding methods at the same time, further improving the algorithm performance [23]. Wu et al. proposed a video humanoid parsing algorithm based on semantic transfer. This method uses the complementarity of image semantics and video semantics to propose a module that can integrate two semantics at the same time, and applies it in the convolutional neural network structure [24].

III. THEORIES RELATED TO VIDEO SEMANTIC UNDERSTANDING TECHNOLOGY

A. Video Structure

Faced with a variety of complex information, traditional information management methods have been stretched to the limit, and human beings must develop new technologies to help themselves deal with information [25,26]. Traditional video management is basically realized by the underlying features. However, many years of practice and practical experience tell us that video management must analyze the semantics of video. Video language, as a camera technology applied in video, can give people a strong impact on vision. Video image language not only has a passionate expression, but also has a calm way of thinking, bringing more visual feelings to people. Using video language in visual communication design can make advertisements and posters more personalized and aesthetic [27,28]. By combining video language with visual communication design, designers can make better use of film and television effects when designing advertisements, bringing more visual impact to people. A video is composed of continuous image changes. When the image changes more than 24 frames per second, the human eye can no longer distinguish whether the received picture information is still a static image. It looks like a series of fluent pictures. This is called video (Fig. 1). In general, video is composed of continuous image sequences, and the semantic association between each image constitutes the semantic information of the whole video. Moreover, the video data has a much larger capacity than the text data (Table I).

Fig. 1. The composition of each level of the video structure.

Video is mainly divided into structure and composition of each level. First, the adjacent video frames in the time dimension are divided into multiple different shot units without intersection. Key frames of shot units are extracted. The number of key frames extracted for each shot depends on the situation of the shot itself. Observe the video key frames and determine the combination of shots to get the video scene.

TABLE I. COMPARISON OF TEXT DATA AND VIDEO DATA

Features	Text data	Video data
Symbol set	Limited	Infinite
Resolving power	Low	High
Explanation ambiguity	Low	High
Interpretative function	Low	High
Data capacity	Small	Big

Semantic differences make it impossible for humans to directly apply the information of video data. There is a gap between the low-level features of images that can only be obtained by computers and the high-level semantics. When watching video, human can judge the events in the video by integrating their own knowledge. The computer has limited ability to obtain image features such as image color and texture, but has no ability to judge. Generally speaking, video semantics can be divided into three levels: low-level semantics, middle level semantics and high-level semantics. The semantics of the bottom layer includes the semantics of all the features of the video bottom layer, including the description of color, texture, edges, dynamics and other features. The middle

level includes the description of video target action, density, traffic statistics, etc. The high-level semantics is the description of video event attributes. According to this division, we get the video semantic architecture of Fig. 2. In the multimodal analysis method of video semantic understanding, fusion is an indispensable step. Early integration and late integration are the two main integration methods at present. Most existing semantic concept detection methods are based on these two schemes. Pre-fusion refers to combining the features of single modality before learning and training, while post-fusion refers to learning the features of single modality separately, and then fusing and analyzing the results of multiple modalities.

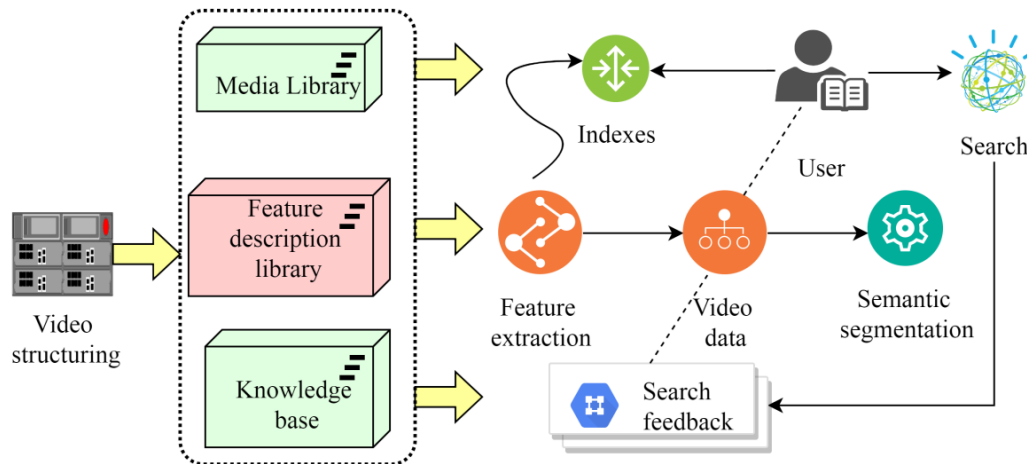

Fig. 2. Multi modal fusion steps for video semantic understanding.

In general, it is natural for an event model to have two or more state variables from a semantic perspective, forming a state chain over time. Factorization of state space into polymorphic chains is another way to simplify the event model. These multiple chains can correspond to sub-events that interact with one compound event or multiple objects at the same time.

B. Application in Visual Communication Design

In the process of visual communication design activities, designers can greatly enhance the user's emotional experience, realize the interaction of multiple senses, and let the audience experience in an all-round way through the application of video semantic understanding technology. Under the background of new media, designers can avoid aesthetic fatigue by reasonably designing graphics, words and videos, and communicate them in the eyes of people by animation, which has a good sense of experience. The central meaning of visual design is "the desire of artistic Fig. materialization". The whole design should be expressed around people's wishes, and it must have human visual visibility and readability. To make the semantics of visual form accurate, we must first understand the potential language of each design factor, understand the design principles, text semantics, graphic semantics, color semantics and psychological implications, and so on, so as to comprehensively convey information. Visual communication cannot be conveyed through people's mouth like people use language, but depends on the media: "shape" is conveyed in the system of people, shape and people.

Therefore, it is necessary for people to strictly control and study the rules of "the meaning of form". The semantic meaning of the form with visual communication as the main content (such as signs, advertisements, posters, publicity cards, etc.) mainly conveys the idea of the producer. The semantic meaning of the shape with the use function as the main content (such as cars, rain gear, etc.) makes the user clear and easy to use through the information displayed by the shape, color, etc.

Visual communication design is a complete process of information design and dissemination. Under the influence of digital media technology, great changes have taken place in the mode of information dissemination and reception in people's lives. In the process of the integration of visual communication technology with computer and digital media, the communication mode has changed from dynamic to static, from passive to active, which leads to certain communication characteristics of visual communication design.

IV. INTRODUCTION TO ALGORITHMS

A. Semantic Concept Modeling

We obtain the contribution score of each action sample to its action semantic concept by preprocessing the classifier, and according to the score, integrate the sample subsets into a fusion vector encoding multi-domain invariant action information. This process can be modeled as:

$$G(x, y) = \sum_{i=1}^l r_{ij}(x_i y_j) \quad (1)$$

Where, x_i is the embedded matrix corresponding to the i field, and r_{ij} is the weight of action sample $x_i y_j$.

In order to further explore the potential association between multiple action semantic concepts, we use constraints to limit the number of non-zero rows in matrix W to control the number of sparse features in the model. Constraints are modeled as:

$$\text{cons}(R) = \sum_{i=0}^n I(\|w_i\| > 0) \leq u \quad (2)$$

$$P_r(B_t|x) = \frac{p_r(x|w_i)}{\sum_{j=1}^r p_j(w_i)} \quad (3)$$

When the Mercer condition is satisfied, replacing the dot product in the optimal classification surface with the inner product S is equivalent to transforming the original input space into a new feature space, and the corresponding high-level multimodal fusion function is:

$$f(x) = \text{sgn} \left[\sum_{i=1}^n a_i k(s_i, s) + b \right] \quad (4)$$

Where, $a_i > 0$ is the lagrange coefficient and b is the domain value of classification.

Because of the potential correlation between semantics,

Fig. 3. Multilayer recurrent neural network.

C. Attention Model

When people observe an image, they focus not on all visual content, but on each pixel area of the image selectively.

Firstly, RNN feature $V = \{v_1, v_2, \dots, v_n\}$ is extracted from the video sequence, and then the feature sequence is weighted using the attention model according to the following formula:

$$a^t = \sum_{i=1}^n a_i v_i^t \quad (6)$$

multi semantic modeling is essentially a process of establishing mathematical models for interrelated tasks. Traditional machine learning methods often adopt single task learning mode, and learn a model independently for each task. This single task learning method ignores the association between multiple tasks (semantic concepts), and loses hidden information existing between data or model parameters.

B. Recurrent Neural Networks

Recurrent Neural Networks (RNN) are often used to process sequence data, such as time dependent voice data, video data, and natural language data with semantic coherence. Like convolutional neural network, cyclic neural network also uses the idea of weight sharing, so similar to convolutional neural network, it can process images of different sizes, and cyclic neural network can be used to process sequence data of any length. The basic principle of recurrent neural network can be expressed as:

$$h_t = f_w(h_{t-1}) \cdot x_t \quad (5)$$

Where, h_t is the hidden state information representation vector of time t , encoding the sequence information input at the first t times.

Fig. 3 shows a multi-layer recurrent neural network. Single layer refers to the number of layers of the recursive function itself, not the number of moments of the expanded graph. Multilayer recurrent neural network, that is, recursive function, has the form of multilayer network. Multilayer networks have more nonlinear structures and are often used to model sequences with complex structures.

By adjusting the attention weight a_i^t at any time, the model strengthens the correlation between the output words and the video content, thereby improving the quality of the output sentences.

Channel attention first performs global average pooling on features to generate vector Z and its t -th element:

$$Z_k = \frac{1}{h \cdot w} \sum_{i=1}^h \sum_{j=1}^w \theta_i(i, j) \quad (7)$$

D. Feature Extraction

Let the cumulative color histograms of two frames be $H_i(p)$ and $H_j(p)$ respectively, and P is a color statistic in the histogram. If $s_{ij}(p)$ is a local similarity measure around P , their global similarity is:

$$s_{ij} = \sum s_i(p)q_j \quad (8)$$

It can be calculated according to normalized cross-correlation:

$$a_i(p) = \sum H_i(p-q)W_t(q) \quad (9)$$

$$b_j(p) = \sum [H_j(p-q) - a_i(p-q)]^2 \quad (10)$$

where W_t is a window function of length t .

As long as the cross-correlation is added up, a global similarity can be obtained, and a global similarity can be obtained. Generally, the very dissimilar frames are removed and then judged. For a shot, the first frame is compared with the last frame of the first five or six shots. If a match is found, all shots between them can be considered as belonging to the same scene.

Due to the different observation of video events and the uncertainty of translation, a probabilistic event model is proposed. Bayesian model is a probabilistic event model, which uses the main semantic knowledge and is very powerful in factorizing the state space into variables. See formula (11) for the hierarchical characteristics of the simulated video events of this natural model.

$$\Delta k = \min(\alpha\Delta_1, \alpha\Delta_2, \dots, \alpha\Delta_n) \prod_{i=1}^n \Delta\alpha_i^{\frac{1}{2}} \quad (11)$$

This is because the probability output at the top node of the sub event network can be easily integrated into an event model "observation" node at a higher level. Although these networks are large, effective inference can be realized according to the existing structure. Hierarchical model semantics adopt hierarchical Yebes network layer. Each layer corresponds to a higher-level semantic unit.

$$p(y|x) = \frac{yx^T w}{1 + yx^T w} \quad (12)$$

The next position of eye movement shall be based on the maximum distribution of each image slice:

$$H = 0.5 \sum_{i=1}^n \log(1 + \lambda_i / \mu) + n \log(2\pi) \quad (13)$$

Among them, λ_i is the eigenbit of the pixel covariance matrix in the middle part of each image slice, and μ is the noise level that is different from the pixel grayscale quantization value.

In order to detect the changing image position, the contrast is used to calculate, that is, the normalized result of the standard deviation of the local pixel gray level inside the image to the average gray level of the entire image, which helps to select the area with relatively high contrast as the eye movement pre-attention center.

$$c = G_N \sum_k (I_{ij} - I_k)^2 \quad (14)$$

When the problem is linear and indivisible, a nonlinear mapping algorithm is needed for transformation. The properties of high-dimensional feature space change when the low dimensional input linearly indivisible examples are converted to high-dimensional feature space, so that people can use it. The principle must be from linearly separable to linearly indivisible in more complex cases, and even nonlinear functions are applicable. According to the statistical theory of limited samples, the inequality is established by probability:

$$R(Q) \leq R_{emp}(Q^*) + \sqrt{\frac{c}{l} (\frac{p^2}{m^2} \log p - \log m)} \quad (15)$$

In the formula: P is the spherical radius of the entire sample space, M is the space edge, and l is the number of samples in the sample space.

V. EXPERIMENTS AND RESULTS

In order to evaluate the effectiveness of the proposed method, a large number of experiments have been carried out on the NYUDv dataset and the SUN-RGBD dataset. First, we introduce the experimental setup, including experimental details, data sets and evaluation indicators, and then conduct ablation experiments to determine the segmentation performance of the newly proposed network. Finally, the proposed method is compared with the existing method in the above two datasets. General data enhancement strategies are adopted, such as random scaling, random horizontal flipping and random clipping of images within [0.1, 0.5] scales. For the above data set, adjust the size of the input image to 480×640 pixels (Table II). In the test, the prediction results for semantic segmentation are obtained only from the main branch of the decoder.

TABLE II. COMPARISON RESULTS IN EACH CATEGORY WITH OTHER RGBD IMAGE SEMANTIC SEGMENTATION METHODS ON THE NYUDV DATASET

Method	Image A	Image B	Image C	Image D	Image E
Deep Lab	4	12.2	8.3	6	5.9
Literature [18]	6.2	3.6	6.4	13.3	7.1
CANet	4.7	9.3	1	9.3	13.4
Literature [22]	1.4	5.8	14.5	7.8	9
This paper	7.1	8.1	5.1	1.7	6.7

Here we combine the above two strategies. For the unlabeled sample video, we first calculate the score through temporal dependency and semantic relevance strategies, and then linearly fuse them to get the final score. Fig. 4 shows that the application of sample 1 in the two strategies further

improves the classification performance than that of sample 2.

Fig. 4. The results of 18 feedbacks of the two sample combinations.

In the process of video data information mining, the low-level features at the bottom of the above video image, including texture, color, motion vector, detection edge, histogram and other information, are first extracted. Such information is beyond the scope of people's understanding ability, which provides a basic work for the mining of meta semantic information. People then use object detection [31], tracking and extracting semantic information from image

feature comparison. Noise in natural images can affect the accuracy of super pixel similarity to some extent, and further hinder the propagation of associated attributes. In general, the interference of noise on natural images is reflected in their statistical characteristics, and mLab can be regarded as a special statistical feature of images. Compare the characteristics of the three segments to obtain Fig. 5 and 6.

Fig. 5. Original image.

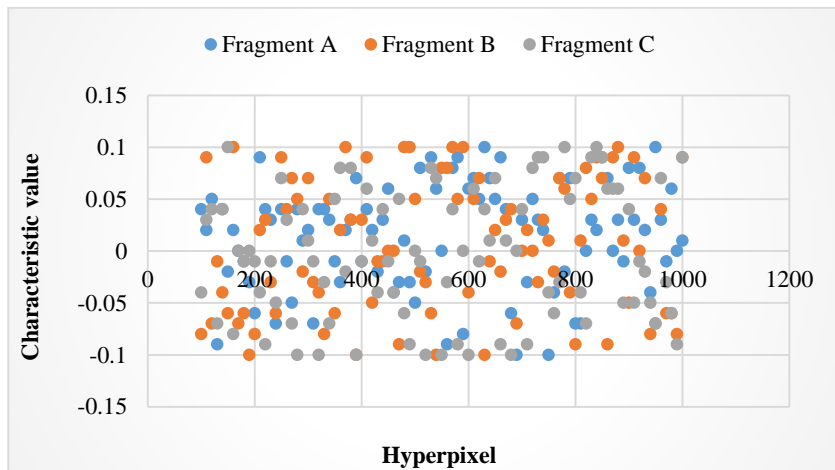

Fig. 6. Smoothed image.

From the above results, it can be seen that the subspace of multi-scale super pixels is always sparse, and the changes presented are also significantly smaller than the changes in area when the number of super pixels decreases. Therefore, the subspace maintenance can better reveal the membership relationship of super pixels. The smoothed image obtains some different image regions, thus creating sub regions of the image. On the basis of these sub regions, the basic semantic image slice of the image can be roughly obtained by determining the characteristics between the sub regions. And the visual features of the image are obtained on the basis of color and texture acquisition, which is helpful for the transition of image understanding from the underlying visual cognition to the connection between image semantics and the analysis of image structure composition.

TABLE III. COMPARISON OF TWO MODAL PERFORMANCES

RGB mode		Depth mode	
Side view	Foresight	Side view	Foresight
0.6	0.75	0.61	0.59
0.71	0.85	0.75	0.78

0.79	0.84	0.62	0.63
0.74	0.73	0.53	0.74
0.73	0.69	0.62	0.85
0.66	0.76	0.7	0.74

It can be seen from the comparison of the performance of the two modes in Table III that the cross-modal feature propagation improves the performance of semantic segmentation. MFF algorithm handles the details well, and accurately captures the differences between classes and the consistency within classes. In order to segment the super pixel image at different scales, it is necessary to construct a hybrid graph to describe the relationship between pixels and super pixels and between super pixels and super pixels. First, a multimodal fusion module based on attention mechanism is proposed, which aims to process multi-level pairing complementary information in the dual stream encoder, that is, to process color and depth images respectively in the same backbone network. In order to clearly test the effect of each link, we respectively evaluate in RGB and depth scenes of NYUDv database.

Fig. 7. Evaluation of RGB modal scene feature extraction methods.

It can be seen from the data in Fig. 7 that compared with No-CE sub-experiment, CE sub-experiment can achieve better classification performance, which is nearly 28.2% and 17.6%

higher than No-CE in RGB and depth scenes, respectively, which proves the effectiveness of multi-domain embedded matrix.

Fig. 8. Evaluation of deep modal scene feature extraction methods.

It can be seen from the data in Fig. 8 that by comparing the performance of CE sub experiment and multimodal feature fusion algorithm, the classification performance of MDMTL

in depth scenes is 15.4% higher than that of CE, which proves the effectiveness of multi domain feature fusion.

Fig. 9. Comparison of semantic information accuracy of three algorithms.

Fig. 9 shows that because the algorithm in this paper integrates the action semantic information in the multi domain scene, it has a certain anti-interference ability on the impact of feature noise. Therefore, its performance is nearly 24.33% higher than that of the Literature [18] algorithm, and nearly 14.58% higher than that of the Literature [22] algorithm. So, we conclude that with the help of video semantic understanding technology, visual designers can better grasp consumers' psychology with the support of technology. So as to better grasp the initiative in the whole design process and guide consumers to obtain information. This article

emphasizes that the MFF algorithm achieves deeper semantic understanding by integrating action semantic information from multiple domain scenes. Compared with those researches that only rely on single modal information [29] (such as only vision or only audio), MFF algorithm can capture key information in video more comprehensively.

The comparison results in Fig. 9 show that the MFF algorithm is significantly better than the other two algorithms in terms of semantic information accuracy. This is mainly due to the MFF algorithm integrating action semantic information from multiple domain scenes and possessing certain

anti-interference capabilities. In practical applications, video data often contains various noise and interference factors, such as lighting changes, occlusion, motion blur, etc. The MFF algorithm effectively reduces the impact of these noise factors on segmentation results by introducing multimodal feature fusion and attention mechanism [30], thereby improving the accuracy and reliability of semantic information. With the help of video semantic understanding technology, visual designers can gain deeper insights into consumer psychology and more accurate scene understanding. This helps designers to better grasp the initiative throughout the entire design process, enhance consumer participation and satisfaction through precise information communication and guidance. Meanwhile, video semantic understanding technology also provides designers with rich data support and decision-making basis, making the design process more scientific and intelligent. Therefore, applying video semantic understanding technology to visual communication design not only helps improve the quality and effectiveness of design works, but also promotes innovation and development in the design industry.

VI. CONCLUSIONS

This study thoroughly explores the application of multimodal feature fusion algorithm (MFF) in video semantic understanding, successfully demonstrating its significant advantages in improving the efficiency and effectiveness of visual communication design. The MFF algorithm integrates action semantic information from multiple domain scenes to achieve comprehensive and accurate analysis of video image features, providing a richer and deeper semantic understanding foundation for visual communication design. The experimental results show that compared with existing algorithms, the MFF algorithm achieves performance improvements of 24.33% and 14.58%, respectively, which fully demonstrates its superiority in the field of video semantic understanding. This study not only enriches the theoretical system of video semantic understanding technology, but also brings new technical support and creative inspiration to the field of visual communication design. Through the application of MFF algorithm, designers can have a more comprehensive and in-depth understanding of video content, thereby better grasping consumers' psychology and needs in the design process, and achieving a comprehensive, three-dimensional, and open understanding and perception of design thinking. This technological innovation not only enhances the quality and attractiveness of design works, but also points out the direction for the future development of the visual communication design industry.

Although significant progress has been made in the combination of video semantic understanding technology and visual communication design in this study, there are still some limitations. Firstly, this study mainly evaluates based on specific databases such as NYUDv, which may not fully cover all possible video scenes and design requirements. Therefore, the generalization ability of the algorithm needs further verification. Secondly, although multimodal feature fusion algorithms integrate action semantic information from multiple domain scenes, their performance may be limited when dealing with extremely complex or highly dynamic video content. In addition, this study did not delve into the

specific needs and application scenarios of video semantic understanding technology in different design fields (such as advertising, animation, film, etc.), which limits the wide applicability of the research results.

A Deep Reinforcement Learning (DRL) Based Approach to SFC Request Scheduling in Computer Networks

Eesha Nagireddy

Computer Science, University of Texas at Dallas UTD, Plano, United States of America

Abstract—This study investigates the use of Deep Reinforcement Learning (DRL) to minimize the latency between the source and destination of Service Function Chaining (SFC) requests in Neural Networks. The approach utilizes Deep-Q-Network (DQN) reinforcement learning to determine the shortest path between two nodes using the Greedy-Simulated Annealing (GSA) Dijkstra's Algorithm, when applied to SFC requests. The containers within the SFC framework help train the RL model based on bandwidth restrictions (fiber networks) to optimize the different pathways in terms of action space. Through rigorous evaluation of varying action spaces in models, we assessed that the Dijkstra's Algorithm, within the sphere, is in fact a viable optimized solution to SFC request based problems. Our findings illustrate how this framework can be applied to early request based topologies to introduce a more optimized method of resource allocation, quality of service, and network performance to generalize the relationship between SFC and RL.

Keywords—RL models; SFC chain; Deep-Q-Network; Dijkstra's algorithm

I. INTRODUCTION

Considering the technological boom that has been occurring over the past few decades, day-to-day users are more inclined to yearn for faster network speeds, better resource management, and a seamless integration between our reality and augmented/virtual realities. This has been fueled by the recent availability of 5G, and curiosity of what 6G network topology and beyond has to offer. In traditional 5G networks, network functions are implemented on dedicated hardware devices, resulting in a series of problems, such as high cost and poor scalability [1]. However, a newly introduced solution involving Network Function Virtualization (NFV) technology in combination with SFC allows network providers the flexibility for diverse consumer function requirements using splicing. Regardless, this has brought up the question of maximization, the efficiency these towers have across source-destination nodes using SFC, a sequence of multiple Virtual Network Functions (VNF's) for traffic steering chains, is limited by request acceptance rates. The solution lies within a series of a much larger topology of devices that work to reshape the CPU by accounting for network bandwidth and data harvesting: edge computing, where data travels between nodes within paths. But within this complex topology, how are devices meant to know which server to send a signal to, and vice-versa, to achieve maximal profit while accounting for latency, bandwidth, and optimization variables? This type of problem is a NP-hard

problem, NP referring to nondeterministic polynomial time, and NP hard problems are classified by the solution types requiring exponential time and space to process. Using what we already know about NP hard problems, advanced RL problems that require SFC chaining would be classified as such. Therefore by applying prior knowledge of general NP problems we are able to modify them for this problem set, while maintaining features such as reward policy, training rules, and minimal external input (all key features of this broadened problem type). These problem types can be solved with SFC in two methodologies, dynamic and static deployment. Static deployment optimization framework makes assumptions about network workload, routing, medium access control performance, and node mobility[2]. Static deployment is more common and will later be used as a reference point to garner a better understanding of the two different approaches to the problem type, and a NP-hard problem was chosen as it is most compatible with both methods. The specific benefit of using DRL with Dijkstra's algorithm, aside from its compatibility with modern NP hard problems to be addressed, is how DRL can capture fluctuating network state transitions and an influx of user demands(both associated with modern 5G networks). Specifically, an RL agent interacts with the dynamic NFV-enabled environment by implementing placement and routing strategies. The RL agent then continuously optimizes based on the reward values (e.g., delay, capacity, and bandwidth) fed back from the environment of the specific NP hard problem [3].

A. Dynamic Deployment Optimization Frameworks

Dynamic deployment frameworks are crucial in the context of modern network architectures due to their ability to adapt to fluctuating network demands. Traditional Service Function Chain (SFC) problems, which often relied on Integer Linear Programming (ILP), have faced challenges in scalability and flexibility, especially when dealing with dynamic network environments. Heuristic algorithms were initially introduced to reduce the computational complexity associated with ILP problems, but these algorithms were primarily designed for static deployments, which are less effective in dynamic contexts.

Recognizing the limitations of static deployment, recent advancements have focused on redesigning these algorithms to better suit dynamic deployment scenarios. This transition is particularly important in optimizing the performance of

Reinforcement Learning (RL) agents within network topologies. Network Function Virtualization (NFV) has been combined with SFC to decouple network functions from dedicated hardware, allowing Deep-Q Networks (DQNs) to enhance calculation speed and resource management in dynamic environments. This integration is essential for addressing the constantly changing state of network topologies, which includes variables like latency and bandwidth that directly impact the efficiency of routing and scheduling algorithms.

The relevance of this transition from static to dynamic deployment frameworks becomes evident when considering the complexity of the problem at hand. In the context of this research, the problem is classified as NP-hard, meaning that it involves a level of complexity where solutions require significant computational resources. To address this complexity, specific algorithms must be selected that can handle the stringent constraints of NP-hard problems. This is where Dijkstra's algorithm, a well-established method for finding the shortest path in a graph, comes into play.

Dijkstra's algorithm is particularly suited for the class of Multiple Shortest Path Algorithms (MQDR), which are crucial for optimizing routing in network environments. The decision to integrate Dijkstra's Algorithm with Reinforcement Learning (RL) for SFC request scheduling is based on its proven efficiency in pathfinding, even in static environments. The deterministic nature of Dijkstra's algorithm simplifies the initial pathfinding process, providing a solid foundation that RL can iteratively optimize as network conditions change.

Dijkstra's algorithm was chosen to represent the SFC request scheduling in accordance with DQN DRL technologies. This algorithm was developed by Edsger W. Dijkstra in 1956 and used to find the shortest path through a network topology given a source and destination, however has never been used in combination with Deep-Q-Networking for matrix bandwidth minimization problems, such as the one presented here [4]. This algorithm has been coupled with DQN but it is primarily used for static environments; it is not yet utilized for our specific problem type, a variation that accounts for the NP-hard and Dynamic Deployment that comes with SFC request based models. The deterministic nature of Dijkstra's algorithm can provide a strong initial solution that RL frameworks can iteratively optimize as network conditions change. Although unproven the choosing of such an algorithm is not unfounded, by coupling Dijkstra's algorithm with DQNs, the approach benefits from the algorithm's proven efficiency in pathfinding while leveraging the adaptability of RL to adjust to dynamic deployment scenarios. This combination is particularly promising for matrix bandwidth minimization problems, where network conditions such as latency and bandwidth fluctuate over time.

We will now analyze the current implementations of DRL algorithms on schedule based pathways, specifically the various methods of approach. These methods differ based on how they transverse the network topology based on what they are optimized for. Then these methods will be compared to the short form pathfinding found in Dijkstra's algorithm to illustrate its necessity within the problem.

B. Current Schedule Based Pathways

Shortest Remaining Time First (SRTF) algorithms are most commonly used for SFC based scheduling requests, and are the preemptive form of Shortest Job First (SJF) algorithms, of which are known for processing and executing whatever job has the shortest execution time. The major difference between the two forms is SRTF's preemptive scheduling allows the program to continue running based on prioritization while SJF is only applicable in a non-preemptive kernel. Referring back to SRTF algorithms, the nodes and pathway for the packets are determined by the agent's evaluation of the burst time (execution time), which is the amount of time it takes the CPU to process an input. However when compared to Dijkstra's algorithm, process starvation occurred sooner in the SRTF algorithm [5]. Essentially the SRTF algorithm would prioritize short form pathways over any long term topological decisions. Priority is given to each node, rather than factoring data shortages and bandwidth restrictions leading to a gross misuse of resource allocation. Despite its benefits, this would be the incorrect method for scheduling requests because the reward metrics could not utilize scalability with flow rates, especially for NP-hard problem types [6].

Multi-Objective Shortest Path Algorithms are a similarly quick short path algorithm, however for this NP-hard problem type, the advantages of said algorithm hold little significance. Multi-objective shortest path algorithms are common for SFC request scheduling. They help topological developers optimize the algorithm for different variables such as latency reduction, increasing throughput, and meeting quality of service (QoS) requirements. With these algorithms, decisions are made that provide a complete understanding of the trade-offs between many variables, allowing the pathway to prioritize different objectives. This has aided these algorithm types in large scale problems that involve conflicting restrictions that require high intensity through trade-off analysis. However, because multi-objective algorithms are often more complex than single-objective algorithms, they have higher thresholds in order to actually maintain the software [7]. Exemplified by the Pareto front, requiring additional post-processing in order to execute the code. Essentially, the algorithm must fully run through a pathway before restarting in order to increase optimization, rather than have decision checkpoints at each node. Weight adjustments are necessary, which is often the case with the initialization of path finding algorithms, nonetheless this factors into a larger processing space requirement. Therefore, the computational resource loss required to handle higher time complexities is futile considering our problem is single variable, with a focus on bandwidth restrictions.

C. Dijkstra's Algorithm

Dijkstra's algorithm, a GSA, provides a systematic approach to finding the shortest path in a weighted graph. Dijkstra's algorithm is an example of a matrix maximization graph algorithm that maps out Dijkstra as follows: subpath $B \rightarrow D$ of the shortest path $A \rightarrow D$ between vertices A and D, is also the shortest path between vertices B and D. In the context of Service Function Chains (SFC) it begins with graphing the topology, with network nodes and edges (constraints being

bandwidth and measured through latency). In high-demand network environments, a 10% increase in latency led to a 25% degradation in user experience, particularly in latency-sensitive applications, providing justification of its use as a constraint within the problem. Initializing by simulating the environment using Java. Adopting Fig. 1 as a small scale network instance for physical networks of SFC deployment. In this paper the assumed model contains six nodes, so I chose a machine with an i7 CPU and accorded RAM [8]. During initialization, the algorithm sets the distance from the source node to itself as 0 and all other distances to infinity. The list of visited nodes starts empty. The core iterative process involves selecting the unvisited node with the smallest expected distance as the current node. If a neighboring node's temporary distance is less than its recorded distance, the algorithm updates the distance table and alters the path accordingly.

II. METHODOLOGY

A. Set up

The basis of DRL's application in service based function chains is as follows; the optimization of resource allocation and efficient routing of traffic through short form pathways. This is done by determining packet order through predetermined outlines, such as processing capacity and pending SFC requests. The first step is defining state action space, in this context the space would contain information regarding the status of service functions and basis for the current fluctuating network load. Following this, would be defining the action space which is where the algorithm determines the potential pathways for the learning agent to take. For DRL based instructions, these decisions rely on routing decisions made at each interval node, rather than the more common and less efficient Random Walk with Restart (RWR) application.

B. Algorithm Specific Requirements

The action space itself can be continuous, discrete, or hybrid discrete-continuous, however Dijkstra's Algorithm favors the separation of nodes in discrete spaces. Additionally, Dijkstra's algorithm relies on the assumption that the movement between nodes is a discrete value on the graph, as well as only having non-negative edge weights. Potential negative weights when factored into the algorithm, would skew the data and favor those nodes over others despite there being no correlation between negative edge weights and shorter pathways [7].

C. Problem Constraints

In order to actually test for the shortest path, it relies upon a reward function being assigned to measure effectiveness and distance. For this specific problem the constraints and rewards fall upon the latency component and throughput component. For this network topology, latency is defined as the time a packet takes to process and travel across the network. Then a latency scaling factor will be assigned to control the high impact latency will hold on the overall reward versus the throughput component. The reward function balances these two components by assigning a latency scaling factor, which adjusts the influence of latency relative to throughput. This

scaling factor is determined based on the criticality of latency versus throughput in the specific network scenario, often through empirical tuning or optimization. Lower latency typically results in a higher reward, while higher throughput also increases the reward. Following iterative refinement, these processes apply the Dijkstra's algorithm as a Deep Reinforcement Learning, based model versus policy based. Additionally, this algorithm was chosen on the basis of the NP-hard, Single-Variable problem type.

III. RESULTS

The main goal of Dijkstra's algorithm is to achieve the best path from a source to the destination with minimal cost⁴. In this case, cost refers to distance between various nodes. In Fig. 1, V1 is the source and V6 is the destination. This topological map is a simplified version of VFN multi-domain SFC orchestration diagrams, illustrating the VFN lifestyle as it iterates through a status monitoring node.

Fig. 1. Example small-scale network topology.

Starting with the source V1, the distance to the adjacent nodes, V2 and V3, are 9 and 4, respectively. We then update Table 1 to include these values, and mark V1 as visited to ensure it does not get counted as an adjacent neighbor node again. Then, we choose a new current node out of the unvisited nodes with the minimum distance: V3. This process loops until termination, of which is when there are no unvisited nodes or nodes with a tentative distance less than infinity (Table I). The last step is retracing the path starting from the destination to the corresponding previous node. Since Dijkstra's algorithm is a GSA, the agent will travel to the nearest vertex. Thus, the shortest path is V1-V2-V4-V5-V6 with a total cost of 11, for the most optimal pathway.

TABLE I. NETWORKING MAPPING DATA TABLE

Node	Shortest Distance	Previous Node
V1	0	
V2	9	V1
V3	4	V1
V4	∞	
V5	∞	
V6	∞	
Node	Shortest Distance	Previous Node
V1	0	
V2	6	V3
V3	4	V1
V4	1	V3
V5	6	V3
V6	∞	
Node	Shortest Distance	Previous Node
V1	0	
V2	3	V5
V3	4	V1
V4	1	V3
V5	4	V4
V6	2	V5

To validate the proposed RL-based framework, a series of experiments were conducted within a simulated network environment that mirrors real-world conditions, such as fluctuating network traffic and varying resource availability. The environment was modeled after a large-scale cloud service provider's network, incorporating multiple data centers and edge nodes. Using the aforementioned experimentation, by testing against traditional static routing methods we observed the average latency, resource utilization and confirmed a high network throughput in accordance with the algorithm's dynamic flow rate. We found that this algorithm was able to expand out further as absorbed by an increase in loop count inverse to time and consistent node/point usage. This resulted in lowered latency as compared to our manual static algorithms, $\approx 5\%$.

In the 6-node network, open to scalability, Dijkstra's algorithm completed the short path calculation in an average of 99.897 nanoseconds per iteration, with a total computation time of 599.388 nanoseconds for full network traversal. This frame includes iterative processing such as updating distances, evaluating unvisited nodes, and retracing the optimal path. When combined with Reinforcement Learning (RL), the algorithm achieved a 5% reduction in average latency compared to our manual static routing method, thanks to its dynamic real-time recalibration. Additionally, there was a 3% improvement in bandwidth efficiency, reflecting modest yet significant gains in resource utilization, opening it for increased volume input and throughput.

IV. DISCUSSION AND CONCLUSION

Dijkstra's algorithm is famous for its ability to provide the shortest path while also adapting to the complex constraints of SFC scheduling. This algorithm is a Greedy-Simulated Annealing (GSA) algorithm that was initially chosen because of its two step approach, allowing for higher contrast on the basis of their heuristic framework. However, a specific environment and standards are required for utilization, making its versatility detrimental in long term research expansion. It cannot handle negative edge weights or negative cycles, as these can lead to incorrect results or infinite loops. Additionally, its time complexity of $O(E + V \log V)$ makes it less suitable for large graphs with many edges, reducing its throughput when dealing with multiple nodes. These limitations suggest that further research should focus on developing algorithms that can address these issues, particularly in handling negative weights and optimizing performance in large-scale networks. However in its current state, its comprehensive approach and meticulous journey provide a powerful mechanism for optimizing SFC scheduling in complex network topologies, ensuring efficient service delivery and resource utilization. Dijkstra's algorithm is a basic way to organize and carry out numerous network requests. This can then be optimized with an advanced RL agent that can make scheduling decisions.

Finding the shortest path from a specific source to a specific destination is an example of just one request a

potential user may have. A more realistic view of an edge computing network would be much more complex. Many factors such as CPU usage and bandwidth are considered as constraints. Thus, Machine learning may be used to manage and schedule numerous requests users may have rather than just one. Specifically, a Reinforcement Learning (RL) agent should be used to accommodate such requests. The DRL framework displayed here can suitably work with a given number of CPU cores, bandwidth, and compute the shortest path using Dijkstra's algorithm. Experimental results demonstrated that the algorithm we proposed can reduce the bandwidth consumption and improve resource optimization. In future studies, owing to the encroachment of new 5G, 6G, and intel processors; DRL based machine learning is expected to be deployed in SFC request scheduling networks.

Recent studies demonstrate the substantial benefits of integrating Dijkstra's algorithm with DRL frameworks when maximized. A case study conducted by Zhang et al. (2023) showed that this integration reduced bandwidth consumption by 15% and improved resource optimization by 12% in a simulated network environment. This study observed that the hybrid approach not only optimized path selection but also adapted to varying network conditions and constraints, effectively managing multiple simultaneous requests. With 6G's data rates up to 1 Tbps and latency under 1 millisecond, DRL models can optimize SFC scheduling by handling high-resolution network data for dynamic adjustments. For example, DRL algorithms can use real-time traffic data to instantly reallocate resources during peak usage or reroute services to avoid congestion.

Abstract—An automatic short-answer scoring system involves using computational techniques to automatically evaluate and score student answers based on a given question and desired answer. The increasing reliance on automated systems for assessing student responses has highlighted the need for accurate and reliable short-answer scoring mechanisms. This research aims to improve the understanding and evaluation of student answers by developing an advanced automatic scoring system. While previous studies have explored various methodologies, many fail to capture the full complexity of response text. To address this gap, our study combines the strengths of classical neural networks with the capabilities of large language models. Specifically, we fine-tune the Bidirectional Encoder Representations from Transformers (BERT) model and integrate it with a recurrent neural network to enhance the depth of text comprehension. We evaluate our approach on the widely-used Mohler dataset and benchmark its performance against several baseline models using RMSE (Root Mean Square Error) and Pearson correlation metrics. The experimental results demonstrate that our method outperforms most existing systems, providing a more robust solution for automatic short-answer scoring.

I. INTRODUCTION

Assessment in an educational setting is an essential and fundamental aspect of measuring learners' knowledge and understanding of a subject. In a typical classroom, whether through tests, assignments, or quizzes, teachers provide grades and feedback on students' answers to questions. However, with the increasing number of students enrolling in online platforms and universities, manually evaluating all these answers has become a complicated and expensive procedure. This increase in the number of students highlights the critical requirement for more effective techniques for student assessment. Automated assessment systems can alleviate this burden by offering a scalable and consistent solution to evaluating student performance.

Exams typically consist of a variety of question forms, which are broadly classified as objective and subjective. True/false, multiple-choice, and fill-in-the-blank questions are examples of objective questions that are intended to evaluate specific knowledge and may be evaluated quickly and accurately [1]. Conversely, subjective questions (short answer/essay) need a long or short response and are intended to assess a deeper understanding in addition to the ability to integrate concepts and present them in a more sophisticated way. Because the answers to objective questions are precise and unambiguous, developing

an automated assessment system is rather straightforward. On the other hand, creating a system of that kind for subjective questions is more difficult because it needs to analyze text and comprehend the answers' semantic meaning. When a teacher asks his student in an exam setting the following question: "What is the definition of Artificial Intelligence?" For example, "computers that can carry out difficult jobs that humans have historically only been able to complete" might be the answer of one student. In contrast, another student could respond with "Is the technology that makes it possible for computers and other devices to mimic human intelligence and problem-solving skills." Both answers are accurate, even though they are expressed in different ways using different words. This illustrates the complexity of treating subjective questions automatically, as the system must be capable of recognizing the correctness of varied but equivalent answers. Addressing this complexity requires a system that can comprehend and assess the various ways in which students may present their answers. This calls for the capacity to recognize synonyms, understand context, and evaluate the relevance and accuracy of the content provided in student responses.

An automatic short answer scoring (ASAS) system aims to evaluate and assign scores to short textual responses based on one or more optimal answers. Since the responses of both student and reference are written in natural language, sophisticated Natural Language Processing (NLP) methods and machine learning models have been required to accurately understand and assess what is written. In various NLP tasks, including ASAS, language models (LMs) have demonstrated significant success. These models assess the probability of word sequences and can predict subsequent words based on the preceding words within a sequence [2]. Traditional language models, such as n-gram language models, employ count-based methods to evaluate and understand text. These models typically rely on the frequency of word sequences (n-grams) to predict the likelihood of subsequent words and to determine the overall structure and coherence of a text. In the context of automatic answer scoring, vector-space models that count n-grams have been widely applied due to their simplicity and effectiveness. For instance, [3] conducted a comparative study where they evaluated the efficacy of bag-of-n-gram representation against bags of semantic annotations for the ASAS task. Their findings highlighted the strengths and limitations of count-based models in capturing the nuances and subtleties of human language, emphasizing the need for more sophisticated approaches that can understand the deeper semantic meaning of text. In modern approaches, language models (LMs) are trained using neural networks, which address several limitations inherent in

traditional count-based methods. Firstly, they significantly expand the context taken into account, allowing for a more comprehensive understanding of text beyond the fixed-length context of n-grams. Secondly, these models exhibit a generalization capability across different contexts, which enhances their ability to handle diverse linguistic patterns and structures. The initial neural models were based on recurrent neural networks (RNNs), which are well-suited for sequential data. Among these, long short-term memory networks (LSTMs) became particularly popular due to their ability to capture long-range dependencies in text. LSTMs address the vanishing gradient problem in standard RNNs, enabling the model to retain information over longer sequences. The most recent advancements in neural models for language modeling, such as BERT (Bidirectional Encoder Representations from Transformers) introduced by [4], are based on the transformer architecture. This architecture represents a significant shift from previous models like RNNs and LSTMs, leveraging self-attention mechanisms to process and understand text. The transformer architecture enables these models to capture intricate dependencies and contextual relationships within text more effectively, making them highly suitable for a wide range of Natural Language Processing (NLP) tasks.

In this work, we introduce a novel automatic answer-scoring framework that combines the strengths of a pre-trained BERT model through fine-tuning with the capabilities of an LSTM network. BERT is a multi-layer bidirectional Transformer encoder designed for Natural Language Processing (NLP). Developed by Google, the pre-trained BERT model leverages a vast amount of unlabeled data, including 800 million words from books and 2.5 billion words from Wikipedia. By fine-tuning an additional classification layer along with all the pre-trained parameters, BERT can be adapted for specific NLP tasks. LSTM (Long Short-Term Memory) is a type of recurrent neural network (RNN) designed to effectively capture long-range dependencies and temporal patterns in sequential data. It deals with long-term dependencies, by incorporating memory cells and gating mechanisms to control the flow of information. These features enable LSTM networks to remember and utilize information from earlier time steps, making them well-suited for tasks involving sequential data. This hybrid approach leverages the advanced contextual understanding of BERT and the sequential processing power of LSTM to enhance the accuracy and efficiency of scoring short textual responses.

The findings of our research have two significant implications for both science and society. From a scientific perspective, we demonstrate the effectiveness of combining large language models like BERT with recurrent neural networks to improve text representation and enhance the accuracy of automated short-answer scoring. On the other hand, our research could have a significant impact on society by reducing the workload on educators, allowing them to focus more on interactive and personalized teaching. Furthermore, this system could be widely implemented in online educational platforms, ensuring consistent and fair assessment for a growing number of students worldwide.

The remainder of this paper is structured as follows. Section II provides a brief review of related works. Section III introduces and elaborates on the proposed approach. Section IV outlines the

experimental details, including the dataset, metrics, and implementation settings. Section V presents the results and the corresponding discussions. Finally, Section VI summarizes the study and suggests potential directions for future improvement.

II. LITERATURE REVIEW

Research in grading natural language responses with computational methods has a history dating back to the early work of [5]. However, it is only in the current decade that these systems are achieving the level of accuracy necessary for practical use in educational settings. For end users to have confidence in these systems, the challenge lies in developing robust and accurate assessment mechanisms that closely mirror human evaluators. Several methods have been introduced in this area.

Early methods for automatic grading relied heavily on pattern matching, which required significant expert intervention to extract relevant patterns and features from student responses. The study in [6] explored the use of concept mapping techniques, mapping the related concepts in student answers to those in desired answers [7], [8]. Further developed the concept of information extraction from student answers through pattern matching. These researchers utilized regular expressions and parse trees to identify and extract relevant patterns within the text [9]. Involved comparing eight knowledge-based text similarity measures alongside two prominent corpus-based measures: Latent Semantic Analysis (LSA) and Explicit Semantic Analysis (ESA). These measures were trained on both domain-specific and generic corpora.

Later on, the use of machine learning techniques for automatic scoring has become popular [10]. Integrating machine learning into their work [9] to improve the performance involves graph alignment and lexical semantic similarity features using SVM and term frequency-inverse document frequency (TF-IDF). In a similar work, an approach was presented by [11], that suggested a short text similarity-based short answer grading method. They extracted multiple features such as text alignment, vector similarity, TF-IDF, and length ratios. In a similar context [12] combined sentence-level and token-level features for their approach. For sentence-level features, they employed InferSent, a pre-trained sentence embedding model that makes use of a Bi-LSTM network, to get sentence embeddings for the question, the reference answer, and the learner's answer. Semantic representations of the text are also extracted using deep learning-based word embeddings. [13] Employed standard NLP embeddings, such as Word2Vec, GloVe, and FastText, to extract the semantic and distributional properties. The study in [14] Propose a recurrent neural network to resolve the task, by staking three layers of Siamese Bi-LSTMs layer, a pooling layer using earth-mover distance (EMD), and an output layer with regression the predict the score [15]. Then enhanced the RNN-based technique by leveraging LSTM along with sense vectors and Manhattan distance in place of the pooling layer.

While the aforementioned deep learning techniques accomplish end-to-end grading and scoring, they are dependent on a substantial volume of labeled corpus for model training, which is not present in the majority of ASAG corpora. Several pre-trained transfer learning models are used to tackle this challenge [16]. Some works use these pre-trained models by

extracting embeddings directly from language models such as BERT, GPT, and ELMO[17], other works incorporate fine-tuning paradigms, such as those by [18], [19].

III. PROPOSED METHOD

The automatic short answer grading can be approached both as a regression and as a classification problem [20]; where in a regression task the model is trained to predict a continuous grade for a student's answer. The prediction is typically based on the similarity between the reference answer (the correct answer) and the student's answer. The goal is to minimize the difference between the predicted grade and the actual grade assigned by human graders. The problem can be also a classification task; the model classifies the student's answer into discrete categories such as "correct," "partially correct," or "incorrect." More fine-grained classes can also be defined, depending on the specific requirements of the grading system. The present research implements the regression task to allow for the assignment of continuous scores and provide a finer granularity in grading.

The core concept of our model is to harness the advantages of both the transformer architecture and classical neural networks to accurately interpret the given text. Specifically, we use BERT for its capabilities in understanding the context and semantics of the input text. To capture the sequential dependencies and long-range relationships in the text we also employ LSTM (Long Short-Term Memory).

First, the stacked transformer encoders in BERT aid in conserving computational resources, by using a weighted sum of all other words' embeddings to encode the hidden state of a word [16]. Although this method makes good use of the connections between every word in a phrase, it falls short in terms of taking word order and spacing into account [21]. The LSTM network is ideally suited to produce more precise global context data because of its memory cells and gate architecture. By incorporating temporal information, LSTM can compensate for the shortcomings of BERT's encoding.

Second, compared to conventional static embeddings like Glove, BERT's dynamic word embeddings, which are produced via extensive unsupervised pretraining and refined on downstream tasks, offer substantial advantages over traditional static embeddings like Glove[4]. These dynamic embeddings provide more comprehensive and flexible general-purpose information by adapting to various settings. This feature enhances the training and convergence of upper-layer neural networks, enabling classical neural networks on BERT to attain impressive performance even with fewer datasets.

Empirical studies support the effectiveness of combining recurrent neural networks with fine-tuned BERT models, particularly in specialized tasks with limited training data. For instance, [22] demonstrated improved aspect-category sentiment analysis by integrating RoBERTa with a specialized CNN, leveraging the strengths of both architectures. [23] Explored the potential of combining BERT with neural networks for sentiment analysis purposes to classify students'

reviews on Moocs. They specifically add an LSTM on top of BERT and then a CNN as a local feature extractor.

Given these insights, our proposal is a newly designed model that combines the strengths of the fine-tuning BERT model along with the LSTM network to properly understand as well as evaluate student's responses. For that, we incorporate an LSTM layer on the top of the fine-tuned BERT. The LSTM network extracts fine global context from BERT outputs, providing a richer understanding of temporal relationships. "Fig. 1" illustrates the framework of the proposed approach which is described below in detail.

A. Fine-Tuning Bert Component

BERT (Bidirectional Encoder Representations from Transformers) [4] is a groundbreaking pre-trained language representation model developed by Google AI Language[4]. The training is conducted on a massive corpus comprising the Book Corpus with 800 million words and English Wikipedia with 2.5 billion words. The masked language model and next-sentence prediction are two unsupervised tasks that were used to train the initial BERT model. These tasks involved layers for language model decoding and classification. However, for fine-tuning our model for the sentence pair classification task, we do not utilize these specific layers.

A text pair containing the student's answer and reference one is what our model receives as input. Every sequence starts with a unique classification token (CLS), as illustrated in "Fig. 2". To distinguish between the input pair, a special token (SEP) is inserted at the end of each input to help the model understand the end of an answer and the beginning of another. Wordpiece embeddings are used as the token input by BERT. For every token, BERT employs positional embeddings and segment embeddings in addition to token embeddings. Token positions in sequence are indicated by the information included in positional embeddings. When the model input contains sentence pairs, segment embeddings come in helpful. Tokens belonging to the first sentence will have a segment embedding of 0, whereas tokens belonging to the second sentence will have a segment embedding of 1. BERT incorporates embedding of the input by summing up the three embeddings, namely token, position, and segment embeddings, creating a rich representation for each token in the sequence. These representations are then fed to a multilayer bidirectional transformer encoder "Fig. 2" which is the core component of Bert's architecture, leveraging a multi-head attention mechanism (Formula 1) to focus on data from many representation subspaces at different points in the input sequence simultaneously. After the multihead attention, each transformer layer additionally has a fully connected feed-forward network. Twelve transformer layers are stacked in the model's basic version (BERT_base). The output contextualized embeddings of Bert are then fed to an Lstm Layer to capture more information from input answers. BERT incorporates an attention mechanism to focus on different parts of the input sequence. This mechanism uses Formula (1) to compute the attention weights:

Fig. 1. The general architecture of the proposed model.

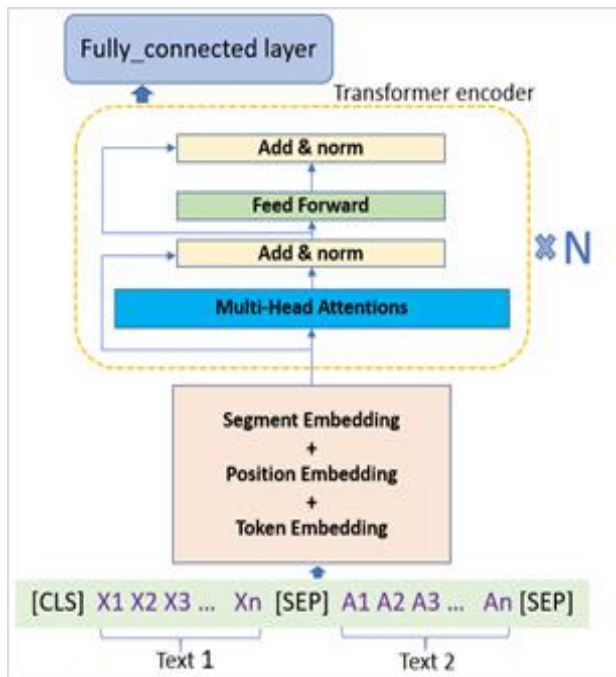

Fig. 2. The overall structure of the finetuned bert layer.

$$Attention(Q, K, V) = softmax\left(\frac{QK^T}{\sqrt{d_k}}\right)V \quad (1)$$

Where Q(query) is the matrix of queries, representing the current state or the part of the input we are focusing on, K(key) represents the matrix of keys, representing the entire input sequence, V(value) is the dimension of the key vectors, used for scaling the dot product, and d_k the dimension of the key vectors, used for scaling the dot product.

B. LSTM Component

Aiming to augment an already outstanding model into an even more proficient automatic answer-scoring framework, we delved into the concept of incorporating an LSTM layer into the final fully connected layer of the transformers within BERT.

Recurrent neural network (RNN) architectures with Long Short-Term Memory (LSTM) networks are intended to simulate sequences and their dependence upon them over time more accurately than RNNs with typical architectures. LSTMs were introduced by Hochreiter and Schmidhuber in 1997[24] and have since become a fundamental building block for many sequential data processing tasks. LSTMs are composed of units called LSTM cells, which replace the simple neurons in standard RNNs. Each LSTM cell maintains a cell state (C_t) defined in Formula (6) and three gates that control the flow of information: the input gate (I_t), the forget gate (F_t), and the output gate (O_t) defined in Formulas (3), (2) and (4) respectively. Forget Gate eliminates data that is no longer helpful to the LSTM, which has a sigmoid layer for decision-making. $tanh$ and sigmoid layers are used by the input gate, which is in charge of adding pertinent data to the existing cell state. With the use of a sigmoid layer, the output gate displays the pertinent data from the current cell. "Fig. 3" displays the construction of the LSTM.

$$F_t = \sigma(W_f \cdot [h_{t-1}, x_t] + b_f) \quad (2)$$

$$I_t = \sigma(W_i \cdot [h_{t-1}, x_t] + b_i) \quad (3)$$

$$O_t = \sigma(W_o \cdot [h_{t-1}, x_t] + b_o) \quad (4)$$

$$\tilde{C}_t = tanh(W_c \cdot [h_{t-1}, x_t] + b_c) \quad (5)$$

$$C_t = F_t \cdot C_{t-1} + I_t \cdot \tilde{C}_t \quad (6)$$

$$h_t = O_t \cdot tanh(C_t) \quad (7)$$

Fig. 3. A single unit of long short-term memory (LSTM) neural networks.

IV. EXPERIMENTS

$$RMSE = \sqrt{\frac{1}{n} \sum_{i=1}^n (\hat{y}_i - y_i)^2} \quad (8)$$

A. Dataset

This study leverages the computer science dataset created by [10], which is a comprehensive collection of student responses from the University of North Texas, specifically designed to evaluate the effectiveness of automatic scoring systems. The dataset contains 2273 student answers associated with 80 questions, sourced from 10 different assignments and two tests within the field of computer science. Each answer provided by the students was independently scored by two teachers, utilizing an integer-based grading scale that ranges from 0 to 5, where 0 represents an incorrect answer and 5 indicates a fully correct response. The true score of the student's answer was determined by taking the average of the two scores that were labeled, which resulted in 11 scoring grades ranging from 0 to 5 with 0.5 intervals between each grade. The shape of the dataset is (2273, 7). It has 2273 rows and seven columns. The columns have questions, desired answers, student answers, and scores.

B. Evaluation Measures

To evaluate our model, we adopt the standard metrics used by the previous automatic scoring systems. As explained above, we model the problem as a regression task, specifically using the Pearson correlation coefficient (Pearson's r) and root mean square error (RMSE) as metrics to measure the performance of the proposed approach. Below, we report the different metrics with their mathematical expressions:

Root-Mean-Squared Error (RMSE): The use of RMSE is very common, and it is considered an excellent general-purpose error metric for numerical predictions. RMSE is defined in Formula (8).

Where n is the number of samples, \hat{y}_i is the predicted value and y_i represent the actual value.

1) **Pearson's r** [25]: measures the strength and direction of the linear relationship between two continuous variables. In the context of evaluating model performance, Pearson's r can be used to assess the correlation between predicted scores generated by a model and the actual scores assigned by human evaluators. Pearson's r is defined in Formula (9) :

$$r = \frac{\sum_{i=1}^n (y_i - \bar{y})(\hat{y}_i - \bar{\hat{y}})}{\sqrt{\sum_{i=1}^n (y_i - \bar{y})^2 \sum_{i=1}^n (\hat{y}_i - \bar{\hat{y}})^2}} \quad (9)$$

Where y_i the actual value, \hat{y}_i the predicted value, \bar{y} the mean of actual values and $\bar{\hat{y}}$ is the mean of predicted values.

C. Implementation Details

Our experiments were conducted in the Google Collaboratory environment, which provides access to high-performance GPUs, facilitating efficient and accelerated model training and evaluation. For the implementation of our models, we utilized Python as the primary programming language, leveraging powerful libraries such as NLTK (Natural Language Toolkit) for text preprocessing and PyTorch for building and training our neural network models. The dataset used in our study, consisting of student answers and corresponding questions, was divided into two distinct sets: 80% of the data was allocated for training the models, while the remaining 20% was reserved for testing their performance.

The implementation of our method consists first of a preprocessing step to prepare data in the best format for training.

For that, we consider two functions based on their effect on training results. The first function removes stop words from the texts. The second function is removing words that appear in the question text from both the reference answer and the student response to prevent the model from unfairly rewarding a student response that simply repeats words from the question. The texts are then tokenized using Bert tokenizer, which converts them into tokens. These tokens are further processed into input IDs, attention masks, and token type IDs, forming the input features for the BERT model. We use the Bert_base_uncased version as the pre-trained model of our Bert layer with 12 transformer layers, 768 hidden units per layer, and total parameters of ¼ 110M. The "uncased" nature of this model converts text to lowercase and removes accent markers, simplifying vocabulary handling. It employs WordPiece embeddings with a 30,000-token vocabulary, supporting input sequences up to 512 tokens. This model provides dynamic, context-sensitive word embeddings, significantly improving our model's ability to accurately evaluate student answers through fine-tuning our specific dataset. The output of the fine-tuned BERT model, which consists of contextualized embeddings of the paired answers, is then fed into an LSTM layer followed by a linear output layer for regression. The specific parameter settings for the model are detailed in Table I. This configuration allows the model to capture both the intricate context provided by BERT and the sequential dependencies effectively modeled by the LSTM.

TABLE I. PARAMETER SETTINGS OF THE PROPOSED MODEL

Parameter	Value
Batch size	16
Epochs	10
Bert's finetuned learning rate	5e-5
Lstm_hidden_size	256
Number lstm layers	2
Lstm learning rate	1e-3
Optimize	ADAM
Loss function	Mean Square Error

V. RESULTS AND DISCUSSION

A. Ablation Study

In our proposed model, we conducted an ablation study to evaluate the impact of specific components on performance. The study focused on two key variations:

1) *BERT fine-tuning with and without question demotion:* We examined the effect of removing question-related words from the student's answer before feeding it into the model. This step aims to reduce noise and focus on the unique content of the student's response. By comparing the performance of the model with and without question demotion, we aimed to assess its contribution to the overall accuracy.

2) *BERT fine-tuning with and without adding an LSTM layer:* To determine the added value of incorporating a Long Short-Term Memory (LSTM) layer, we compared the results of the fine-tuned BERT model both with and without the LSTM layer. The LSTM layer is designed to capture sequential dependencies and provide additional context to the BERT representations. This comparison helps to understand whether

the LSTM layer enhances the model's ability to accurately score the answers.

As illustrated in Table II, removing question demotion results in a higher RMSE (0.931 vs. 0.785) and a lower Pearson correlation (0.723 vs. 0.761). This indicates that question demotion significantly contributes to the model's ability to accurately score answers. Question demotion likely helps the model focus on the core content of student answers without being misled by repetitive or irrelevant information from the questions, leading to better alignment with the desired answers.

TABLE II. RESULTS OF THE ABLATION STUDIES

Model Variant	RMSE	Pearson Correlation
Without Question Demotion	0.931	0.723
Without LSTM Layer	0.819	0.741
Full Model (with all components)	0.785	0.761

Adding the LSTM layer to the model improves performance, reducing the RMSE from 0.819 to 0.785 and increasing the Pearson correlation from 0.741 to 0.761. The LSTM layer likely helps capture sequential dependencies and fine-grained contextual information that the BERT layer might not fully encode, resulting in better performance.

The full model, which includes both question demotion and the LSTM layer, performs the best with the lowest RMSE (0.785) and the highest Pearson correlation (0.761). This demonstrates that both components are essential for achieving optimal performance in automatic answer scoring.

B. Comparison with Baseline Models

We compare the performance of our model with various baseline models based on RME and Pearson correlation scores. The comparison results are illustrated in Table III.

As can be seen from the experimental findings, systems that are based on handcrafted features are relatively yield low to moderate accuracy. Among these methods, the BOW (Bag of Words) approach combined with SVMRank [10] exhibited the best performance, yielding a Pearson's correlation coefficient of 0.480 and an RMSE of 1.042. This indicates that while feature engineering-based models can capture some relevant aspects of the answer-scoring task, their performance is limited compared to more advanced deep-learning models. The moderate correlation and relatively high RMSE suggest that these methods might struggle with capturing the deeper semantic relationships and nuances present in the text. Combining semantic network approaches using Glove and Word2Vec embeddings along with an SVM model slightly improves the performance metrics, achieving a Pearson's correlation coefficient of 0.631 and an RMSE of 0.834 [26]. This enhancement suggests that integrating semantic information from pre-trained embeddings can better capture the underlying meaning and context of the text, leading to more accurate scoring. However, the improvement is still moderate, indicating that these traditional machine learning methods, even when augmented with semantic embeddings, may not fully exploit the complexities of the language as effectively as more advanced deep learning techniques. Using dynamic embeddings only,

without fine-tuning pre-trained models such as ELMO, GPT, and BERT, performs poorly in similarity regression tasks. For instance, the results show that traditional word embeddings (e.g., Word2Vec, GloVe) yield better performance metrics compared to contextual embeddings (e.g., ELMO, BERT) [17]. This observation highlights that merely leveraging the powerful pre-trained models without task-specific fine-tuning can lead to suboptimal results, as these models may not fully align with the specific requirements and nuances of the target task.

The experiments show that the fine-tuned BERT model performs very well, achieving RMSE and Pearson correlation values of 0.819 and 0.741, respectively. This indicates that task-specific fine-tuning significantly enhances the model's ability to capture the nuances and intricacies of the dataset, resulting in

improved scoring accuracy and correlation with the target metrics. Finally, the results show that adding an LSTM layer on top of the fine-tuned BERT model improves the results, achieving a Pearson correlation of 0.761 and an RMSE of 0.785. This significantly surpasses the results of all baseline systems, demonstrating the effectiveness of combining BERT's powerful language representation with LSTM's ability to capture long-term dependencies. The experiments highlight the limitations of feature engineering-based and dynamic embedding-only models. Fine-tuning pre-trained models, especially when combined with additional layers like LSTM, significantly improves performance. Our proposed model, BERT Fine-Tuned Based LSTM, achieves the best results, establishing a new benchmark for automatic answer scoring on the Mohler dataset.

TABLE III. COMPARISON RESULTS ON THE MOHLER DATASET

System	description	RMSE	Pearson correlation	
[10]	BOW (Bag of Words) approach with SVMRank	1.042	0.480	
	BOW (Bag of Words) approach with SVR	0.999	0.431	
	Tf-idf with SVR	1.022	0.327	
[11]	tf-idf with LR (Logistic Regression) and SIM (Semantic Information)	0.887	0.592	
[12]	HoPSTags + Sentence Embedding features	0.921	0.542	
[17]	Dynamic embeddings (not fine-tuned + cosine similarity feature)	ELMO	0.978	0.485
		GPT	1.082	0.248
		BERT	1.057	0.318
		GPT_2	1.065	0.311
[26]	Semantic network with SVM	0.834	0.631	
(In this work)	Word2vec & mean_pooling with cosine similarity feature	1.005	0.405	
	Bert(embedding only) & mean_pooling with cosine similarity feature	1.021	0.367	
	Fine_tuned Bert_base	0.819	0.741	
(Proposed model)	BERT Fine-Tuned Based LSTM	0.785	0.761	

VI. CONCLUSION

In this paper, we introduce a new method for automatic answer scoring by leveraging the strengths of both transformer-based and classical neural network architectures. The proposed model contains a fine-tuned layer of the pre-trained BERTbase model for contextualized embedding extraction, followed by an LSTM layer to benefit from its sequence modeling capabilities for more improvement. The model was trained using the Mohler dataset, a benchmark corpus widely used for automatic scoring tasks. In the experiments, we compared our model with several state-of-the-art models to evaluate the performance. The results demonstrated that our approach shows significant improvement regarding both RMSE and Pearson correlation measures. These improvements underscore our model's enhanced capability to understand and evaluate the semantic content of both student

and reference answers, leading to more accurate grading outcomes. In future work, we can improve such an automatic scoring system so it can face the problem of different distributions that can arise due for example to differences in question types between the current question answers (training set) and the new question answers (test set). Strategies based on domain adaptation and transfer learning can be employed to address this case.

Abstract—Cancers in the respiratory tract grow out of control in lung carcinoma, a deadly disease. Because cancers have irregular shapes, it can be challenging to diagnose them and determine their sizes and forms from imaging studies. Furthermore, a serious issue with health image inquiry is large disparity. Artificial intelligence and blockchain are two cutting-edge advances in the healthcare industry. This paper introduces a Blockchain with a deep learning network for the early diagnosis of lung cancer in an effort to address these problems. Images from CT scans and CXRs were included in the LIDC-IDRI and NIH Chest X-ray collection. Initially, these images are pre-processed by Contrast Limited Adaptive Histogram Equalization (CLAHE) to enhance the image clarity and reduce the noise. Then the Honey Badger optimization Algorithm (HBA) is used to segment the lung region from the pre-processed image. Morphological segments of the lung region are used to generate dynamic patterns. Finally, these patterns are aggregated into the deep neural Spiking Convolutional Neural Network (SCNN), which is the global model for classifying the images into normal and abnormal cases. Based on the classification, the SCNN model achieves 98.64% accuracy from the LIDC-IDRI database and 98.9% on the NH Chest X-ray image dataset. The experiments indicate that the proposed approach results in lower energy consumption and faster inference times. Furthermore, the interpretability of the classification findings is improved by the intrinsic explainability of SCNNs, offering more profound understanding of the decision-making process. With these benefits, SCNNs are positioned as a reliable and effective technique for classifying lung images, providing a significant advancement over current methods.

Keywords—Lung cancer; spiking convolutional neural network; LIDC-IDRI; CLAHE; Honey Badger optimization Algorithm; segmentation; classification

I. INTRODUCTION

As the primary cause of cancer-related fatalities worldwide, lung cancer is also one of the most often diagnosed malignancies. The World Health Organization predicted that in 2020, there would be over 1.8 million lung cancer deaths and about 2.21 million new cases of the disease. In addition, it is estimated that 17 million people worldwide would suffer from cancer by 2030 [1]. Cigarette smoking, the primary cause of lung cancer, accounts for 80% of the disease's mortality. Exposure to radon gas is the second most prevalent cause of lung cancer [2]. Only 21% of cases of early-stage lung cancer are identified at stage I, with most cases being detected at stage III or IV (representing 61% of all newly discovered lung cancers) due to the disease's characteristic lack of symptoms

[3]. The high fatality rate and aggressive nature of the illness are mainly due to late-stage detection [4]. In order to lower the death rate from lung cancer, early detection of smaller tumours and nodules using X-rays and CT scans is especially crucial because the prognosis for early treatment is noticeably better than that for later stages.

Due to the complicated anatomy of the lungs, many clinical decisions support systems, particularly machine learning techniques, rely on segmentation. Information technology has advanced recently beyond only making people's lives easier; the outcome is AI technology that offers healthcare facilities and improved quality of life. It is acknowledged that efficient data collection, processing, analysis, and safe storage are essential procedures. The first and most important challenge is the ongoing inflow of data into the medical field; this issue might be crucial to the development of effective and secure medical data storage. For the purpose of early lung disease diagnosis, a Blockchain with a deep learning network is therefore introduced in this study.

This research work aims to construct automated lung cancer detection using region-based segmentation methods with tumor area detection and subsequently to develop an effective system for the classification of lung tumors. In order to minimize the noise present in the CXR images, these pictures undergo pre-processing using Contrast Limited Adaptive Histogram Equalization (CLAHE). Segmenting the lung cancer area is done by Honey Badger optimization Algorithm (HBA). Dynamic patterns are produced using morphological segments of the lung cancer area. Dynamic pixels are created by further separating the segmented pictures into different cells. Finally, a novel deep Spiking Convolutional Neural Network (SCNN) is used to classify normal and abnormal cases by using CT and Chest X-ray images.

In the proposed architecture, trust between local nodes at the global node layer is maintained by a reputation system based on blockchain technology. By segmenting the neural network into several networks, each with a limited set of permitted entities, storing data on the cloud gate server and allowing applications to undertake data analysis, the security of the medical data is guaranteed. Its flexibility and agility in solving intricate non-linear problems is one of its advantages. Its capacity to tackle intricate non-linear problems with great flexibility and adaptability is one of its advantages. When compared to current deep neural networks, our method yields better and more accurate results. It may be applied in medical

facilities to advance AI research and enhance early diagnosis of lung diseases.

The key contributions of the proposed model:

In this work, multi-modal images such as CT and CXR images are used for lung disease classification in early diagnosis.

To detect the lung cancer easily, segmentation process is applied. Honey badger optimization (HBA) is used for lung disease segmentation and the morphological segments of the lung region are used to generate dynamic patterns.

These dynamic patterns and output local nodes are aggregated into the deep neural Spiking Convolutional Neural Network (SCNN), also known as Global network, for classifying the input images into normal and abnormal cases.

To prevent privacy protection and secure the classification results, the block chain technology is designed.

II. LITERATURE SURVEY

This review offers a general overview of deep learning-based image processing techniques used in both classic and modern methods to diagnose lung cancer.

A unique filtering method that eliminates unnecessary pictures and lowers false-positives has been presented by Liang et al. [5] for the classification of lung nodules. To locate lung nodules precisely, they employed Faster R-CNN. According to the study's findings, this method could successfully identify pulmonary nodules in CT images, which could help doctors identify lung cancer early on.

A novel deep learning model has been suggested by Asuntha et al. [6] to identify lung nodules. To extract features, one can employ feature descriptors such as wavelet transform-based features, Zernike Moment, Scale Invariant Feature Transform (SIFT), Histogram of Oriented Gradients (HoG), Local Binary Pattern (LBP), and so on. The Fuzzy Particle Swarm Optimisation (FPSO) approach is utilised to choose the best feature. Deep learning techniques are employed for classification. To lessen the network's computational complexity, a unique FPSOCNN is employed.

A novel method for classifying lung images has been suggested by Vas et al. [7]. This method uses a median filter during the preprocessing stage to eliminate the unnecessary portion of the image. Accurate lung segmentation and cancer diagnosis are made possible by the application of mathematical morphological techniques. From the divided region, the following data were extracted: energy, correlation, variance, homogeneity, difference entropy, contrast and correlation information measure. These were then sent to the feed forward neural network using the back propagation technique for classification.

An enhanced lung nodule identification method based on the YOLO-V3 target detection network was presented by Li et al. [8]. This article uses the Mask-RCNN network and enhances it using the channel shuffle convolution method and Densenet's dense block structure. A computer-aided technique for the early identification of lung cancer using CT images was

proposed by Elnakib et al. [9]. A genetic algorithm (GA) is trained to optimize the obtained data set in order to determine the most significant elements. A variety of classifiers are finally looked at in order to identify the pulmonary nodules properly. Comparing the suggested technology to other earlier methods like VGG-16, AlexNet and VGG-19 networks, encouraging results are obtained.

Srinivasulu et al. [10] introduced a novel blockchain based lung cancer detection using extended CNN. There are primarily two architectures like U-Net and VGG-16 are used in the suggested method to categorize lung nodules and predict the amount of malignancy. The Internet of Things (IoT) may be used for the proposed multistage lung cancer detection and classification,

An algorithm for detecting lung nodules has been developed by Vaishnavi et al. [11]. For pre-processing, they used a discretely sampled wavelet in the Dual-tree complex wavelet transform (DTCWT). GLCM is a texture analysis technique that determines how often different Grey level combinations co-occur in an image using a second-order statistical method. They used a Probability Neural Network (PNN) classifier, whose accuracy in classification and training was evaluated.

The Faster R-CNN method for lung cancer detection was first described by Su et al. [12]. They illustrate the quicker R-CNN's suitability for lung knob recognition based on the training set. CNN and alternative optimization are the two training techniques used in the Faster R-CNN approach. Low tiny object identification accuracy is a common problem with many network models; hence, in order to increase the sensitivity to small things, the model needs to be enhanced and optimized.

A cat swarm optimization-based computer-aided diagnostic model for lung cancer classification (CSO-CADLCC) was reported by Vaiyapuri et al. [13]. The Gabor filtering-based noise reduction approach is the first pre-processing method used by the proposed CHO-CADLCC technology. Additionally, the NASNetLarge model is used to extract features from the pre-processed pictures. The CSO method with the weighted extreme learning machine (WELM) model comes next and is used to classify lung nodules. In order to optimise the WELM model's parameter tuning and get better classification performance, the CSO method is finally applied.

Inception V3, CNN, CNN GD, Resnet-50, VGG-16, and VGG-19 are the six deep learning models that Rajasekar et al. [14] suggested be used to diagnose lung cancer effectively. Based on the histopathological and CT scan pictures, experimental studies were carried out. This approach will be effective in detecting lung cancer and helpful to those in need due to the inherent benefit of the suggested methodology. The I3DR-Net is a single-stage detector that was proposed by Harsono et al. [15] to identify and categorise lung nodules. A feature pyramid network with pre-trained image weight from the inflated 3D ConvNet (I3D) was combined with a multi-scale 3D Thorax CT scans database to build the model.

For the purpose of detecting lung nodules, Schultheiss et al. [16] created the CNN-based RetinaNet architecture. The input

picture is segmented using the U-Net technique. An important part of this work was investigating the possibility that foreign substances may cause inaccurate selections in CNN-based nodule recognition systems. A multicrop CNN was presented by Shen et al. [17] that can automatically extract salient module features by max-pooling procedures performed at different times and cropping different sections from feature maps.

A lung nodule classification method based on a deep residual network is proposed in [22]. In [23], the CT image sub-block preprocessing strategy was used to extract nodule features for enhancement and alleviate the aforementioned problems. The experimental results showed that the effective classification time cost based on the original Faster R-CNN

detection method. The research in [24] presented the Non-Local network by adding channel-wise attention capability and apply Curriculum Learning principles for the classification task. Assorted Scale Integrated Alternate Link Model Convolutional Neural Network method is proposed in [25] for Lung Nodule Detection. A new hybrid deep learning framework by combining VGG, data augmentation and spatial transformer network (STN) with CNN is proposed in [26]. Multiscale Rotation-Invariant Convolutional Neural Networks technique is designed to find the lung texture classification results [27]. The article [28] offered hybrid CNN along with the SVM classification method with tuned hyperparameters for Lung Cancer Detection from X-Ray Images. Table I presents the summary of existing work.

TABLE I. SUMMARY OF EXISTING WORK

REFERENCES	NETWORKS	ADVANTAGES	LIMITATIONS
[5]	R-CNN	Eliminates unnecessary pictures and lowers false-positives	Model is not strong because of insufficient samples
[6]	FPSOCNN	Find best feature	Can improve the performance with advance classification methods
[7]	FFNN	Eliminate the unnecessary portion, extract some data	insufficient data sample size
[8]	Mask-RCNN	Segmentation and classification	Need to improve the network performance and the recognition accuracy.
[9]	AlexNet	Improved the contrast of image	Insufficient training data
[10]	U-Net	classify and organize and assess threat level	Limited input and output
[11]	PNN	Classify normal and abnormal	Limited pattern neuron
[12]	R-CNN	Improved detection accuracy than existing	Used too small samples
[13]	NASNet	Preprocessing, feature extraction and classification	Can be used more samples
[14]	CNN	histopathological images are considered for the identification	Can be used advanced optimization technique
[15]	3D ConvNet	texture detection and classification	Can be implemented in real-time
[16]	U-Net and RetinaNet	Find critical positions	Used limited images
[17]	MC-CNN	Initialization approach of characterizes nodule semantic attributes	Can use more samples
[22]	ResNet	Less false positive rate	Long training time
[23]	FR-CNN	reduced the rate of misdiagnosis	Used less samples
[24]	ProCAN model	achieved state-of-the-art performances	Can improve accuracy
[25]	ASIAL CNN	More convolutional pathways	Can improve prediction accuracy
[26]	VDS net	Determine the condition of patients	Need more samples
[27]	MRCNN	Change overlapping adjacent patches	Used only CT samples
[28]	OCNN-SVM	Categorizing lung image	Want to use various data sets

III. PROPOSED METHODOLOGY

The proposed work has three stages: (a) Preprocessing, (b) Segmentation and (c) Classification. Fig. 1 demonstrates the proposed work.

A. Pre-processing using CLAHE

The accuracy of the lung image classification process is enhanced by this pre-processing phase. In this work, input CT and Chest X-ray image enhancement is achieved with Contrast Limited Adaptive Histogram Equalization (CLAHE). When compared to AHE, it processes computationally more quickly since there are no overlapping blocks [18]. The CLAHE

technique effectively equalises the image histogram in addition to enhancing contrast [19].

One type of adaptive contrast augmentation method is called CLAHE. Adaptive histogram equalisation, or AHE, can be used to sharpen the borders of each picture region and boost local contrast. Updates to the enhancement computation are made for CLAHE using the maximum contrast enhancement factor and the highest clip level value, respectively. After that, the neighbouring picture areas are blended by bilinear interpolation to eliminate artificially stimulated region borders. Using this approach, medical photos can have better quality and contrast. The histograms for each region are first calculated utilising restrictions for contrast expansion and clipping in

order to maximise picture improvement. After that, the calculated histogram is re-distributed to maintain the height inside the clip limit. For CLAHE grayscale mapping, Cumulative Distribution Functions (CDFs) are computed by Eq. (1), and the histogram equalisation is obtained by estimating the CDF.

$$F_{a,b}(q) = \frac{(Q-1)}{p} \sum_{s=0}^q r_{a,b}(s) \cdot q = 1, 2, \dots, Q - 1 \quad (1)$$

The pixel units and grayscales for each area are given as P and Q in the above assessment. If the histogram of the (a, b) region is $F_{a,b}(q)$, for $q = 1, 2, \dots, Q - 1$, the CDF estimate, scaled by N-1 for grayscale mapping, is provided.

Fig. 1. Schematic representation of lung disease diagnosis framework.

B. Segmentation using Honey Badger Algorithm (HBA)

The Honey Badger Algorithm (HBA) is an excellent segmentation algorithm because of its adaptive balance between exploration and exploitation. This balance enables the algorithm to effectively navigate complex search spaces and avoid local optima. Because of its exceptional boundary detection precision, it can accurately segment images even in difficult cases with overlapping structures or fuzzy edges. It produces consistent results across various datasets and is more adept at managing noise and variability, which are prevalent in medical imaging. Additionally, it is flexible, scalable, and converges quickly, making it suitable for real-time applications.

Hence the HBA is used in the suggested way to benefit from a cutting-edge segmentation method. The segmented images are separated into various cells, which are then further separated into dynamic pixels. The center value and its neighboring bits are selected in each cell in dynamic pattern. Based on the center value, the pattern was generated by changing the gray scale values to binary values. Finding a method that can effectively separate the lungs from the CT and CXR pictures would be great, according to the previous studies. The algorithm's developers called the first technique the "digging phase" and the second the "honey phase". Fig. 2 depicts the honey badger's improved optimization algorithm.

Fig. 2. Basic honey badger algorithm.

This section presents the algebraic formulation of the suggested HBA method. Since HBA includes periods for both exploration and exploitation, a global segmented technique might be considered. The following is a mathematical breakdown of the phases in the proposed HBA.

The following are the main phases of the HBA and the corresponding equations for them: The population of potential solutions for HBA is expressed in Eq. (2).

$$Pops = \begin{bmatrix} x_{11}x_{12}x_{13} \dots x_{1D} \\ x_{21}x_{22}x_{23} \dots x_{2D} \\ \dots \dots \dots \dots \\ x_{n1}x_{n2}x_{n3} \dots x_{nD} \end{bmatrix} \quad (2)$$

$x_i = [x_i^1, x_i^2, \dots, x_i^D]$ is the formula for the i th position of the honey badger derived from the previous equations.

1) *Step 1 Initialization stage:* The issue space's upper (Yu) and lower (Yl) bounds identify the first potential solution at this stage. Consequently, the first solutions, as given by Eq. (3), are made up of random sets that may be generated using the subsequent method.

$$Y_a = Yl + R_1(1, d) \times (Yu - Yl), \quad a = 1, 2, 3 \dots n. \quad (3)$$

In this case, n solution providers (honey badgers) are given, Y displays every potential solution, and d indicates the magnitude of the solution.

2) *Step 2 Updating positions:* The Y_{new} coordinates for the candidates have been updated. For example, this may mean excavating or using a strategy that takes advantage of the honey phases. The ability of the hunter's scent and the distance between the prey and the honey badger (F) determine the potential search areas during the digging phase. The honey badger excavates in a circle. The following Eq. (4) describes how it moves:

$$Y_{new} = F + D_i \times \beta \times Min \times F + D_i \times R_3 \times (F - Y_a) \times (\cos 2\pi R_4) \times (1 - \cos 2\pi R_5) \quad (4)$$

where β is the food-gathering capacity of an insect. Using a uniform distribution and a range of 0 to 1, the R_3 , R_4 , and R_5 are randomly chosen random variables. The level of intensity is attained. As a sign of a search strategy, the D_i is created by the following Eq. (5):

$$D_i = \begin{cases} 1 & \text{if } R_6 \leq 0.5 \\ -1 & \text{if else} \end{cases} \quad (5)$$

The honey badger phase Use the honey stage to go over with the lead bird in search of beehives. The honey phase was calculated using the following Eq. (6):

$$Y_{new} = F + D_i \times R_7 \times \sigma \times (F - Y_a) \quad (6)$$

where R_7 is a randomly generated number between 0 and 1, and F is the highest outcome thus far.

3) *Step 3 Modeling intensity min:* The following computation in Equation 6 for each candidate's level of odour intensity *min* of the prey is needed, after which the honey badger's ability to detect insect odour controls its movements.

$$Min = \frac{R_2 \times (Y_a - Y_{a-1})^2}{4\pi(F_p - Y_a)} \quad (7)$$

The prey's location is indicated by F_p in the equation (7) above, and R_2 is an arbitrary sum between 0 and 1.

4) *Step 4 Density parameter modeling (σ):* Between the local and global search stages, the information flow is regulated by the sigma value. The following Eq. (8) illustrates the hypothesis that beta is represented throughout every iteration:

$$\sigma = C \times \exp\left(\frac{-r}{r_{max}}\right) \quad (8)$$

Where, the values for r and r_{max} represent the current iteration and the total number of iterations. C stands for constant, and its recommended value is 2.

5) *Step 5 Escaping from local results:* The search direction is signalled with a warning D_i , which the algorithm authors utilised to avoid becoming stale on regional fixes. HBA is known as a global optimisation method due to its exploration and exploitation stages. HBA is easy to use and understand, and there are fewer operators to alter. Finally, segmented pictures are used to classify lung carcinomas. The segmentation accuracy was measured using the rate of truepositive, rate of true negative, rate of false positive, and rate of falsenegative from the algorithm.

C. Classification using Spiking Convolutional Neural Network (SCNN)

The architecture of a Spiking Convolutional Neural Network (SCNN) is similar to that of traditional Convolutional Neural Networks (CNNs), but it is adapted to work with spike-based representations and to leverage the principles of spiking neural networks (SNNs).

A dynamic pattern refers to how the rules for updating each cell's state vary dependent on multiple circumstances, such as the cell's present state, its neighbours, or external inputs. Each cell has a dynamic pattern of selection for the center value and the bits surrounding it. Binary values were substituted for the grey scale values to create the pattern based on the center value. Ultimately, the global model for categorizing the pictures into normal and abnormal situations is the deep neural Spiking Convolutional Neural Network (SCNN), which is comprised of various patterns. With almost a billion spiking neurons, the Spiking neural network architecture is a massively parallel neurocomputer design intended for categorization. A spike-carrying neural network (SCNN) may broadcast and receive large quantities of information based on the relative timing of its spikes. Basic outline of the SCNN architecture is depicted in Fig. 3:

Fig. 3. SCNN network architecture.

As shown in the above figure, the convolutional layer, pooling layer, and spiking fully connected layer comprise the spiking CNN. Both the fully connected layer and the convolutional layer include layer-wise learning.

1) *Convolutional layer:* The convolutional layer of the network may be constructed after the convolutional filters are obtained. As in a traditional CNN, the convolutional layer employs weight sharing to lower the number of parameters. However, spike trains—rather than actual values—are used to transport the information in a spiking CNN.

The normalized grey scale pixel intensity in the range of (0,1) determines the pace at which spike trains representing the input picture ($r \times c$ pixels) are generated. The picture is sent to the network for $T = 20$ ms split into 1 ms time increments, as was previously mentioned. The convolution process is displayed in the network's first layer, which is illustrated in Fig. 2. To create feature maps with $(r - p + 1) \times (c - p + 1)$ LIF neurons, a collection of D filters (trained as mentioned in the previous section) are individually convolved with the picture throughout the 20-time-step presentation period. A particular aspect of the image is represented by each feature map that has LIF neurons in it. When threshold is reached, a LIF neuron in a feature map emits a spike. It aggregates the convolution results for a specific picture patch across $T = 20$ time steps. Upon firing, the membrane potential is returned to its resting value of zero. The membrane potential, U , of neuron m in feature map k at time t is computed using Eq. (9).

$$\frac{dU_m^k(t)}{dt} + U_m^k(t) = I_m^k(t) \quad (9)$$

If $U_m^k(t) \geq \theta^{conv}$, then $U_m^k(t) = 0$

I_m^k is defined below Eq. (10).

$$I_m^k(t) = \sum_{i=1}^p \sum_{j=1}^p W_k^{ex}(i, j) \cdot S_m(i, j, t) \quad (10)$$

A representation of the filter's convolution is $I_m^k(t)$. W_k^{ex} , and at $T = 20$ time steps, the presynaptic spike train, S_m . The spike train that represents a pixel value in the (i, j) coordinate of patch m is called $S_m(i, j)$.

Every neuron receives inputs in the form of p^2 spike trains with λ_{ij} rate parameters. The predicted value of the injected current at time step t , as determined by filter k for neuron m , is provided by Eq. (11).

$$E[I_m^k(t)] = \sum_{i=1}^p \sum_{j=1}^p W_k^{ex}(i, j) \cdot \lambda_{ij} \quad (11)$$

This may be compared to $I = (w^{ex})^T \cdot x$, where w^{ex} is a filter that represents pixel intensities and x is scaled to the average firing rates. Consequently, the convolution over T time steps may be used to approximate classical convolution.

2) *Pooling layer*: The spike trains generated from the convolutional layers are downsampled by the pooling layers. Spike-based representations allow for the adaptation of max-pooling processes, which usually include choosing the maximum number of spikes inside the pooling areas.

Following convolution, a neuron with the most activity within a square neighborhood of $lp \times lp$ presynaptic neurons is chosen by the pooling layer (max pooling). Additionally, parameter lp acts as the pooling layer's stride value. The spike rate of each neuron in a feature map may be used to describe its activity. Consequently, a feature map measuring $(r - p + 1) \times (c - p + 1)$ is converted to a smaller feature map measuring $(r - p + 1)/lp \times (c - p + 1)/lp$.

Robustness against local translation and scale changes is aided by the max pooling layer. In Fig. 2, the pooling layer appears as the second layer of the network. Nonadaptive relationships exist between the pooling maps and convolutional maps.

3) *Fully connected layer*: Fully connected layer classifies the image into normal or CVD. The spike trains that are released by the pooling layer divide the image's many visual elements among the D feature maps (D might have values of 16, 32, or 64). The output units receive spike trains emanating from the pooled feature maps at the third layer of the network, known as the fully connected (H) layer. The information's dimension is decreased in the feature maps by this layer.

For a neuron in the H layer to fire at a certain time step, it has to fulfill two requirements. The initial one is that it crosses its conventional LIF threshold, θ^h . Among the other neurons in the H layer, it does well in a non-exclusive winners-take-all (WTA) competition. As a result, we refer to the units in this layer as WTA-threshold LIF neurons. A WTA score is assigned to each unit in the H layer based on how its net input compares to the inputs of the other units in the layer. The synaptic weights, W , and the presynaptic spike vector, y_t , together yield the net input at time t .

$$WTAScore_h(W, y_t) = \frac{e^{W_h^T y_t}}{\sum_{j=1}^H e^{W_j^T y_t}} \quad (12)$$

IV. SECURE MANAGEMENT USING BLOCK CHAIN

Deep learning and blockchain are two extremely innovative technologies that are changing the standard operating procedures in the medical field. Using smart contracts, its solution improves transparency, safety, dependability, and data transmission capabilities. Among blockchain's many notable benefits are the ability to create smart contracts. This enables users to manage data access according to predetermined standards and agreements.

To guarantee that the data is private and secure, the classified lung picture in the proposed work is encrypted. By using encryption, the pictures are protected from being viewed by unauthorized users who do not have the necessary decryption keys to view them on the blockchain. Even if someone acquires unauthorized access to the blockchain, encryption makes sure they are unable to view the image without the correct decryption key.

After that, the encrypted lung image is hashed to provide a distinct digital fingerprint. The process of hashing transforms the image data into a fixed-length string of characters that while uniquely expressing the image, is unretrievable through reverse engineering. This hash serves as the lung image's special identification.

On the blockchain, a block contains the hash of the lung picture and associated metadata. Afterwards, a network of nodes receives this block, which is added to a chain of earlier blocks. Blocks cannot be removed or changed after they are put to the blockchain, making them immutable. By doing this, the classification is permanently preserved and the lung image data is kept impervious to manipulation.

The original image can only be viewed by authorized individuals who possess the relevant decryption key. By automatically providing or refusing access in accordance with pre-established guidelines, smart contracts enforce access policies. Algorithm 1 is the pseudocode for the proposed work.

Algorithm 1: Proposed Work

- 1: Load Dataset
 - 2: Resize the image
 - 3: Declare CLAHE
 - 4: Threshold for contrast limiting
 - 5: Initialize the number of honeybadger
 - 6: Sort the fitness vale of honeybadger
 - 7: Find optimal value
 - 8: Calculate Density
 - 9: Calculate intensity
 - 10: Find digging phase
 - 11: Sort fitness value
 - 12: Update global optimization solution
 - 13: Train the model
 - 14: Test the model
 - 15: Predict normal or abnormal
 - 16: Integrate Blockchain for Data Integrity

V. EXPERIMENTAL EVALUATION

A. Dataset Description

This part implements the LIDC-IDRI dataset to identify instances of lung cancer. The database has 848 nodules that have been enhanced in 17 different methods, 442 of which are benign and 406 of which are malignant. The dataset from LIDC-IDRI contains lesion annotations from four thoracic radiologists with expertise. Included in LIDC-IDRI is 1018 low-dose lung CT scans from 1010 lung patients.

A popular and effective medical imaging technique is a chest X-ray. In certain cases, the clinical examination of CXR pictures might be even more challenging than the study of a

chest CT scan. The 112,120 CX-ray pictures in the NIH Chest X-ray Dataset are associated with individual diseases.

B. Evaluation Metrics

The following statistical measures, including accuracy, precision, F1 score and recall are used to evaluate the efficacy of the proposed lung nodule classification technique. The terms *TruPos*, *TruNeg*, *FalPos* and *FalNeg* are represents the True-Positive, True-Negative, False-Positive and False-Negative, respectively. The following equations can be utilized to compute the metrics.

$$Accuracy = \frac{(TruPos + TruNeg)}{(TruPos + FalPos + TruNeg + FalNeg)}$$

$$Precision = \frac{TruPos}{(TruPos + FalPos)}$$

$$Recall = \frac{TruPos}{(TruPos + FalNeg)}$$

$$F1Score = 2 \times \frac{(Recall \times Precision)}{(Recall + Precision)}$$

VI. RESULT

The suggested approach for segmenting and categorizing lung nodules is presented here with the experimental results. The recommended approach was put into practice using a MATLAB environment. Accuracy, F1 score, precision, and recall metrics were used to assess the classification performance. Two sets of lung nodule pictures, such as CT and Chest X-ray (CXR) images, were used for the experiments. Table II shows the classification results of the proposed SCNN model on LIDC-IDRI dataset.

TABLE II. CLASSIFICATION RESULTS OF THE PROPOSED SCNN MODEL ON LIDC-IDRI DATASET

Performance Measures	Proposed SCNN
Accuracy	98.64
Precision	92.42
Recall	93.76
F1-score	93.08

Fig. 4. Performance of the proposed SCNN model on LIDC-IDRI dataset.

The proposed SCNN model achieves 98.64% of accuracy, 92.42% of F1score, 93.76% of precision and 93.08% of recall on LIDC-IDRI images. The effectiveness of the suggested model is visually represented in Fig. 4.

Table III displays the classification results of the proposed SCNN model on NH Chest X-Ray images. The suggested model achieves 98.9% accuracy, 97.3% precision, and 94.44% recall and 95.84% of F1score on NH Chest X-Ray images.

TABLE III. CLASSIFICATION RESULTS OF THE PROPOSED SCNN MODEL ON NH CHEST X-RAY DATASET

Performance Measures	Proposed SCNN
Accuracy	98.9
Precision	97.3
Recall	94.44
F1-score	95.84

The suggested SCNN classifier's classification performance is illustrated in Fig. 5. It demonstrates that the suggested model produces higher predictions of accuracy, precision, recall, and F1-score across the board. The effectiveness of the suggested model is visually represented in Fig. 5.

Fig. 5. Performance of the proposed SCNN model on NH Chest X-Ray dataset.

A. Comparative Analysis

A comparison between the suggested model and traditional neural networks is also done in this section. The comparative analysis of Lung cancer detection in terms of accuracy of the proposed Spiking CNN model with existing methods on CT dataset is displayed in Table IV. It is clearly detected that the proposed Spiking CNN classifier gives superior results than the other previous research work based on accuracy. It gives 98.64% of accuracy which is +6.19% than ASAIL CNN approach, +4.53% than ProCAN approach, +8.94% than Improved FasterR-CNN, +2.83% than Inception V3, +0.41% than Deep residual network, +8.74% than ResNet method, +14.5% than CNN model. The results of this technique's performance comparison with standard methods indicate that the proposed method outperforms them.

The intended model yielded better performance than the earlier networks. The expected outcomes seem to be rather reliable in distinguishing between typical and anomalous instances. The result shows the effectiveness of the proposed

model based on blockchain dynamic pattern techniques applied in deep Convolutional Neural Network.

TABLE IV. COMPARATIVE ANALYSIS OF SCNN WITH OTHER CLASSIFIERS ON CT IMAGES

Author/Year	Methods	Accuracy (%)
Song et al./2017 [20]	CNN	84.14
Nibali et al./ 2017 [21]	ResNet	89.90
Wu et al./ 2020 [22]	Deep residual network	98.23
Wu et al/ 2020 [22]	Inception V3	95.81
Shiwei et al. /2021 [23]	Improved FasterR-CNN	89.7
Al-Shabi et al/2022 [24]	ProCAN	94.11
Parveen Banu et al/ 2022[25]	ASAIL CNN	92.45
Proposed Method	SCNN	98.64

Fig. 6 presents a visual representation of the comparison findings between the proposed technique and the existing methods on CT images.

Fig. 6. Comparative analysis of the proposed method and existing methods on CT images.

The comparative analysis of Lung cancer detection in terms of accuracy of the proposed Spiking CNN model with existing methods on Chest X-Ray dataset is displayed in Table V. It is clearly detected that the proposed SCNN classifier gives superior results than the other previous research work based on accuracy. It gives 98.9% of accuracy which is +0.2% than OCNN-SVM approach, +8.8% than Gabor-LBP+MRCNN approach, +25.9% than VDSNet model. The results of this technique's performance comparison with standard methods indicate that the proposed method outperforms them. The intended model yielded better performance than the earlier networks. The expected outcomes seem to be rather reliable in distinguishing between typical and anomalous instances.

Fig. 7 presents a visual representation of the comparison findings between the proposed technique and the existing methods on Chest X-Ray images.

TABLE V. COMPARATIVE ANALYSIS OF SCNN WITH OTHER CLASSIFIERS ON CHEST X-RAY IMAGES

Author/Year	Methods	Accuracy (%)
Bharati et al./2020 [26]	VDSNet	73
Wang et al./2018 [27]	Gabor-LBP+MRCNN	90.1
Sreeprada et al/2023 [28]	OCNN-SVM	98.7
Proposed Method	SCNN	98.9

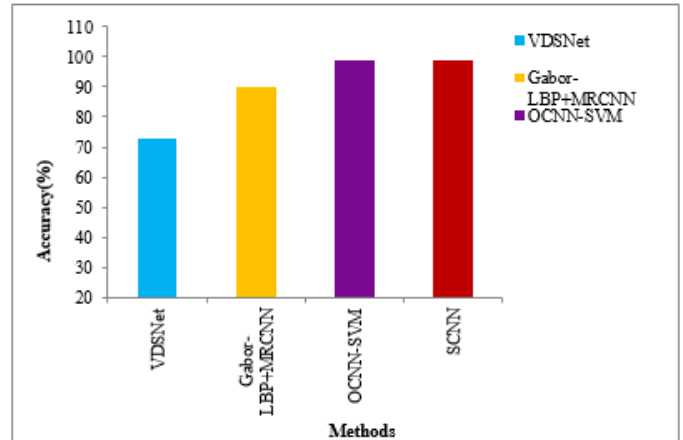

Fig. 7. Comparative analysis of the proposed method and existing methods on Chest X-Ray images.

The pre-processing, segmentation, and classification outcomes of the suggested work are shown in Fig. 8. The original CTX and CT pictures are displayed in the first column. The pre-processing results using CLAHE are shown in the second column. The segmentation result using the Honey Badger method is displayed in the third column. The categorization result is shown by the value in the final column. With the CT image dataset, the suggested operator achieves 98.64% classification accuracy, and with the CXT dataset, it achieves 98.9% accuracy.

Image Type	Input	Preprocessing	Segmentation	Classification

VII. DISCUSSION

A very efficient lung image analysis pipeline is a result of the synergy between CLAHE, HBA, and SCNNs. The utilization of contrast enhancement in CLAHE proven to be crucial in emphasizing nuanced traits that are necessary for precise segmentation and classification. Because of its dynamic nature, the Honey Badger Algorithm ensured accurate segmentation even in difficult situations, minimizing errors that could have spread to the classification stage. The excellent accuracy and computational efficiency that SCNNs brought made them a good choice for use in healthcare settings where prompt and dependable decision-making is crucial. The outcomes demonstrate that this integrated strategy, which offers a well-balanced mix of accuracy, efficiency, and interpretability, is well-suited to meet the difficulties associated with lung image processing.

VIII. CONCLUSION

This study proposed a novel neural network model (SCNN) for lung nodule classification, which combines the theories of deep learning, blockchain, and dynamic pattern features to address the issues with lung nodule classification, including a difficult classification detection process and low classification accuracy. The CT scan and CXR image databases from the NIH Chest X-ray and LIDC-IDRI were used. Initially, these images are pre-processed by Contrast Limited Adaptive Histogram Equalization (CLAHE) to enhance the image clarity and reducing the noise. Then the Honey Badger optimization Algorithm (HBA) is used to segment the lung region from the pre-processed image. Morphological segments of the lung region are used to generate dynamic patterns. Finally, these patterns are aggregated into the deep neural Spiking Convolutional Neural Network (SCNN) is the global model for classifying the images into normal and abnormal cases. Based on the LIDC-IDRI and NH Chest X-Ray, the SCNN model achieves 98.64% and 98.9% of accuracy respectively. This methodology provides a comprehensive solution that tackles the particular issues of lung image analysis by combining strong preprocessing, sophisticated segmentation, and effective classification. In the end, the suggested method improves patient outcomes in the field of lung health by laying the groundwork for more precise, understandable, and resource-efficient diagnostic instruments.

Application of Improved CSA Algorithm-Based Fuzzy Logic in Computer Network Control Systems

Jianxi Yu

School of Engineering & Economics, Henan Institute of Economics and Trade, Zhengzhou, 450046, Henan, China

Abstract—In the past few years, with the high-speed popularization of computers and the widespread use of smart phones and mobile devices, the Internet has gradually become an indispensable part of people's daily lives. The Internet is constantly driving the process of digital society and providing people with more convenient and innovative applications. However, the internet industry also faces challenges such as runtime ambiguity, instability, large data volume, and difficulties in network situational awareness. In response to the above issues, this study combines the standard cuckoo algorithm with a fuzzy neural network to design a computer network situational awareness system. It uses principal component analysis to deduct the dimensions of the original data and then adds Gaussian noise to introduce appropriate randomness. The test proved that the improved model had a significant optimization effect on real network data, with an improvement of about 81.2% compared to the standard cuckoo algorithm. In the 220th iteration of the test set, the Loss function value was 0, which could accurately predict the network situation, with an accuracy rate of 98%. The designed system identification has higher recognition accuracy and less time consumption and has certain application potential in computer networks.

Keywords—CSA; computer network; fuzzy logic; principal component analysis method; network operation; situation awareness

I. INTRODUCTION

Since the beginning of the 21st century, information technology has rapidly advanced, and the Internet has played an increasingly important role in social production and life. The average monthly traffic volume of the population has been increasing year by year [1]. The application of this technology is becoming increasingly diversified, giving rise to new industries such as 5G technology, the Internet of Things, edge computing, cloud computing, and data center optimization. This is constantly changing people's way of life and work, but it also brings new challenges and opportunities. It is widely acknowledged that the network runtime state exhibits several characteristics that present significant challenges to the development of the internet industry. These include ambiguity, instability, a considerable volume of data, and a lack of situational awareness within the network. In response to the above issues, experts and scholars in the field of the Internet have applied the cuckoo algorithm to computer network control systems. This algorithm is a heuristic optimization algorithm inspired by the reproductive behavior of cuckoo birds [2]. The algorithm realizes the optimization of the computer network control system by initializing the cuckoo group, generating new solutions, evaluating and selecting, updating and iterating, judging the convergence conditions, and analyzing the results

[3]. However, the related research precision is not high, the generalization ability is low, the training time is long, and the rate of convergence is slow. In this study, the Principal Component Analysis (PCA) is first used to reduce the dimensions of the huge and changeable network data, and then Gaussian noise is introduced to lift the rate of convergence of the algorithm. Based on the standard Cuckoo Search Algorithm (CSA), a computer Network Situational Awareness Model (NSAM) is designed by integrating a Fuzzy Neural Network (FNN). The paper mainly consists of five sections. Section II summarizes the research status of scholars in the industry on the difficulties of Internet situational awareness. Section III establishes a computer NSAM that integrates CSA and fuzzy logic. Section IV conducts comparative experiments and efficiency verification on the optimization effect of the model. Section V is a summary of the research and an explanation of the direction for improvement.

II. RELATED WORKS

As a result of the growing use of mobile internet in a range of sectors, predictive models with enhanced network situational awareness capabilities are increasingly attracting interest from businesses and researchers. Liu C et al. introduced cloud control middleware to manage service requests to meet constraints, aiming at the problem that traditional cloud computing mode makes it difficult to provide real-time computing resources. They developed a conceptual computing framework built on cloud and mist combination, which has better performance in energy consumption and response time [4]. Abed Algoni B H et al. used a special type of opposition-based learning ECS model to address the problem of CSA being prone to suboptimal situations. The experiment showed that ECS exhibited better performance than all tested variants [5]. Cheng P et al. proposed Particle Swarm Optimization (PSO) - CSA to predict local comfort and global comfort by artificially solving the problems of motion state and being unable to be directly used for model analysis. This model had a high prediction accuracy [6]. Eltamally A M et al. proposed PSO and CSA to capture global peaks in the P curve of Photovoltaic (PV) arrays, which have advantages in optimizing control parameters [7]. Fan J et al. designed a chaotic CSA image segmentation model to address the issue of difficulty in improving accuracy in noisy images. This model improved accuracy and reduced uncertainty [8]. Li J et al. designed a balanced learning differential CS extension algorithm to solve the problem of CSA easily falling into local optima, which lifted the algorithm's global search capacity and accuracy [9].

CSA has unique advantages in group optimization problems and provides a certain reference for Internet network situational

awareness. Chen S Y et al. designed a variable order fuzzy fractional proportional integral differential control system to address the issue of the inability of integral differential (PID) controllers to achieve high-precision control. This system could achieve better control response and anti-interference characteristics than Integer Order (IO) controllers [10]. Muhammad K et al. designed a television camera monitoring system based on fuzzy logic to continuously monitor the phenomenon of a large amount of data generated by television cameras every day. This model could handle data uncertainty in the real-world domain [11]. To solve the problem of autonomous decision-making of mobile robots to overcome obstacles, Ben Jabeur C et al. established a decision model based on an intelligent PID optimization neural network and fuzzy logic controller. The mobile robot applying this model could quickly execute tasks and adapt to constantly changing environmental conditions [12]. Costa R et al. designed a mountain flood prediction model based on classification and regression trees, deep learning neural networks, and fuzzy logic to identify slopes with a high probability of mountain flood outbreaks. The prediction accuracy exceeded 84% [13]. In response to the issue of insufficient drone controllers to cope with weather disturbances, Ulus Ş designed a drone control model by integrating classic PID and fuzzy logic controllers. This controller had better performance than other controllers [14]. Katsikis V N et al. designed a multi-objective evolutionary network framework to address the lack of flexibility in fuzzy logic neural networks, which has advantages in effectiveness and interpretability [15].

In summary, the application of fuzzy logic and CSA in computer network control systems has sufficient theoretical and practical foundations, but relevant research rarely combines the two to solve the problem of network situational awareness difficulties. Therefore, this study improves CSA and combines fuzzy logic to design NSAM to promote further development of the internet industry.

III. OVERALL PLAN DESIGN FOR NETWORK OPERATIONAL SITUATION AWARENESS

This chapter is mainly divided into five sections. The first section is divided into establishing an indicator model and NSAM, while the second section improves the CSA and integrates fuzzy logic. In the third section, the computer network control system based on fuzzy logic is established, and PCA is taken to decrease the dimension of the original data.

A. Establishment of NOSA Model

Network Operational Situation Awareness (NOSA) refers to the real-time monitoring, analysis, and identification of various activities, events, and resources in the network to obtain a comprehensive understanding of the network's operational status [16]. NOSA can help organizations or network administrators detect abnormal activities, attack attempts, or system failures promptly, and take corresponding measures to protect the security and stability of the network. Hence, this system needs to include the whole links from data to situation analysis to users. By the above requirements, this manuscript proposes the NOSA system, as exhibited in Fig. 1.

Fig. 1. Schematic diagram of network operation situational awareness system.

Fig. 1 shows a system that includes four modules: data, data fusion, situation visualization, and business application. Specifically, the results of the data fusion module can direct the management operations of the business application module. After the business application module manages the network, it will transmit new analysis results to the data fusion module through it. This cyclic process enables the system to

continuously optimize and improve to better meet user needs. With the guidance of the above NOSA system model, a network operation situation indicator system can be constructed. This research presents a network operation situation indicator system, which is constructed from the perspectives of network performance and network traffic. The system is designed to integrate the TCP/IP five-layer model, as illustrated in Fig. 2.

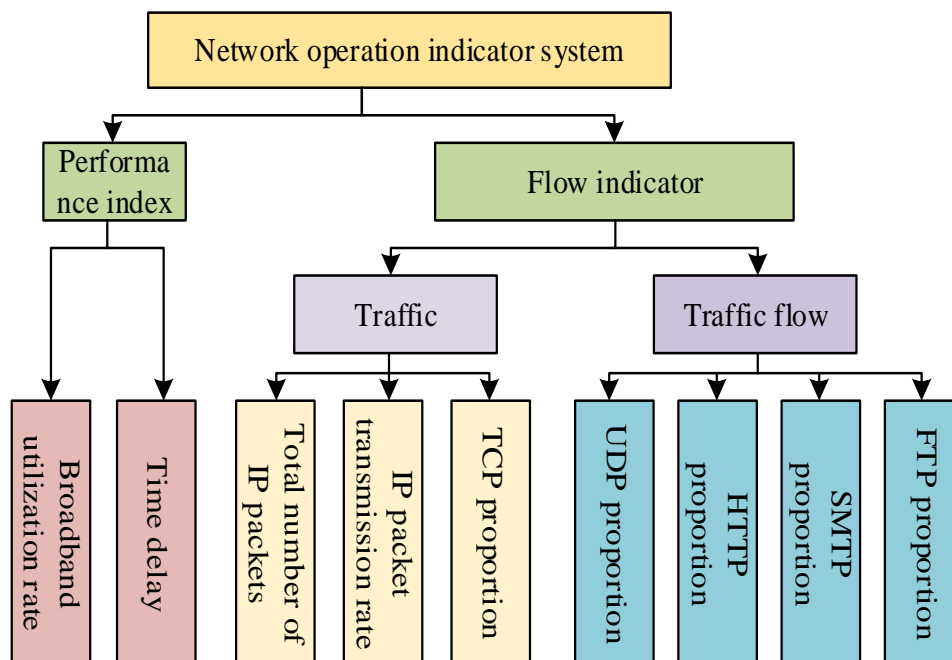

Fig. 2. Network operation situation indicator system.

Fig. 2 shows the network traffic indicators, including IP throughput, link utilization, the size and proportion of traffic based on network protocols, and the size and proportion of traffic. The network protocol traffic mainly covers protocols such as TCP, UDP, ICMP, etc; Business traffic mainly includes protocols i.e. HTTP, FTP, and SMTP. The goal of this study is to reflect the operational situation of the network from a business perspective. Therefore, it is necessary to integrate multiple protocol layer indicators [17]. The transport layer protocol traffic data, namely TCP, UDP and ICMP, are added to the network traffic indicator. After establishing the network operation situation indicators, it is also essential to sort out the original data according to the relevant calculation formulas. Broadband utilization is an important performance indicator in a network, which represents the current load level and Resource Utilization Efficiency (RUE) of the network. This characteristic indicator is calculated by Eq. (1).

$$L = \frac{T}{B} \quad (1)$$

In Eq. (1), T is the average transmission rate of the network, while B represents the maximum transmission rate of data packets in the network. In addition, this indicator system is one-way delay. Delay is used to represent the network Transmission delay. The calculation formula is Eq. (2).

$$Delay = \frac{\sum d}{sum} \quad (2)$$

In Eq. (2), d means the delay of all data packets transmitted by the network, and sum is the sum of the number of transmitted data packets. The quantity of data packets transmitted by the network per unit time is called the

IP packet transmission rate, and its calculation formula is Eq.

$$(3). V_{IP} = \frac{sum}{t} \quad (3)$$

In Eq. (3), sum represents the total number of IP packets transmitted by the network, while t represents the total transmission time. In this indicator system, the proportion of protocol traffic between the application layer and the network layer is introduced. This type of indicator is represented by acc , and its calculation formula is Eq. (4).

$$acc = \frac{sum_protocol}{sum} \quad (4)$$

In Eq. (4), $sum_protocol$ represents the gross of protocol packets per unit time, and sum represents the total number of IP packets during that period.

B. Fuzzy Logic Model based on CSA Algorithm

CSA heuristic swarm intelligence optimization algorithm simulates the process of cuckoo's foraging and nest protection to achieve global optimization. The basic idea of the algorithm is to represent the candidate solutions of the problem as nests of cuckoo birds, with each nest corresponding to a solution vector. Then, the quality of each nest is evaluated based on the fitness function of the problem. CSA has good global search ability and high parallelism. It is suitable for various optimization problems, especially continuous optimization problems. The performance of the algorithm is still affected by factors such as parameter settings, nest protection strategy, and nest elimination strategy, and needs to be adjusted and optimized according to specific problems. Fig. 3 shows the algorithm flowchart.

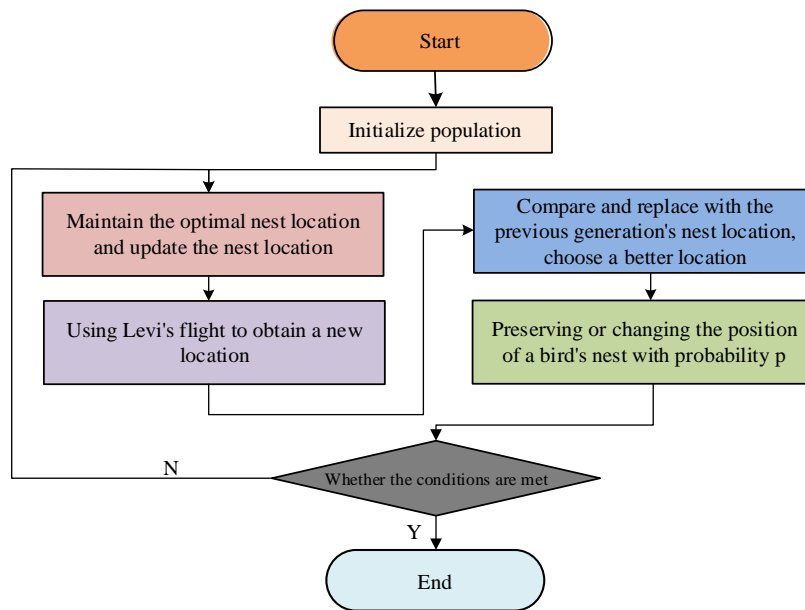

Fig. 3. Flowchart of cuckoo algorithm.

Fig. 3 is the CSA flowchart. Firstly, a set of feasible solutions is randomly produced as the initial population, and the optimal nest position is retained by adjusting the positions of the parents and parasitic birds. This step can use some heuristic methods, such as random walk or local search algorithms. Then, the position is updated by adjusting the position of the parent and parasitic birds. The next step is to eliminate solutions with lower fitness with a certain probability. Finally, to determine whether the termination condition is met, i.e. reaching the max-

iterations or finding a solution that meets the requirements. Step 2 is repeated to 5 until the termination conditions are met. Although CSA has certain advantages and application value, there are also some shortcomings. For example, the rate of convergence is slow, the parameter selection is difficult, and the dependence on problem characteristics is strong. To solve the above problems, the idea of fuzzy logic is used to improve traditional CSA. The schematic diagram is shown in Fig. 4.

Fig. 4. Fuzzy mapping diagram.

Fig. 4 is a fuzzy inference system, which mainly consists of four parts. The first part is a fuzzy generator, mainly responsible for converting the precise input values into fuzzy membership values, that is, mapping the input to the corresponding membership functions. The second part is the fuzzy rule library, which defines a set of fuzzy rules, each containing a series of prerequisites and a conclusion. The preconditions and conclusions are described by fuzzy sets. The third part is the inference engine, which uses the inference mechanism to calculate the fuzzy output according to the given rules and the fuzzy input. The final part is to convert the fuzzy output back to precise values through anti-fuzzification. Unlike traditional binary logic, which only has true and false values, fuzzy logic allows variables to have a continuous range of values, with fuzziness between 0 and 1. Assuming the input variable is $x = [x_1, x_2, \dots, x_n]^T$, each component is a fuzzy variable. Each

fuzzy variable is segmented into n fuzzy sets, and the fuzzy set of each component in the input variable is Eq. (5).

$$T(x_i) = \{A_i^1, A_i^2, \dots, A_i^k\}, k = 1, 2, 3, \dots, n \quad (5)$$

In Eq. (5), A_i^k is the k -th variable value of the i -th input component. The fuzzy outputs vector $y = [y_1, y_2, \dots, y_n]^T$ in this fuzzy model, if x_i is A_i^k , the output fuzzy output vector is equation (6).

$$y_{ir} = p_{0r}^i + p_{1r}^i x_1 + \dots + p_{nr}^i x_n \quad 0 < r < k^n \quad (6)$$

In Eq. (6), p_{0r}^i represents the output of the i -th output vector under rule r . This fuzzy rule can be represented as an IF THEN statement, as shown in Eq. (7).

IF $x_i \in A_i^k$, THEN

$$\begin{cases} y_{1r} = p_{0r}^1 + p_{1r}^1 x_1 + \dots + p_{nr}^1 x_n \\ \dots \\ y_{ir} = p_{0r}^i + p_{1r}^i x_1 + \dots + p_{nr}^i x_n \end{cases} \quad (7)$$

In Eq. (7), x_i represents the k -th variable value of the i -th input component. By using single point fuzzification to represent input variables, the applicability of each rule can be calculated, as shown in Eq. (8).

$$T_r = \mu_{1k} \wedge \mu_{2k} \dots \wedge \mu_{nk} = \mu_{1k} \square \mu_{2k} \dots \mu_{nk} \quad (8)$$

In Eq. (8), T_r represents the applicability of rule r . The output value of the fuzzy system is the weighted average of each rule, and its formula is Eq. (9).

$$y_i = \sum_{q=1}^{q=r} T_q y_{iq} / \sum_{q=1}^{q=r} T_q \quad (9)$$

Fig. 5. CSA fuzzy neural network.

In Fig. 5, the first is the input layer, which completes the input of training data. The second is the rule mapping layer, which fuzzily divides each input component. The third is the rule fitness layer, where each node represents a fuzzy rule. The fourth is the normalization layer, which normalizes the fitness of each rule. The fifth is the anti-fuzzy layer, which completes the mapping from the fuzzy rule space to the output space through the Activation function. The last layer is the output layer, which outputs the network operational situation level. In

In Eq. (9), y_i is the i -th component of the output vector. Fuzzy logic is widely used in control systems, artificial intelligence, decision support systems, and other fields, especially suitable for problems with fuzziness and uncertainty. Through the reasoning and processing of fuzzy logic, incomplete information and fuzzy concepts in the real world can be better handled, improving the effectiveness of decision-making and control.

C. Computer Network Control System Based on Fuzzy Logic

The large amount of data in computer network control systems has uncertainty and fuzziness, so it is necessary to apply fuzzy theory to solve these problems. In addition, network data also have the characteristics of being massive and multidimensional. Neural network is an effective method to deal with big data. When it is combined with fuzzy theory, it can solve NOSA problem in complex data environment. Therefore, an improved CAS algorithm, CSA-FNN, is designed by combining CAS and FNN, and its structure is Fig. 5.

the above CSA-FNN model, the network operational situation features include 10 indicators, that is, the input data is 10 dimensions. The number of nodes in each layer increases exponential type with the number of nodes in the input layer, resulting in too many nodes. Therefore, it is necessary to reduce the dimensions of the original data. This study uses PCA to reduce and reconstruct the dimensions of the original data. Fig. 6 is the process steps.

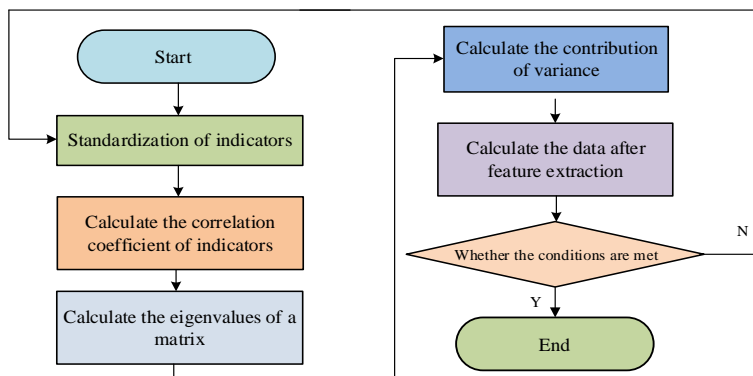

Fig. 6. CSA-FNN.

The first is to standardize the indicators. The dimensions of the original indicator data in computer networks are different, so it is necessary to normalize the indicator data and convert them into data under the same dimension. This article adopts the maximum-minimum normalization method, and its expression is shown in Eq. (10).

$$I = \begin{cases} I_{11} & I_{12} & \cdots & I_{1m} \\ I_{21} & I_{11} & \cdots & I_{2m} \\ \vdots & \vdots & \ddots & \vdots \\ I_{n1} & I_{n2} & \cdots & I_{nm} \end{cases} = (I_1, I_2, \dots, I_m) \quad (10)$$

In Eq. (10), I represents the normalized network indicator data, and m represents that each data has m indicators. I_m represents the m -th dimensional vector of the data, normalized as Eq. (11).

$$i_{jp}' = \frac{i_{jp} - \bar{I}_p}{\sqrt{\sigma_p}} \quad (11)$$

In Eq. (11), \bar{I}_p represents the average value of the p -th indicator. σ_p represents the mean square deviation of the p -th indicator. The correlation coefficient of each indicator in I is calculated to obtain the correlation coefficient matrix, as shown in Eq. (12).

$$A = \frac{1}{m} I^T I \begin{pmatrix} R_{11} & R_{12} & \cdots & R_{1m} \\ R_{21} & R_{11} & \cdots & R_{2m} \\ \vdots & \vdots & \ddots & \vdots \\ R_{m1} & R_{m2} & \cdots & R_{mm} \end{pmatrix} \quad (12)$$

In Eq. (12), R_{ij} ($i, j = 1, 2, \dots, m$) represents the correlation coefficient between the i -th and j -th indicators. The eigenvalue of matrix A and Orthogonalization is calculated, as shown in Eq. (13).

$$a = (a_1, a_2, \dots, a_m) \quad (13)$$

In Eq. (13), a is the matrix obtained by Orthogonalization

(a) CSA

(b) CSA-FNN

Fig. 7. Comparison of CSA and CSA-FNN algorithm errors.

the characteristic matrix of matrix A . Then the contribution of each feature vector is calculated to the square difference, and the contribution calculation formula is Eq. (14).

$$a_i = \frac{\lambda_i}{\sum_{k=1}^m \lambda_k} \quad (14)$$

In Eq. (14), a_i ($i = 1, 2, \dots, m$) is the contribution rate of the mean square deviation of the i -th eigenvector. Finally, the data after feature extraction based on the formula are calculated. After the above 5 steps of processing, the dimension of the data is reduced to 4 dimensions, and the number of nodes is significantly reduced, solving the problem of massive and multidimensional network data. Therefore, the improved CSA algorithm based on fuzzy logic has been successfully applied to computer network control systems.

IV. CSA-FNN MODEL PERFORMANCE TESTING

This chapter mainly verifies the optimization effect of the model. The first section mainly compares and analyzes CSA-FNN with other algorithms to verify the comparative advantages of the algorithm. Then, distinctive datasets are used to verify the generalization ability of the model. The second section mainly conducts simulation experiments to test the efficiency in practical environments.

A. Comparative Analysis of Algorithms and Validation of Generalization Ability

This study uses CSA combined with FNN to establish a computer network control system model, solving the problems caused by the uncertainty and fuzziness of computer network data. The original data dimension is reduced by PCA, which significantly reduces the number of nodes and complexity of the neural network [18]. To evaluate the optimization ability of fuzzy inference systems for computer network control systems, the experiment uses Python 3.8 on the Windows 10 platform and uses the Cooperative Association for Internet Data Analysis (CAIDA) dataset to perform 1000 iterations on the traditional CSA and CSA-FNN models, respectively. Fig. 7 shows the relationship between its training error and the iterations.

Fig. 7 shows the comparison of the effects of CSA before and after improvement on the training dataset. Compared to the standard CSA model, the rate of error reduction in the first 200 iterations of CSA-FNN is not significantly different. However, when the number of iterations reaches the range of [200, 400], the error of the FNN structure rapidly decreases and converges by the 400th iteration. The error of traditional CSA tends to converge after 700 iterations. Therefore, the CSA-FNN model proposed in the experiment has a faster convergence rate and a lower error in the final convergence. To eliminate the impact of dataset selection on experimental results and verify the generalization ability of the model, it is necessary to apply the Measurement and Analysis on the WIDE Internet (MAWI) dataset to train the above algorithms. Table I is the MAWI dataset parameter table.

Table I shows that the MAWI dataset is a very large dataset, including a large amount of network traffic data. Therefore, appropriate preprocessing and sampling are required when using this dataset for analysis and research [19]. The MAWI dataset usually contains more complex network traffic patterns, while the CAIDA dataset focuses more on reflecting the traffic characteristics of the actual Internet. For these two datasets,

researchers preprocess the data, including data cleaning and normalization, to reduce noise and eliminate dimensional differences between features. Afterwards, a comparison is made between CSA-FNN and Whale Optimization Algorithm (WOA), Ant Colony Optimization (ACO), PSO, and Artificial Fish Swarm Algorithm (AFSA) to observe their training performance on different datasets. The results are shown in Fig. 8.

TABLE I. BASIC PARAMETERS OF THE ACTION DATASET

Parameter type	Parameter scale
Traffic data	735000
Time stamp	6900min
Source IP Address and Destination IP Address	900
Protocol	4
Packet size	512bit
Packet Marking	5

Fig. 8. Comparison of MAWI and CAIDA data set.

Fig. 8 shows the trend curve of the accuracy of various algorithms in two datasets as a function of the amount of training rounds. From Fig. 8 (a), the CSA-FNN model performs best, with accuracy tending to converge after 300 iterations, while the other four models only converge after training 600 times. In Fig. 8 (b), the accuracy of all algorithm models decreases when using the CAIDA dataset. However, the convergence of CSA-FNN accuracy does not change much, and it tends to converge after 400 iterations, ultimately converging to around 94%. The above results demonstrate that CSA-FNN has advantages over the other four algorithms, such as fast convergence, high accuracy, high stability, and strong generalization ability.

B. NOSA Simulation Experiment

The comparative analysis of algorithms has successfully

verified the comparative advantages of CSA-FNN compared to other algorithm models, providing a solid theoretical foundation for its application in real computer network control systems. Although the superiority of the CSA has been verified, further simulation experiments are still necessary to evaluate the scalability, robustness, and stability of the algorithm. The experiment utilizes real traffic data from MAWILAB and obtains network traffic data through steps such as data cleaning and normalization [20]. Link utilization, IP packet rate, total number of IP packets, and TCP ratio are used as evaluation indicators. Link utilization refers to the degree to which network links are occupied by valid data. The IP packet rate and total number reflect the strength of network traffic. The TCP ratio represents the proportion of Transmission Control Protocol (TCP) packets to the total number of packets. Table II shows some data.

TABLE II. SOME NETWORK TRAFFIC DATA

Serial Number	Link Utilization	IP Packet Rate	Total Number of IP Packets	TCP Proportion
734	0.0113659	0.009562344	0.011231245	0.442123226
735	0.0132411	0.009878563	0.016324534	0.442661626
736	0.0114534	0.009758231	0.012313122	0.412336123
737	0.0164553	0.009431312	0.011229807	0.412286126
738	0.0174554	0.009341123	0.011123145	0.512326112
739	0.0142432	0.009234133	0.011212343	0.123146126
740	0.0111311	0.009124313	0.011224344	0.642666126
741	0.0141233	0.009413444	0.011224523	0.412312313
742	0.0143133	0.009512312	0.011253451	0.482626126
743	0.0143566	0.009413123	0.011231312	0.144567435
744	0.0163234	0.009434546	0.011212343	0.734341231
745	0.0178621	0.009223431	0.011213217	0.423123126
746	0.0115456	0.009254323	0.011221203	0.442231226
747	0.0112567	0.009256723	0.011231207	0.431234112

Normalizing the original data is helpful to eliminate the dimensional difference between features, improve the training effect and stability of the model, and improve the rate of convergence of the model. Then the normalized real network traffic data are used to verify the improved CSA-FNN structure. The simulation software used in the study is Pychar, and the simulation environment is Python 3.6. 1000 iterative training sessions are performed on CSA and CSA-FNN using the data

shown in Table II. The link weights of the normalization layer and the anti-fuzzification layer are randomly generated by a Gaussian function to circumvent the issue of gradient disappearance or explosion due to an excessive data volume of the model. Furthermore, the introduction of randomness serves to enhance the stability of the model's learning and optimization process. The results are displayed in Fig. 9.

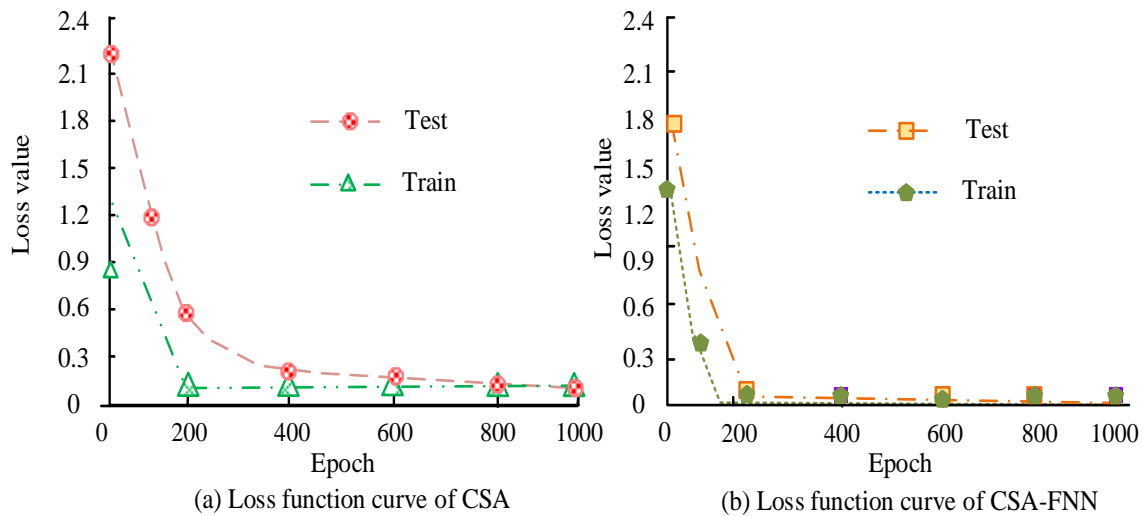

Fig. 9. Loss function curve of CSA and CSA-FNN.

In Fig. 9, the data gradient after the normalization operation is significantly reduced, and the stability of the model is significantly improved compared with the MAWI dataset, and the rate of convergence is accelerated. From Fig. 9(a), the CSA training set curve converges after about 200 iterations, while the test set converges after about 400 iterations. From Fig. 9(b) that during the first 120 iterations of the training set of the CSA-FNN model, the value of the Loss function rapidly decreases

from 1.5 to 0.35, a decrease of about 76.7%. In the 220th iteration of the test set, the Loss function value is basically 0. Comparing the two figures, it can be found that CSA-FNN has increased by about 81.2% compared to CSA. Finally, Capsa software is used to capture real-time data traffic in the current local area network for analysis, intercepting network data traffic information for two consecutive hours. The experimental results are exhibited in Fig. 10.

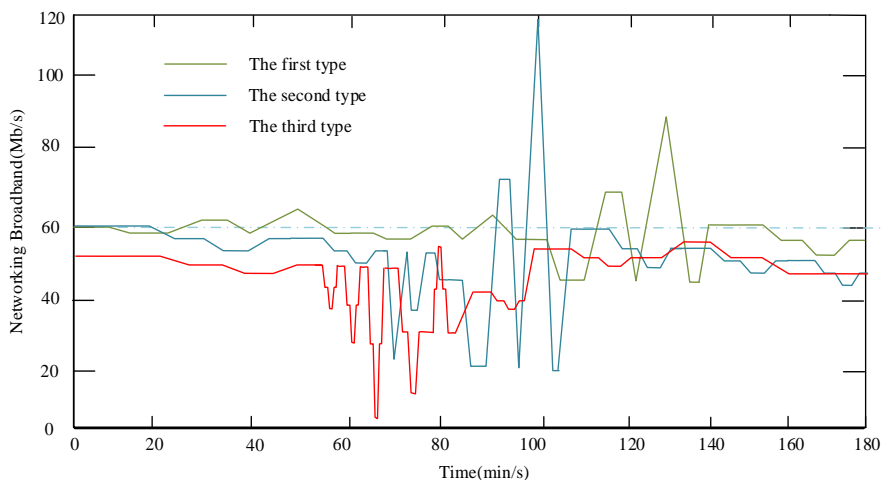

Fig. 10. Map of changes in network operational situational awareness.

Fig. 10 shows the changes in three types of NOSA. From the graph, the network bandwidth of the first type of network operation situation is mostly in a state of 40-60Mb/s, with occasional small fluctuations. This situation may be caused by accidental network changes. The second type of network operation situation is that the network is normal in the first 60 minutes, and severe fluctuations begin to occur in the first 60 minutes. The reason for this situation may be due to unstable factors in the local area network. The third type of network

operation situation curve shows that the network is normal in the first 50 minutes, and then the network quality rapidly decreases. This situation may be due to the sudden addition of new tasks and drastic fluctuations in the network. Compared with the actual data, the network awareness model can accurately predict the network situation, with an accuracy rate of 98%. In addition, the study also records the changes in perception accuracy of the CSA-FNN model in different network environments, as shown in Fig. 11.

Fig. 11. Changes in perception accuracy under different network environments.

Fig. 11 shows the temporal variation of perception accuracy of the CSA-FNN model in different types of network environments (LAN, MAN, WAN, and WLAN). In Fig. 11, with the increase of time, the accuracy of various network environments shows an upward trend, among which LAN and WLAN have higher accuracy, maintaining above 98% and 99% respectively, while MAN and WAN have relatively lower accuracy, but also exceeding 97%. This phenomenon may be due to the relatively simple network environment of LAN and WLAN, which are easy to predict and classify, while MAN and WAN, due to their complex network structure, may have more uncertain factors leading to slightly lower accuracy. In addition,

the fluctuation of each line type in the figure is relatively large, which may be caused by the dynamic changes in the network environment and the irregularity of the data flow. Overall, the CSA-FNN model can maintain high accuracy in various network environments, demonstrating its good adaptability and robustness. Finally, to verify the effectiveness of the algorithm in practical applications, the WSSD system proposed in study [21], the WEA-SA NSAM proposed in study [22], and the OWS-WOA model proposed in study [23] are introduced to compare with the CSA-FNN. The implementation phase comprises the deployment of infrastructure, the implementation of security controls, and the execution of security processes.

These include the installation of network and security hardware, the configuration of network devices and firewalls, the deployment of intrusion detection systems and SIEM systems, and the execution of key security processes such as security auditing, data backup and recovery, patch management, etc. The experimental results are shown in Table III.

TABLE III. COMPARISON BETWEEN CSA-FNN AND OTHER NETWORK SITUATIONAL AWARENESS SYSTEMS

Experimental Group	Detection Rate (%)	False Alarm Rate (%)	Response Time (ms)	Computing Resource Consumption (%)
CSA-FNN	94.2	2.5	35	12
WSSD	91.8	3.1	40	14
WEA-SA	93.0	2.8	38	13
OWS-WOA	92.5	3.0	42	15

According to the data in Table III, the CSA-FNN algorithm exhibits high performance in network situational awareness. Specifically, the detection rate of CSA-FNN reaches 94.2%, which is the highest among the four experimental groups, indicating that it can more accurately identify abnormal behaviors or threats in the network. Meanwhile, the false positive rate of CSA-FNN is 2.5%, which is also the lowest among the four experimental groups, indicating that it performs better in reducing unnecessary alarms and thus minimizing interference with normal network activity. In terms of response time, CSA-FNN is 35 milliseconds, faster than WSSD and WEA-SA, but slightly slower than OWS-WOA. However, a response time of 35 milliseconds is still very fast, which is already fast enough for real-time network situational awareness. In terms of computational resource consumption, CSA-FNN consumes 12% of resources, which is the lowest among all models, demonstrating its advantage in RUE. In contrast, OWS-WOA has the highest resource consumption, reaching 15%. Overall, CSA-FNN performs well in the three key indicators of detection rate, false positive rate, and computational resource consumption, especially in terms of detection rate and resource consumption, indicating that CSA-FNN is an efficient and accurate tool for network situational awareness.

V. CONCLUSION

To solve the problems of fuzziness, instability, large data volume, and difficulty in network situational awareness in network operation, this study designed a computer NSAM based on CSA and fuzzy logic fusion. The experiment used Python 3.8 on the Windows 10 platform and trained CSA and CSA-FNN using the CAIDA dataset. The results showed that the error of the proposed FNN structure rapidly decreased and converged at the 400th iteration. The error of the standard CSA only converged after 700 iterations, and the convergence rate increased by 75%. Then, the performance of CSA-FNN algorithm was evaluated through horizontal comparative experiments with algorithms such as WOA, ACO, PSO, AFSA, etc. The data showed that the accuracy of all algorithm models has decreased when using the CAIDA dataset. However, the accuracy convergence of the CSA-FNN model did not change much, and it tended to converge after 400 iterations, ultimately converging to around 94%. This proved that CSA-FNN had

advantages over the other four algorithms such as fast convergence, high accuracy, high stability, and strong generalization ability. Finally, simulation experiments were conducted using MAWILAB: During the first 120 iterations of CSA-FNN, the testing accuracy improved with the improvement of training accuracy, and the speed was very significant. During this period, the value of Loss function decreased rapidly from 1.5 to 0.35, with a decrease of about 76.7%. Therefore, this model has good practical application capabilities. However, the model still requires a considerable amount of training and a longer training time, which is also an area that can be further improved in future research. The performance of the proposed model is an important consideration when the network size and complexity increase. The scalability of the model is key to ensuring its effective operation in larger or more complex network environments. As the scale of the network expands, models may need to handle larger amounts of data. Therefore, optimizing the data processing flow and algorithm efficiency is necessary to maintain or improve the response speed and accuracy of the model. In addition, the system for monitoring and measuring network status needs to effectively utilize computing resources. In the future, the concept of RUE can be studied and implemented to ensure that the system is efficient in resource utilization, especially in situations where multiple resources are limited.

Application of Sanda-Assisted Teaching System Integrating VR Technology from a 5G Perspective

Zhaoquan Zhang*, Yong Ding

Police Command and Tactical College, Guangdong Police College, Guangzhou 510232, China

Abstract—Since the focus of Sanda teaching is to allow students to master martial arts techniques through confrontational exercises, Sanda teaching in colleges and universities commonly adopts contextualized teaching methods. However, this Sanda teaching method suffers from deficiencies such as poor teaching effectiveness and difficulty in reflecting the effectiveness of Sanda martial arts. In order to solve these problems and make up for the shortcomings of offline Sanda teaching, the study adopts the virtual reality technology and the fifth generation mobile communication technology to construct a Sanda-assisted teaching system for college students. In order to ascertain whether students complete the Sanda movement practice, the study has designed two models: a self-supervised model based on acceleration and angular velocity contrast learning and a multi-task semi-supervised model based on time-frequency contrast learning. These models aim to improve the analytical function of the Sanda-assisted teaching system and address the analytical deficiencies of the existing human movement identification algorithms. The results indicated that the maximum accuracy of the research-designed self-supervised model was 95.76% and 95.89% on the training and test sets, respectively. The multi-task semi-supervised model designed in the study plateaued after nearly 22 and 24 iterations on the training and test sets, respectively. The average response time of the research-designed system was 59ms, and the throughput could reach a maximum of 77651bit/s. The model and the research-designed system both worked well, and they can lower the risk of student injuries while offering technological support for Sanda-assisted teaching and learning in higher education institutions.

Keywords—VR technology; Sanda; teaching system; motion recognition; feature extraction

I. INTRODUCTION

Sanda, as an excellent traditional sport of the Chinese nation, contains valuable national spirit, reflects strong national traditional colors, and has strong vitality and epochal character. University Sanda teaching (UST) can promote the development of Sanda sport in the new era and make it glow with more beautiful colors [1-2]. Most colleges and institutions have embraced the contextual teaching style since it aligns with Sanda teaching's goal. However, this Sanda teaching method has shortcomings such as poor teaching effect and difficulty in reflecting the effectiveness of Sanda martial arts [3]. In order to solve this problem, constructing Sanda-assisted teaching system (SATS) becomes particularly important. Virtual reality (VR) has been progressively incorporated into the domains of education, healthcare, gaming, and entertainment with the advancement of computer technology [4]. Feng and other specialists created a model

based on the combination of VR technology and Web application design to increase students' enthusiasm to learn. They then used the model's data to teach physical education (PET). The findings demonstrated how well VR and PET work together to increase students' excitement for athletics and interest in studying [5]. Gao and other researchers designed a medical system based on remote VR technology to address the problem of medical informatization. The system contained two major functional sections, namely, consultation management and system management. Among them, the consultation management section included all remote business consultation processes, and the system management version involved managing medical resources and user data. The findings demonstrated significant time and cost savings in the areas of remote VR technology adoption, safety, and rehabilitation-improvements of 85%, 92%, and 96%, respectively [6]. To help architecture students learn more effectively, researchers like Elgewely created a VR platform for architectural details based on VR technology and building information modeling. Additionally, the platform was validated in three main areas, namely pilot, system usability and immersion and learning gains. The results showed that students' learning progress increased by 30% after experiencing the VR environment [7]. Experts such as Almousa designed a VR-based virtual clinical simulation system with Oculus Quest headset in order to promote global academic collaboration. In addition, the system was able to connect and communicate in real time with an instructor control panel application. The results showed that this virtual clinical simulation system was able to provide realistic clinical training in a virtual space simulating a hospital environment and promote academic collaboration [8].

In SATS, the most important thing is to judge whether the student has completed the exercise or not, and this requires the use of human motion recognition (HMR) algorithm model. Common HMR methods include traditional machine learning, such as K-nearest neighbor classification algorithms, self supervised learning (SSL) methods, semi supervised learning, and wearable device based methods [9-10]. To solve the problem that the existing HMR-based algorithms cannot fully explore the spatio-temporal properties of motion, Yangzhi and other researchers designed a HMR algorithm based on a spatio-temporal attention graph convolutional network model that integrates spatial and temporal attention mechanisms. The comparison results show that the algorithm designed in the study has improved the accuracy of Top-1 and Top-5 by 5.0% and 4.5%, respectively [11]. To increase the precision of video HMR and the computational effectiveness of large-scale datasets, Gao and other specialists created a motion capture

multidimensional data model and deep learning framework based video image motion recognition. In addition, the study also used Gaussian mixture model and gradient histogram. The outcomes indicated that the average value (AV) of the classification accuracy of the method was 85.79% and the maximum running speed was 20 frames per second [12]. To improve the accuracy of the rehabilitation robot on HMR and to reduce the recognition time, Chen and other researchers designed an improved sparrow search algorithm based on multiple strategies. According to the results, this upgraded algorithm's recognition accuracy was 2.835% higher than that of the original classifier, which should make it easier for the rehabilitation robot to understand the intention behind a person's movements [13]. Ye and colleagues developed an enhanced time-slotted video down sampling technique based on Gaussian model and proposed a human interaction recognition algorithm based on parallel multi-feature fusion network to identify human actions. Convolutional kernels with various scales were employed in the study to extract features. The findings demonstrate that the approach can identify six interaction acts with an accuracy of 88.9% [14].

In summary, the current studies on VR-based systems and HMR are relatively rich and use a variety of methods. However, these studies also have certain shortcomings, such as not fully considering the complexity and specificity of human motion sensing signals, and still facing the problems of underutilization of human motion sensing data and difficulty in feature extraction. Therefore, in an attempt to compensate for the shortcomings of Offline Sanda teaching (OST), the study designed a SATS based on VR and 5th generation mobile communication technology (5G), constructed self-supervised model with contrastive learning of acceleration and angular velocity (SSMCLAA) and semi-supervised multi-task model with time-frequency (TF) contrastive learning (SSMTFCL). The study aims to improve the speed and accuracy of HMR, accelerate the judgment of whether students complete Sanda exercises, reduce the probability of

student injuries, and improve the effectiveness of UST. The innovativeness of the study is that it combines 5G technology and VR technology to alleviate the problem of insufficient data labeling, and realize the consistency of TF characteristics of data and the improvement of HMR speed and accuracy.

There are five sections to the study overall. Section II is the design of the research methodology, which includes the construction of SATS based on 5G and VR technologies, the design of SSMCLAA model and SSMTFCL model. Section III is the performance validation of SATS, SSMCLAA model and SSMTFCL model. Discussion is given in Section IV. Section V is the conclusions, shortcomings and future prospects of the study.

II. METHODS AND MATERIALS

To address the problems of OST, the study designed SATS based on 5G and VR technologies, and designed the structure and functions of teaching system (TS). In order to realize the judgment of whether students complete the exercises in TS, the research adopts the HMR algorithm, and designs the corresponding recognition model for the problems existing in the current HMR, respectively.

A. SATS Design Based on 5G and VR Technologies

UST suffers from deficiencies such as poor teaching effectiveness, difficulty in reflecting the effectiveness of Sanda martial arts, and the frequency of accidental injuries or even serious permanent injuries to students. To compensate for the shortcomings of OST, the study adopted 5G and VR technologies. Since VR technology can simulate real-world situations in three dimensions, it has been included into college and university curricula. The majority of these institutions have started to create VR teaching laboratories [15]. 5G technology has ultra-high speed rate, which can quickly enjoy 360° panoramic VR and display more high-definition VR images [16]. The structure of SATS is shown in Fig. 1.

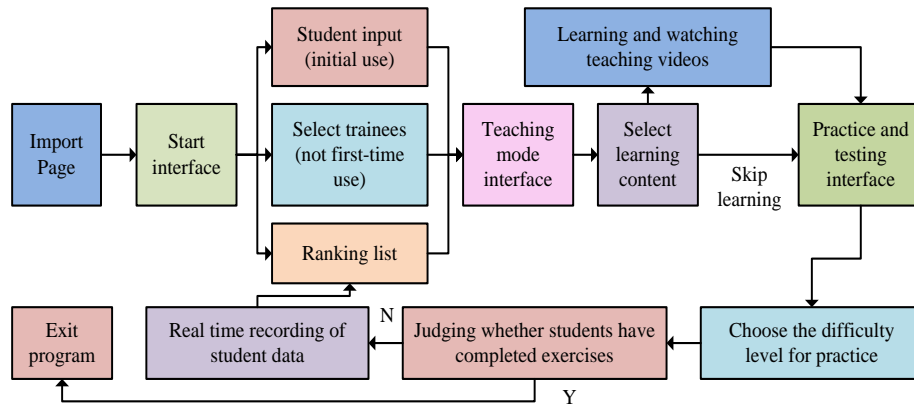

Fig. 1. The structure of sanda-assisted teaching system.

In Fig. 1, the structure of SATS involves import page, start interface, ranking list, student input (initial use), select trainees (not first-time use), teaching mode interface, select learning content, learning and watching teaching videos, skip learning, practice and testing interface, choose the difficulty level for practice, judging whether the difficulty level is too

high or too low level for practice, judging whether students have completed exercises, real time recording of student data, and exit program. SATS involves four main functions, which are action demonstration function, practice and test function, interaction function, and data analysis function. Among these, the action demonstration function requires 5G technology to

guarantee that students can view the video with clarity and fluidity without experiencing any latency. Both the practice and test function and the interaction function need to allow

students to follow the instructions on the VR interface to practice and get feedback from the system. The composition of the interaction function is shown in Fig. 2.

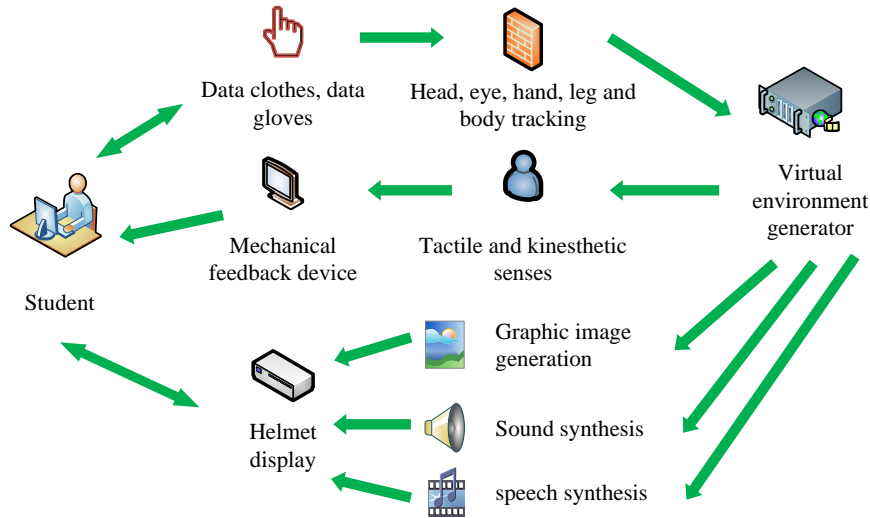

Fig. 2. Composition of interactive functions.

In Fig. 2, the interaction function requires the use of different wearable devices, a data suit, data gloves and a helmet display, as well as a mechanical feedback device. The camera in the helmet display is able to recognize the movement of the student's hand. The data suit and data gloves are able to track the student's head, eyes, hands, legs and body, and the mechanical feedback device mainly involves haptic and kinesthetic senses. The data analysis function is to collect the data changed in the VR scene through the data collection device in the background, and analyze and diagnose these data to determine whether the students have completed the exercise or not. In the parts that follow, the study's design will be thoroughly examined for the purpose of diagnosing these results.

B. Construction of the SSMCLAA Model

To make a judgment on whether a student has completed the exercise or not, the study uses the HMR algorithm. The human movement time series data collected using wearable sensing devices has a complex multidimensional spatial structure. To address the problems of complexity and variability of the collected data and the difficulty of feature extraction, the study designed the SSMCLAA model. SSL utilizes the input data itself as a supervisory signal and is beneficial for almost all types of downstream tasks [17]. Wearable sensing devices integrate various types of miniature sensing elements, such as accelerometers, gyroscopes, etc., which are capable of monitoring and tracking human activities in real time and continuously [18]. Therefore, the multidimensional time series data samples used in the study are composed of 3D acceleration data and 3D angular velocity data. The SSMCLAA model adopts the SSL framework, and its specific structure is shown in Fig. 3.

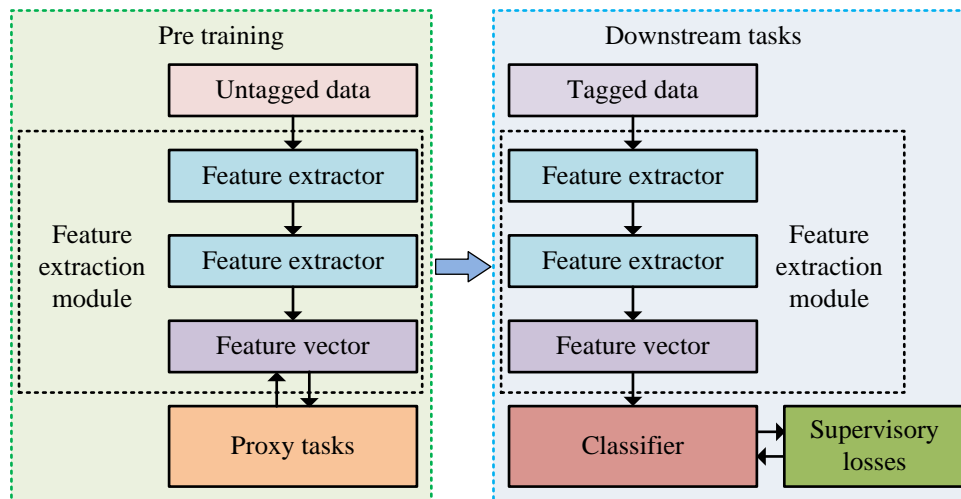

Fig. 3. The specific structure of the SSMCLAA model.

In Fig. 3, the SSL framework contains two main parts, which are pre-training and downstream tasks. Among them, the pre-training part contains unlabeled data (ULD), feature extraction module (FEM), and agent task, where FEM is divided into feature extractor (FE) + eigenvector. In order to carry out the agent task in the pre-training part, the study adopts the contrast learning technique. This technique is a common way to improve the model representation. The downstream task part contains labeled data (LD), FE trained in the pre-training part, eigenvector, classifier and supervised

loss. Since the FE in the pre-training part only learns the feature representation of the data, the downstream task part needs to connect the FE trained in the pre-training part with the classifier, and then supervise the training with a small amount of LD to achieve action classification. In order to fully extract the acceleration and angular velocity features of the students when learning Sanda, the study constructs two independent FEs at the feature extraction module, and both of them use the deep residual network structure. In Fig. 4, the FEs' structure is displayed.

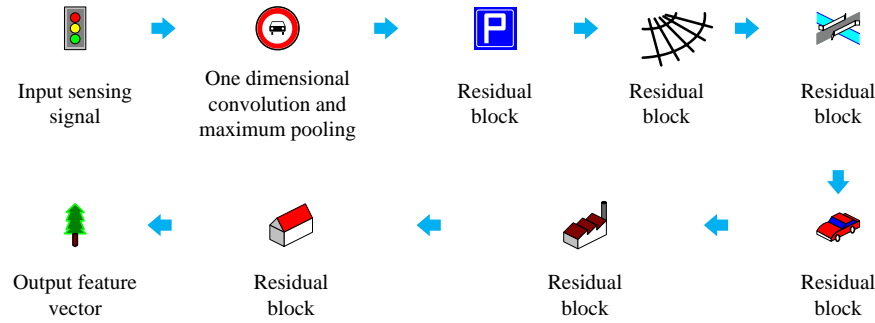

Fig. 4. The structure of a feature extractor.

In Fig. 4, the first step of the FE is the input sensing signal, i.e., the acceleration or angular velocity of the student while performing Sanda learning. The second step is a one-dimensional convolution and maximum pooling operation; after which it goes through six residual blocks. The combination of these six residual blocks together forms a deep residual network. The residual block is mainly composed of three consecutive one-dimensional convolutional layers and an activation function ReLU, and then the output and input of the convolution operation are directly added to solve the problem of gradient vanishing during the training process of deep neural networks, and to enable deep neural networks to learn deeper feature representations. The third step is the output eigenvector. The residual block mainly contains three 1D convolutional layers and ReLU activation function. The purpose of contrast learning pre-training is to enhance the FE representation. The commonly used formulaic definition of contrast learning is shown in Eq. (1) [19].

$$\max_{f_1, f_2} \sum_{i=1}^N \left\{ s(z_1(w_{i1}), z_2(w_{i2})) - \sum_{j=1, j \neq i}^N \left[s(z_1(w_{i1}), z_1(w_{j1})) + s(z_1(w_{i1}), z_2(w_{j2})) \right] \right\} \quad (1)$$

In Eq. (1), f_1 and f_2 represent different FEs, respectively. i and j are both ordinal numbers, and N is the total features. w_i and w_j represent different random samples, z_1 and z_2 are the projected heads of the upper and lower branches (ULB), respectively. $z_1(w_{i1})$ and $z_2(w_{i2})$ represent the features of the ULB of w_i , respectively, and both are set as positive samples. $z_1(w_{j1})$ and $z_2(w_{j2})$ are the features of the ULB of w_j , respectively, and are set as negative samples. s is the metric. The structure of the contrast learning pre-training is shown in Fig. 5.

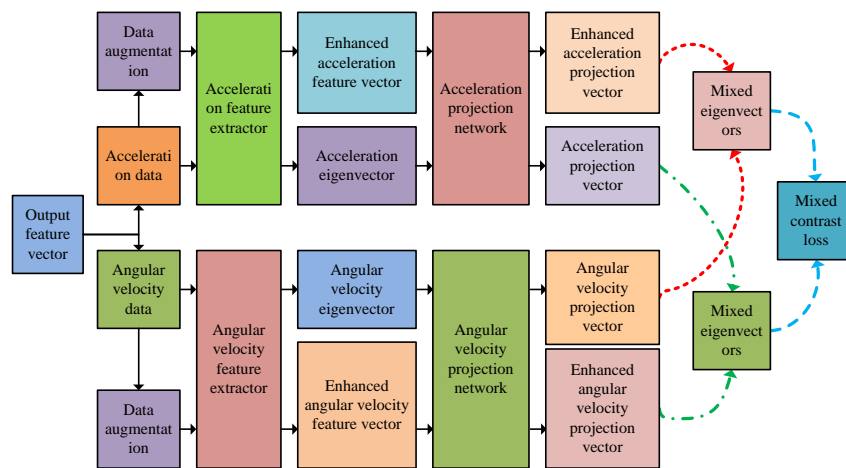

Fig. 5. Comparative learning pre training structure.

In Fig. 5, the contrast learning pre-training structure is mainly divided into the upper and lower halves. Among them, the upper half is the acceleration contrast learning process and the lower half is the angular velocity contrast learning process. In order to facilitate the subsequent unsupervised contrast learning, the study enhances both raw data. The study adds a projection network and obtains a new projection eigenvector in an effort to enhance the impact of FE even more. The acceleration contrast learning loss L_b is shown in Eq. (2).

$$L_b = -\sum_{i \in I} \log \frac{\exp(\text{sim}(z_i^b, z_i^{zb}) / \chi)}{\sum_{h \in H(i)} \exp(\text{sim}(z_i^b, z_h^b) / \chi)} \quad (2)$$

In Eq. (2), I represents the set of acceleration data after data augmentation, and $H(i)$ denotes the subscripts of the rest of the sample data except for the serial number i . χ is the parameter, z_i^b and z_i^{zb} are the corresponding projected eigenvector before and after the acceleration data enhancement, respectively. z_h^b is the projected eigenvector corresponding to the acceleration data other than the serial number i . $\text{sim}(z_i^b, z_i^{zb})$ is the cosine similarity, which is solved as shown in Eq. (3) [20].

$$\text{sim}(z_i^b, z_i^{zb}) = \frac{(z_i^b)^T \cdot z_i^{zb}}{\|z_i^b\| \|z_i^{zb}\|} \quad (3)$$

The expression for $H(i)$ is shown in Eq. (4).

$$H(i) = I \setminus \{i\} \quad (4)$$

The angular velocity comparison learning loss L_g is shown in Eq. (5).

$$L_g = -\sum_{i \in I} \log \frac{\exp(\text{sim}(z_i^g, z_i^{zg}) / \chi)}{\sum_{h \in H(i)} \exp(\text{sim}(z_i^g, z_h^g) / \chi)} \quad (5)$$

In Eq. (5), z_i^g and z_i^{zg} are the projected eigenvectors corresponding to the angular velocity data before and after enhancement, respectively. z_h^g is the projected eigenvector corresponding to the angular velocity data other than the ordinal number i . The hybrid contrast loss function (LF) L_{bg} is shown in Eq. (6).

$$L_{bg} = -\sum_{i \in I} \log \frac{\exp(\text{sim}(z_i^{bg}, z_i^{zbg}) / \chi)}{\sum_{h \in H(i)} \exp(\text{sim}(z_i^{bg}, z_h^{bg}) / \chi)} \quad (6)$$

In Eq. (6), z_i^{bg} and z_i^{zbg} represent the hybrid eigenvector corresponding to the data before and after data enhancement, respectively. z_h^{bg} is the hybrid eigenvector corresponding to the data other than the ordinal number i . The solution of z_i^{bg} and z_i^{zbg} is shown in Eq. (7).

$$\begin{cases} z_i^{bg} = z_i^b \oplus z_i^g \\ z_i^{zbg} = z_i^b \oplus z_i^{zg} \end{cases} \quad (7)$$

The total LF L_{sum} for the pre-training phase of contrast learning is shown in Eq. (8).

$$L_{sum} = L_b + L_g + \beta L_{bg} \quad (8)$$

In Eq. (8), β represents the parameter. The downstream task of the SSMCLAA model is to classify students' Sanda practice movements. In the downstream task, a simple two-layer linear mapping network and activation function are used for the classifier structure, and the cross-entropy loss function (CELf) L_{out} is used for the LF, as shown in Eq. (9) [21].

$$L_{out} = \frac{1}{m} \sum_{i, w_i \in G^d} \sum_{t=1}^T k_{it} \log(\hat{k}_{it}) \quad (9)$$

In Eq. (9), k_{it} and \hat{k}_{it} represent the actual and predicted distribution probabilities, respectively. m is the size of the randomly selected data subset G^d . t and T are the action category ordinal number and total number.

C. Construction of the SSMTFCL Model

To make a judgment on whether a student has completed the Sanda exercise, research designed the HMR model of SSMCLAA to solve the problems of complex and variable collected data and the difficulty of feature extraction. However, the SSMCLAA model is unable to learn the common feature space structure of LD and ULD at the same time. In addition, human motion sensing signals are not only fluctuating and periodic, but also have multimodal characteristics such as time and frequency-domains (FDs) [22]. However, the current HMR only considers unilateral information in the time or frequency domain during feature extraction, ignoring the consistent relationship between time and frequency of human action sensing data, as well as the study of multi-task framework [23-24]. Based on these problems, in order to better judge whether students complete the Sanda exercise, the study also designed the SSMTFCL model and arranged it together with the SSMCLAA model in SATS to judge whether students complete the Sanda exercise. Fig. 6 depicts the SSMTFCL model's structure.

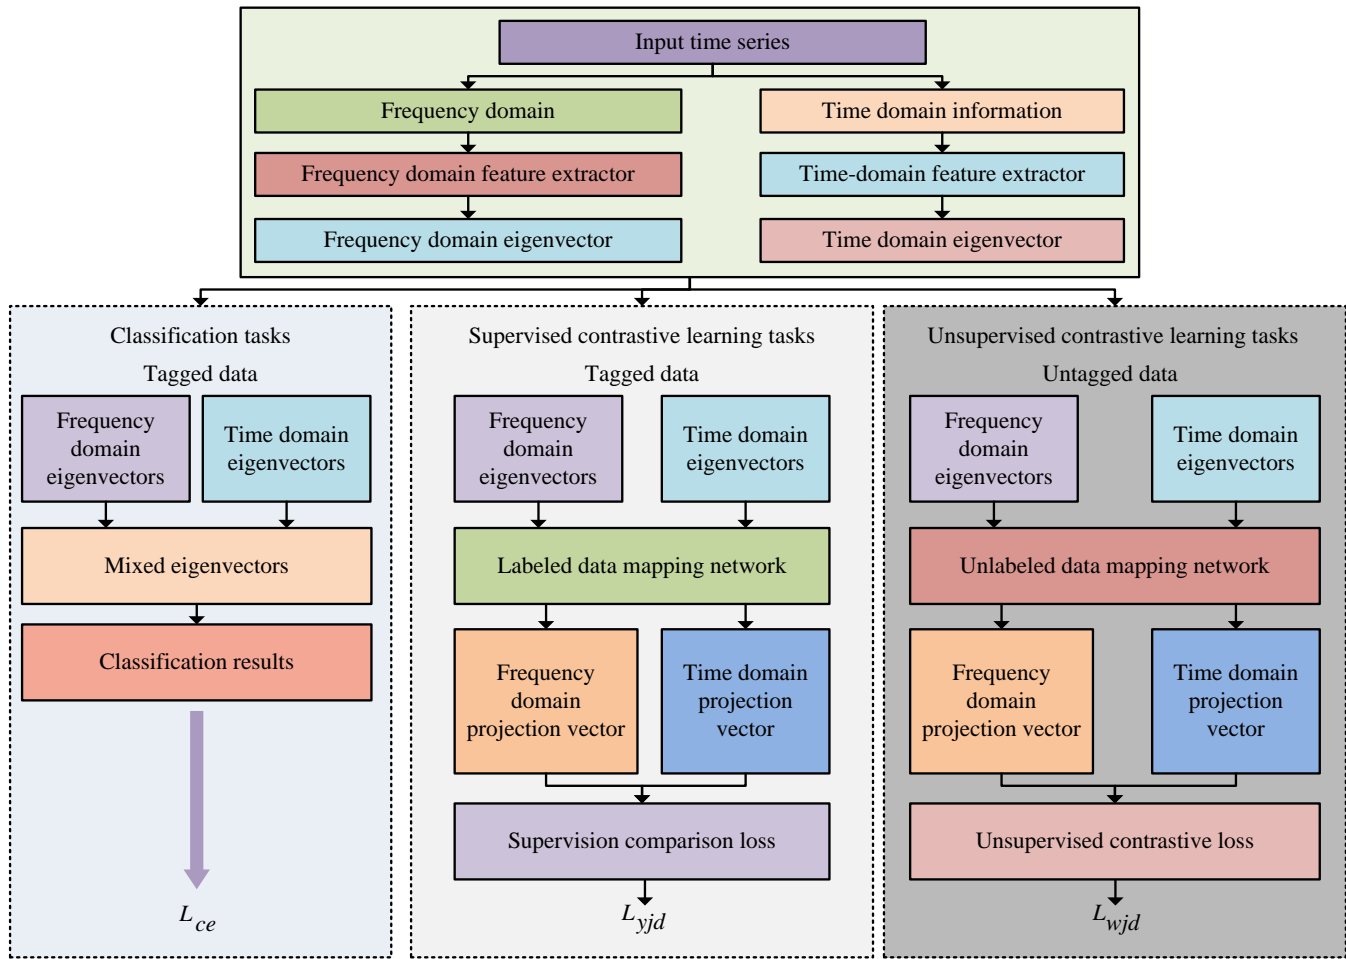

Fig. 6. The structure of SSMTFCL model.

In Fig. 6, the first step of the SSMTFCL model is to input the time series, and the second step is to obtain the FD information x_i' and the time-domain (TD) information x_i . The third step is to input x_i' and x_i into the FD FE V_F and the TD FE V_Q respectively. The fourth step is to output the corresponding FD eigenvector y_i' and the TD eigenvector y_i . The fifth step is to carry out the three tasks in the respective modules, i.e., classification task (CT), supervised contrast learning task and unsupervised contrast learning task, and output the CELF L_{ce} , supervised contrast learning LF L_{yjd} and unsupervised contrast learning LF L_{wjd} . In the CT, in order to maximize the consistency between the frequency domain and the TD of the samples, the study directly compares the TD projection vectors and the FD projection vectors of the data. To obtain the FD information, the study used Fourier transform. The Fourier transform has the advantage of good frequency localization and clearly shows the frequency components contained in the signal [25-26]. The process of Fourier transform is shown in Eq. (10) [27].

$$F(\omega) = \frac{1}{\sqrt{2\pi}} \int f(t)e^{i\omega t} dt \quad (10)$$

In Eq. (10), $f(t)$ represents a non-periodic function and $F(\omega)$ is the representation of the $f(t)$ function in the FD. $e^{i\omega t}$ is a complex exponential function and ω represents the angular frequency. The CELF L_{ce} for the CT is the same as the CELF L_{out} used in the downstream task of the SSMCLAA model, with only a slight difference in the values taken. The expression of L_{ce} is shown in Eq. (11).

$$L_{out} = \frac{1}{m} \sum_{i, x_i \in G^d} \sum_{t=1}^T k_{it} \log(\hat{k}_{it}) \quad (11)$$

To capture deeper TF information, the study constructed two independent FEs to extract the human action eigenvector from TD information and FD information, respectively. The TF feature extraction module is shown in Fig. 7.

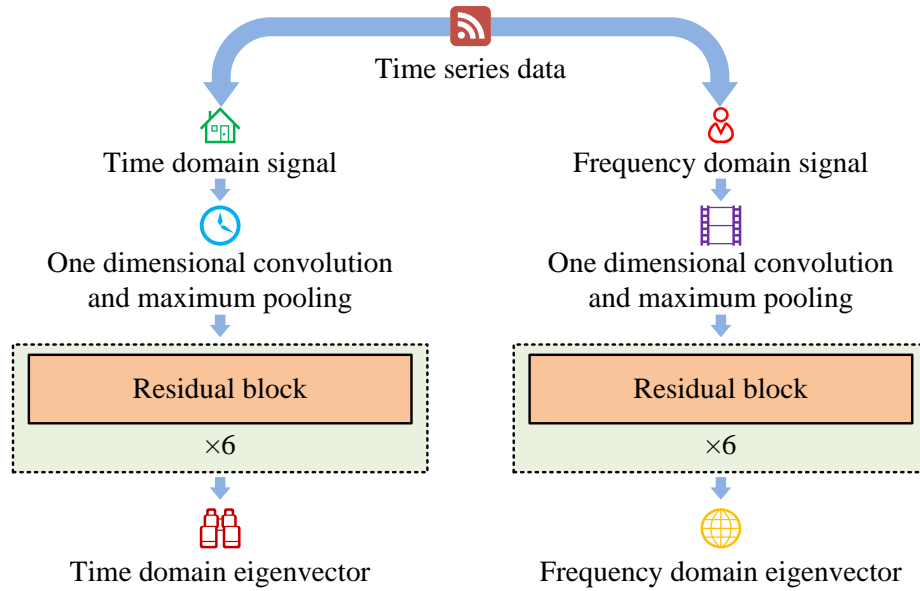

Fig. 7. Time-frequency feature extraction module.

In Fig. 7, the TF feature extraction module mainly consists of a TD signal FE and a FD signal FE. Both signal FEs involve one-dimensional convolution, maximum pooling, six residual block structure and eigenvector output. Both labeled and ULD are subjected to the same feature extraction method, and their respective obtained TF eigenvectors are used in subsequent multi-task learning modules. The supervised comparison learning task and the unsupervised comparison learning task in the SSMTFCL model are mainly used to mine the internal features of ULD and LD, and the supervised comparison learning task takes into account the data labeling information when calculating the loss. The unsupervised comparison LF L_{wjd} is shown in Eq. (12).

$$L_{wjd} = -\sum_{i \in R} \log \frac{\exp(\text{sim}(u_i^v, u_i^w) / \chi)}{\sum_{h \in H(i)} \exp(\text{sim}(u_i^v, u_h^w) / \chi)} \quad (12)$$

In Eq. (12), R is the set of TD eigenvector and FD eigenvector, and u_i^v and u_i^w denote the TD projection vectors and FD projection vectors of ULD, respectively. u_h^w is the TD projection vector corresponding to the ULD other than the ordinal number i . Minimization of unsupervised contrast loss can improve the model's representational ability. The study uses an unsupervised contrast learning task to learn the features of ULD, and also uses supervised contrast learning to perform deep mining of the deep structural features of LD. The study trains two contrast learning tasks in parallel to learn the feature space on the full data. The LF L_{sjd} for supervised contrast is shown in Eq. (13).

$$L_{sjd} = -\sum_{i \in R} \frac{1}{|K(i)|} \sum_{k \in K(i)} \log \frac{\exp(\text{sim}(u_i, u_i') / \chi)}{\sum_{h \in H(i)} \exp(\text{sim}(u_i, u_h) / \chi)} \quad (13)$$

In Eq. (13), $K(i)$ represents the set of sample data of the same category as sample x_i . u_i and u_i' represent the TD projection vector and FD projection vector of the LD, respectively. u_h is the TD projection vector corresponding to the LD other than the serial number i . u_i and u_i' are solved as shown in Eq. (14).

$$\begin{cases} u_i = G_c(y_i) \\ u_i' = G_c(y_i') \end{cases} \quad (14)$$

In Eq. (14), G_c represents the LD projection network. In order to allow the feature encoder to learn the intrinsic structure of the LD more deeply, the study minimizes the supervised comparison loss as well. In order to achieve overall consistency of data features, the study adopts a multi-task learning framework. The study co-trained the three tasks of the model so that they jointly participate in the optimization of the TF feature encoder. Eq. (15) displays the SSMTFCL model's total LF.

$$L_{SSMTFCL} = L_{ce} + \theta L_{sjd} + \varphi L_{wjd} \quad (15)$$

In Eq. (15), both θ and φ are scaling parameters.

III. RESULTS

To validate the performance of the research design SATS and the corresponding student action recognition classification model, the study sets up the experimental environment, experimental parameters and experimental dataset. In addition, the study also describes the comparison model and comparison system. The model comparison mainly involves accuracy, error and time consumption, while the system comparison mainly involves memory occupation, throughput and response time.

A. SSMCLAA Model Performance Validation

To validate the performance of the SSMCLAA model, the study uses the UCI-HAR dataset [28]. Since the length of the time series data is not uniform, the study uses a sliding window mechanism to segment the raw data, and the number of samples after processing is 6400. The study divides the dataset into a training set and a test set with a division ratio of 7: 3. The ratio of LD to ULD in the training set is 1: 9. The β parameter of the SSMCLAA model is set to 1, and the learning rates for the pre-training and downstream task phases are $1e-5$ and $1e-3$, respectively. Other SSL methods selected

for comparison in the study are semi-supervised time model (SemiTime), self-supervised of human activity recognition (SelfHAR) and simple framework for contrastive learning of representations (SimCLR). The operating system used for the experiments is Windows 11 (64-bit), and the processor is Intel Core i5-12600 K with a maximum RWI of 4.9 GHz, a maximum accelerated power consumption of 130 W, and a maximum RAM of 128 GB. Fig. 8 compares the accuracy of the various models in the training and test sets.

Fig. 8. Comparison of accuracy between different models on training and testing sets.

In Fig. 8(a), the maximum value (MaxV) of the accuracy of the research design SSMCLAA model is 95.76% and the minimum value (MinV) is 93.81% on the training set. The MaxVs of accuracy of SemiTime model, SelfHAR model and SimCLR model are 80.50%, 87.42% and 93.03%, respectively, and the MainVs are 77.64%, 83.89% and 90.71%, respectively. The accuracy of SSMCLAA model is significantly higher than the comparison models. In Fig. 8(b), on the test set, the MaxV of accuracy is appeared on SSMCLAA model with a value of 95.89%. The MainV of

accuracy is appeared on SemiTime model with a value of 76.75%. The mean values of accuracy for SelfHAR model and SimCLR model are 86.13% and 91.24% respectively. The SelfHAR and SimCLR models outperformed the SemiTime model. In summary, the research design SSMCLAA model has a higher action recognition accuracy and is able to better recognize and classify students' Sanda actions in order to determine whether the students have completed Sanda training or not. Comparison of mean absolute error (MAE) and mean squared error (MSE) of different models are shown in Table I.

TABLE I. COMPARISON OF MAE AND MSE OF DIFFERENT MODELS

Model	MAE					MSE				
	Number of experiments					Number of experiments				
	1	2	3	4	5	1	2	3	4	5
SemiTime	1.21	1.37	1.19	1.32	1.28	1.31	1.29	1.38	1.42	1.46
SelfHAR	1.03	0.97	1.13	0.95	1.05	1.16	1.21	1.25	1.09	1.18
SimCLR	0.95	1.06	0.98	1.01	0.94	1.07	1.12	1.05	0.99	1.14
SSMCLAA	0.74	0.62	0.67	0.58	0.69	0.64	0.51	0.68	0.73	0.66

In Table I, the maximum and MainVs of MAE for the SSMCLAA model of the research design are 0.74 and 0.58, respectively. As a whole, the MAE values of the SSMCLAA model are significantly lower than those of the comparison models. The MaxVs of MAE for SemiTime model, SelfHAR model and SimCLR model are 1.37, 1.13 and 1.06, respectively, and the MainVs are 1.19, 0.97 and 0.94, respectively. In addition, the MainV of MSE occurs on the SSMCLAA model with a value of 0.51. The MaxV occurs on the SemiTime model with a value of 1.29. The mean values of

MSE for the SemiTime model, SelfHAR model, SimCLR model and SSMCLAA model are 1.372, 1.178, 1.074 and 0.644, respectively. In summary, the values of MAE and MSE for the research-designed SSMCLAA model are significantly smaller than those of the comparison models, which suggests that the SSMCLAA model has a smaller classification error. This suggests that the SSMCLAA model can determine whether or not students have finished the Sanda training with a lower classification error. The time-consuming comparison of different models is shown in Fig. 9.

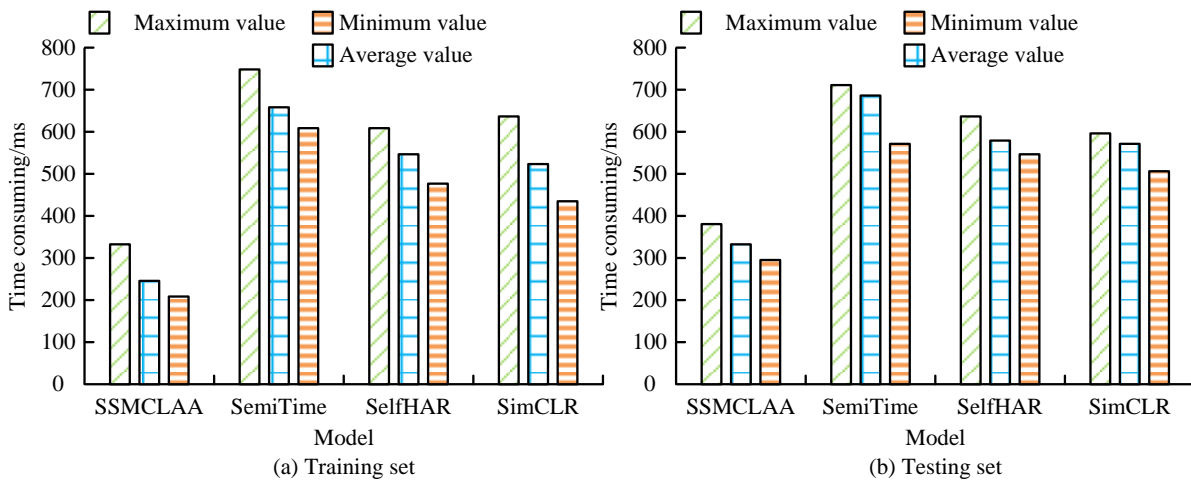

Fig. 9. Comparison of time consumption of different models.

In Fig. 9(a), on the training set, the time-consuming mean of the research design SSMCLAA model is 242 ms, and the time-consuming mean of the comparison models SemiTime, SelfHAR, and SimCLR are 670 ms, 543 ms, and 521 ms, respectively. The time-consuming mean of the SSMCLAA model is less than that of the comparison models, which are 328 ms, 201 ms, and 179 ms. The SSMCLAA model has a greater advantage in time. In Fig. 9(b), on the test set, the time-consuming AV of the SSMCLAA model is 337 ms, which is significantly lower than that of the comparison model. In conclusion, the research designed SSMCLAA model has less time consuming and can make a judgment on whether the students complete the Sanda training in a shorter period of time and reduce the waiting time of the students.

B. SSMTFCL Model Performance Validation

The dataset used in the study, the method the dataset is partitioned, and the experimental setup are all consistent with the SSMCLAA model performance validation, which is necessary to validate the SSMTFCL model's performance. The values of θ and φ in the LF of the SSMTFCL model are both 1.0, and the iterations of the model is 300. In addition, four classical semi-supervised algorithm models are selected for comparative validation of the research models, the double- Π model (Π -model), the MeanTeacher model, the multi task learning model (MTL), and the MixMatch model that combines Mixup and Fixmatch. Comparison of LF curves for different models is shown in Fig. 10.

Fig. 10. Comparison of LF curves for different models.

In Fig. 10(a), on the training set, the research design SSMTFCL model plateaus after almost 22 iterations, while the Π -model, MeanTeacher, MTL, and MixMatch models plateau after 57, 52, 48, and 43 iterations, respectively. The MainVs of loss values for the five models are 0.17, 0.33, 0.25, 0.23, and 0.21, respectively. In Fig. 10(b), on the test set, the MainV of loss values for the SSMTFCL model is 0.15, and the MainVs of loss values for the comparison models Π -model,

MeanTeacher, MTL, and MixMatch are 0.36, 0.27, 0.24, and 0.22, respectively. The five models leveled off after nearly 24, 59, 54, 47, and 45 iterations, respectively. In summary, the research designed SSMTFCL model converges faster and has better performance with smaller loss values. A comparison of the accuracy and receiver operation characteristic, (ROC) curves for the different models is shown in Fig. 11.

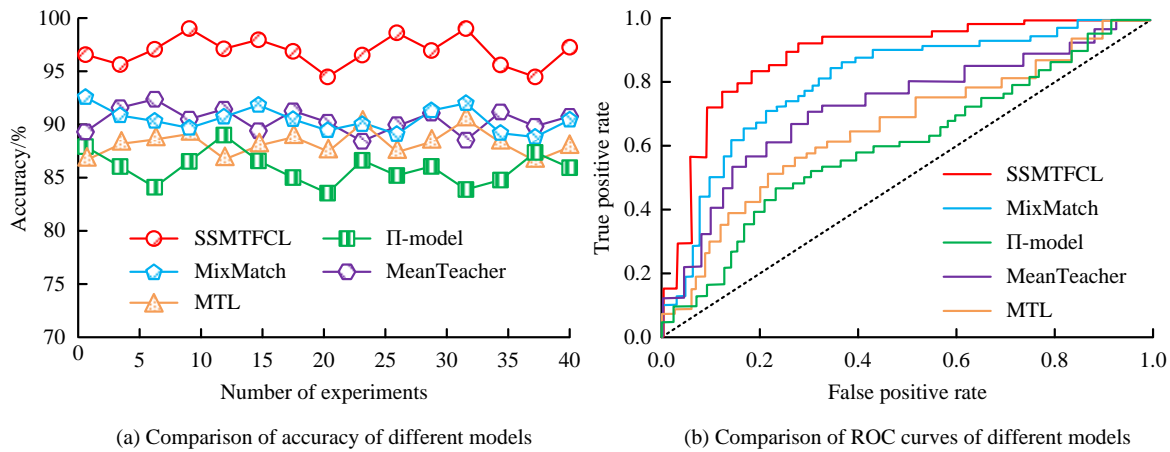

Fig. 11. Comparison of accuracy and ROC curves of different models.

In Fig. 11(a), the MaxV of accuracy of the research design SSMTFCL model is 97.58%, the MainV is 94.21%, and the AV is 96.64%. The mean values of accuracy for the comparison models Π -model, MeanTeacher, MTL and MixMatch are 86.17%, 89.42%, 87.55% and 90.73% respectively. The accuracy of SSMTFCL model is significantly higher than the comparison model. In Fig. 11(b), the area under the ROC curve of the research design SSMTFCL model is the largest with a value of 0.945. It is followed by the MixMatch and MeanTeacher models with values of 0.899 and 0.857, respectively. The smallest are the

MTL and Π -model models with values of 0.821 and 0.798, respectively. In summary, the research design SSMTFCL model has higher accuracy and better performance. To verify the effectiveness of the three tasks in the SSMTFCL model, the study conducted ablation experiments. L_{ce} is the LF for the CT, and L_{yjd} and L_{wjd} are the LFs for the supervised comparison learning task and the unsupervised comparison learning task, respectively. Fig. 12 displays the ablation experiment's outcomes.

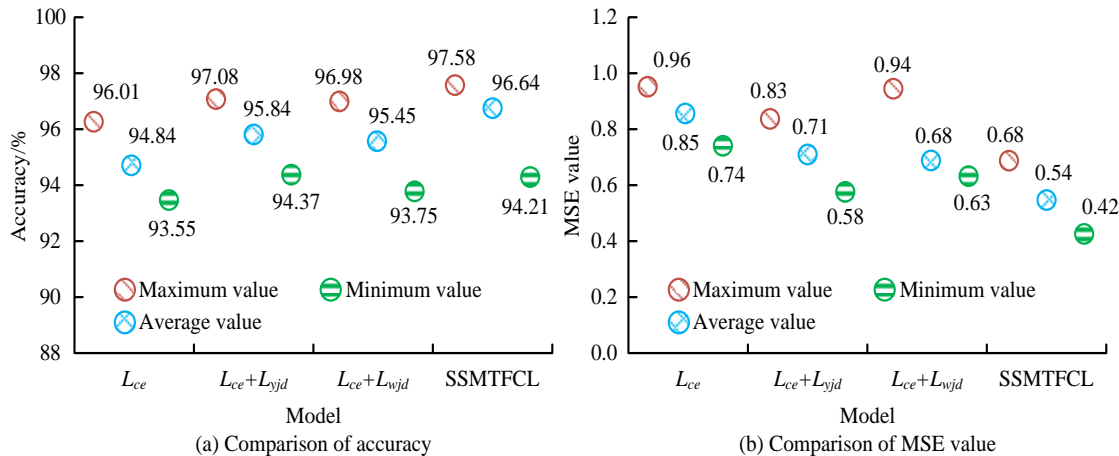

Fig. 12. Results of SSMTFCL model ablation experiment.

In Fig. 12(a), the accuracy mean of the model using only the CT is 94.84%, which is 1.8% lower than the accuracy mean of the full SSMTFCL model of 96.64%. The average accuracy of the model using the CT and the supervised comparative learning task is 95.84%, while the average accuracy of the model using the CT and the unsupervised comparative learning task is 95.45%. In Fig. 12(b), the MSE mean values of the model using only the CT, the model using the CT and the supervised contrast learning task, and the model using the CT and the unsupervised contrast learning task are 0.85, 0.71, and 0.68, respectively. The MSE mean value of the full SSMTFCL model is 0.54. In conclusion, the multi-task learning framework used in the study is effective.

C. SATS Performance Validation

To validate the performance of the research design SATS based on 5G and VR technologies, the study selected other TSs for comparison. Among them, there are psychological virtual simulation experiment TS designed by experts such as D. Chen, PET aid network system designed by scholars such as Li, and piano playing TS designed by researchers such as Liu [29-31]. In addition, the experimental environment configurations used for system performance validation are consistent with those used for SSMCLAA model performance validation. A comparison of the central processing unit (CPU) utilization and memory occupancy of the different systems is shown in Fig. 13.

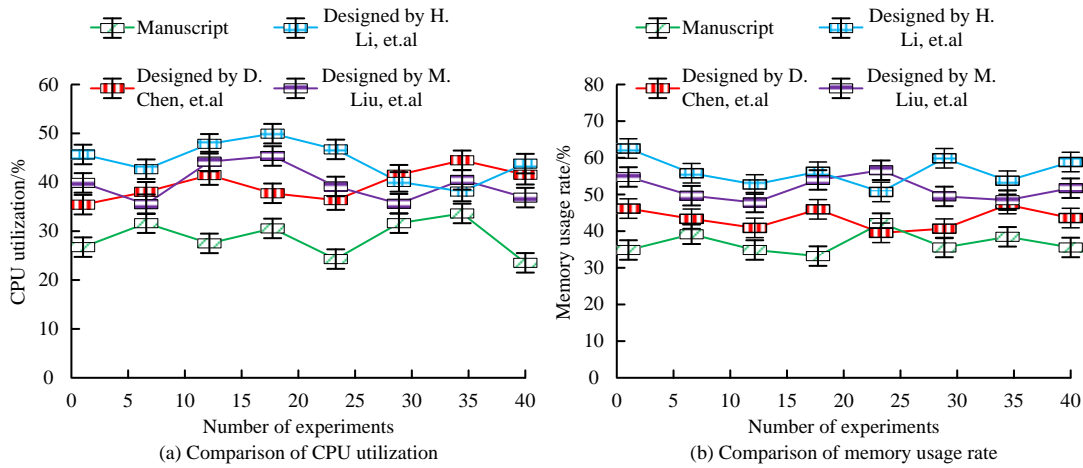

Fig. 13. Comparison of CPU utilization and memory usage rate in different systems.

In Fig. 13(a), the average CPU utilization of the research design SATS is 27.8%, and the average CPU utilization of the psychological virtual simulation experiment TS, the PET aid network system, and the piano playing TS are 37.8%, 42.8%, and 39.7%, respectively. The CPU utilization of the research design SATS is significantly smaller than the comparison system. In Fig. 13(b), in terms of memory occupancy, the AV

of memory occupancy of the research design system is 38%, and the AVs of memory occupancy of the other three comparison models are 43%, 57%, and 52%, which are 5%, 19%, and 14% higher than those of the research design system, respectively. In conclusion, the research design SATS has better performance. The response time and throughput comparisons of the different systems are shown in Table II.

TABLE II. COMPARISON OF RESPONSE TIME AND THROUGHPUT OF DIFFERENT SYSTEMS

System	Response Time/ms					Throughput/(bit/s)				
	Number of experiments					Number of experiments				
	1	2	3	4	5	1	2	3	4	5
Designed by D. Chen, et.al	136	143	132	158	132	63142	64498	65506	68504	63187
Designed by H. Li, et.al	145	162	157	140	142	60988	60543	61279	63885	64771
Designed by M. Liu, et.al	121	137	128	136	134	64312	67329	68634	66032	61062
Manuscript	63	57	61	55	59	74521	76282	75113	76895	77651

In Table II, in terms of response time, the AV of the research design system is 59 ms, and the AVs of the psychological virtual simulation experiment TS, the PET aid network system, and the piano playing TS are 140.2 ms, 149.2 ms, and 131.2 ms, respectively. The response time of the research design system is significantly lower than the comparison system. In addition, the throughput of the research design system can reach a maximum of 77651 bit/s and a minimum of 74521 bit/s. The MaxVs of the throughput of the psychological virtual simulation experiment TS, the PET aid network system, and the piano playing TS are 68504 bit/s, 64771 bit/s, and 68634 bit/s, respectively, and the MainVs are 63142 bit/s, 60543 bit/s and 61062 bit/s. In conclusion, the research design SATS has shorter response time, larger system throughput and better performance.

IV. DISCUSSION

In response to the shortcomings of offline Sanda teaching, this paper designs the SSMCLAA model and SSMTFCL model, and based on this, constructs a Sanda auxiliary teaching system that integrates 5G and VR technology. The results showed that the average memory usage of the Sanda assisted teaching system designed in the paper was 38%,

which was 5%, 19%, and 14% lower than the average memory usage of the other three compared systems, respectively. The average response time is 59ms, which is 81.2ms, 90.2ms, and 72.2ms lower than the average response time of the other three compared systems, respectively. The paper design of a Sanda auxiliary teaching system can improve the effectiveness of Sanda teaching. Liu X et al. designed a decision support system to evaluate the functionality of 5G networks and artificial intelligence in higher education context teaching research in order to achieve teaching objectives. The results show that 5G networks and artificial intelligence algorithms can enhance the effectiveness of situational teaching in higher education [32]. This result is similar to the research findings.

V. CONCLUSION

To make up for the shortcomings of OST, the study constructs SATS based on 5G and VR technologies, and constructs SSMCLAA model and SSMTFCL model. The results revealed that the maximum accuracy of SSMCLAA model was 95.76% on the training set. The MaxVs of accuracy of the comparison models SemiTime, SelfHAR and SimCLR were 80.50%, 87.42% and 93.03%, which were 15.26%, 8.34% and 2.73% lower than the MaxVs of accuracy

of the SSMCLAA model, respectively. The MainVs of MAE and MSE for the SSMCLAA model were 0.58 and 0.51, respectively, and the mean values of time consumed for the training and test sets were 242ms and 337ms, respectively. The SSMCLAA model performed relatively well. On the training set, the SSMTFCL, Π -model, MeanTeacher, MTL, and MixMatch models plateaued after almost 22, 57, 52, 48, and 43 iterations, respectively, with minimum loss values of 0.17, 0.33, 0.25, 0.23, and 0.21, respectively. The AVs of accuracy for the five models were 96.64%, 86.17%, 89.42%, 87.55% and 90.73%. The SSMTFCL model performs better. The AV of CPU utilization for the research design SATS was 27.8%, the AV of memory occupancy was 38%, the AV of response time was 59 ms, and the maximum and MainVs of throughput were 77,651 bit/s and 74,521 bit/s, respectively.

The research design SATS has good performance. The study also has some shortcomings. One, the test of SATS on students in terms of Sanda is limited to the technical level, and future research can include a theoretical question-answering session to enhance students' theoretical knowledge base and further avoid students' injuries. Secondly, the helmet used in the study and other types of sensing devices can cause discomfort to some students after prolonged use, and future research can do in-depth exploration on the comfort of wearable devices. Thirdly, the Sanda auxiliary teaching system still lacks human-machine training, game mode, and competition mode. Future research can compensate for this module to further enrich the Sanda auxiliary teaching system. Fourthly, for the data collected by different data collection devices, future research can simply annotate their location information to improve the recognition efficiency of students' Sanda movements. Fifthly, some students are prone to multiple compound movements due to non-standard movements during Sanda practice, which increases the difficulty of judging Sanda movements. Future research can further improve and optimize the model for recognizing composite actions.

Abstract—Wireless sensor networks are an important technical form of the underlying network of the Internet of Things. The energy of each node in the network is finite. When a node runs out of energy, it can cause network interruptions, which can affect the reliability of data collection. To reduce the consumption of communication resources and ensure the reliability of data collection, the study proposes data collection based on data compression perception positioning technology. This method first uses a Bayesian compression perception method to select nodes, and then adopts an adaptive sparse strategy to collect data. When selecting nodes using this proposed method, wireless sensor networks had the longest network lifespan. In the case of different degrees of redundancy and sparsity, the research method had the lowest reconstruction error, with reconstruction errors of 0.31 and 0.40, respectively. When the balance factor was set to 0.6, the reconstruction error of the research method was the lowest, with a minimum reconstruction error of 0.05. This proposed method has better reconstruction performance, effectively prolongs the lifespan of wireless sensor networks, and reduces the consumption of communication resources.

Keywords—Wireless sensor network; data collection; compression perception technology; Sparse Bayesian Learning; signal reconstruction

I. INTRODUCTION

The development and application of the Internet of Things (IoT) have brought great convenience to people's lives. IoT can connect any object in the physical world with the Internet to achieve real-time monitoring, intelligent control, remote operation and other functions, so as to achieve interconnection between things and people [1-2]. Wireless Sensor Network (WSN) is a key technological component of IoT. Since its inception, WSN has been a hot topic in information research and has been applied to various aspects of society, such as military, agriculture, industry, healthcare, intelligent transportation, and home furnishings [3-4]. However, the energy of nodes in WSN is limited. When energy is depleted, the network will be interrupted, affecting the lifespan of WSN [5]. In addition, there are still issues with anomalies and missing data collected by current wireless sensor network data collection methods, which can result in significant consumption of communication resources. Studying data collection methods can improve the performance of wireless sensor networks, making them more widely applicable in fields such as healthcare, military, and environmental monitoring. Then, compression perception perfectly reconstructs the signal

through nonlinear reconstruction algorithms [6]. Therefore, to reduce the consumption of communication resources and ensure the reliability of data collection, the study proposes data collection based on data compression perception positioning technology.

When using data compression perception positioning technology for data collection, the innovative approach is to first use Bayesian compression perception for node selection. Furthermore, an adaptive sparse strategy was adopted for data collection in the experiment. The main contribution of this study is the proposal of data collection based on data compression perception positioning technology, which reduces the energy consumption of WSN and improves the reliability of data collection.

The study will investigate data collection methods based on data compression perception positioning technology from four aspects. Firstly, a review is conducted on the current research status of data collection methods based on data perception and localization technology in the context of artificial intelligence IoT. Next is the research on data collection methods based on data compression perception positioning technology. Then, experimental verification is conducted on the proposed method. Finally, a summary of the research content is provided.

II. RELATED WORKS

With the continuous development of IoT, the network scale is getting larger and the network environment is becoming more and more complex. This poses significant challenges to energy conservation, transmission efficiency, security, and other aspects of network communication. Compression perception helps to address these issues in intelligent network communication [7-8]. Wang Y et al. proposed a lightweight method based on deep learning to reduce the computational cost of traditional deep learning methods. The sparsity of the scaling factor was enforced through compression perception. This proposed method effectively reduced the model size and accelerated the calculation speed [9]. Cheng G et al. proposed a hyper chaotic image encryption scheme based on quantum genetic algorithm and compression perception. This eliminated the drawbacks of weak key flow, small key space, and small information entropy in chaotic image encryption schemes. This proposed method was more efficient in resisting statistical attacks and plaintext attacks [10]. Liang P et al. proposed a compression perception technique to address the overwhelming

*Corresponding Author

feedback overhead caused by a large number of antennas in base stations. Secondly, a deep learning-based signal recovery solver framework was used on the base station. This proposed method was superior to existing methods and reduced feedback overhead [11]. The remote sensing image size was relatively large in the new type of hyper chaotic system. Nan S et al. proposed a block compression encryption algorithm that combined a novel hyper chaotic system with block compression perception. This proposed algorithm had good encryption performance, reconstruction accuracy, and anti-attack ability [12]. Xu G et al. proposed a sparse synthetic aperture radar imaging technique based on compression perception and machine learning. This solved the limitation of data bandwidth on the resolution of synthetic aperture radar images. This proposed method further investigated sparse imaging in machine learning and improved image resolution [13].

Data collection is a fundamental and important operation in WSN applications [14]. Aziz A et al. proposed an efficient aggregation scheme for multi-hop clusters based on hybrid compression perception, which effectively combined compression perception and routing protocols to collect data. This reduced the energy consumption of sensor nodes and extended the WSN lifespan. This proposed method was more efficient in collecting data and prolonged the WSN lifespan [15]. Sekar K et al. proposed a data collection method based on compression perception. Random singular value decomposition was used in this experiment to achieve compressed matrix factorization. This reduced the amount of data collected and lowers communication costs. This proposed method had higher accuracy at lower sampling rates, reduced data transmission costs, and extended the lifespan of sensors [16]. Mei Y et al. proposed a sampling algorithm based on compression perception to sample conditioned signal data. This changed the design paradigm of low latency large-scale access requiring random access schemes. This proposed algorithm reduced data sample loss when data samples were transmitted wirelessly and could be used for wind turbine fault detection [17]. Lin C et al. proposed a hierarchical data collection scheme to improve the linear programming effect in agricultural detection and reduce energy consumption in data collection. Data sampling was carried out using precise and greedy methods using mixed compression. This proposed method effectively collected data and planned the path of drones with lower energy consumption [18]. Chang CY et al. proposed a mobile receiver for multi-rate data acquisition to improve receiver speed and obtain fresh data. This proposed method significantly shortened the path length of mobile receivers and collected data comprehensively and efficiently [19].

In summary, with the continuous development of the Internet of Things, wireless sensor networks are being applied in more fields. In the process of collecting data, many scholars and scientists have designed a large number of improved models based on compressed sensing to solve the problem of complex network environments and noise interference leading to shortened lifespan of wireless sensor networks. These

models effectively reduce the amount of data collected, but ignore the impact of sensor nodes themselves on wireless sensor networks. Therefore, the study proposes data collection and sensor node selection based on compressive sensing positioning technology.

III. DATA COLLECTION METHOD BASED ON DATA COMPRESSION PERCEPTION TECHNOLOGY

A. Data Collection Method Based on Adaptive Sparse Strategy

Bayesian compression perception is a method that combines Bayesian theory and compression perception to solve signal reconstruction problems. Considering the prior distribution of the signal, Bayesian compression perception can more accurately estimate the original signal and adaptively match the signal sparsity. The main advantage is that it can better handle noise and uncertainty [20-21]. IoT and artificial intelligence technology are constantly evolving. Artificial intelligence IoT has been applied in smart homes, intelligent transportation, intelligent healthcare, and other fields, bringing great convenience to humanity. As the sensing terminal of IoT, WSN mainly consists of three parts, including nodes, sensor networks, and users. Each node in the network needs to reserve energy for long-term use. Energy depletion can cause network interruptions [22-23]. In addition, sensor networks suffer from noise interference, data anomalies, and missing issues, which affect the reliability of data collection. To reduce the consumption of communication resources and ensure the reliability of data collection, the study adopts an adaptive sparse strategy for data collection. The position of the model sensor nodes is fixed, the composition structure is the same, and the energy is sufficient. Fig. 1 shows the WSN structure.

Sparse Bayesian learning is a method for reconstructing sparse signals, which does not require setting regularization parameters. It first considers the observation of a vector and outputs the sample y affected by noise interference, expressed as Eq. (1).

$$y = \Phi\omega + \varepsilon \quad (1)$$

In Eq. (1), ε refers to the observation noise. $\Phi\omega$ refers to the mean. Φ refers to the observation matrix. ω refers to the weights used by model learning to construct each column in Φ . The purpose of Sparse Bayes is to improve the model's generalization ability, interpretability, and efficiency by introducing sparsity, that is, selecting only a few important features. The Gaussian likelihood function model is represented by Eq. (2).

$$p(y | \omega, \sigma^2) = (2\pi\sigma^2)^{-N/2} \exp\left\{-\frac{1}{2\sigma^2} \|y - \Phi\omega\|_2^2\right\} \quad (2)$$

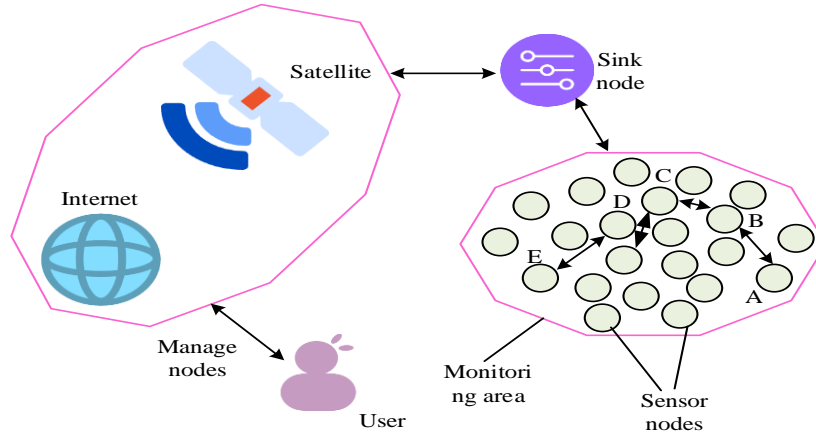

Fig. 1. Wireless sensor network architecture diagram.

In Eq. (2), y refers to the target variable, σ^2 refers to the variance, and N refers to the matrix of the sample. In this case, the task of obtaining maximum likelihood estimation is equivalent to finding the minimum norm solution while obtaining non-sparse solutions. Therefore, to find sparse solutions, the sparse Bayesian learning model estimates parameterized prior weights from the data, represented by Eq. (3).

$$p(\omega; \gamma) = \prod_{i=1}^M (2\pi\gamma_i)^{-\frac{1}{2}} \exp\left(-\frac{\omega_i^2}{2\pi\gamma_i}\right) \quad (3)$$

In Eq. (3), γ represents M hyperparameter vectors. Secondly, Bayesian inference is performed. A posterior distribution is applied to all unknown variables to obtain the mean and covariance of the weight parameters. Finally, the hyperparameters are updated and estimated using Eq. (4).

$$(\sigma^2)^{new} = \frac{\|y - \Phi u\|_2^2}{N - \sum_i \gamma_i} \quad (4)$$

In Eq. (4), u represents the posterior mean. In order to solve the problem of excessive energy consumption caused by ineffective estimation in noisy environments, a compressed sensing adaptive sparse strategy was adopted to collect data. The steps are as follows: first, the sampling rate for data collection is determined to generate sampling random weights. Next, determine whether the data collection is initiated by a node. If the data collection is initiated by a node, then collect perception data and use the compressed perception adaptive sparse algorithm in the data sorting center to compress the original data. The data collection is complete. On the contrary, if there is no initiating node for data collection, it is determined whether the child node data has been received. If the child node data is received, the perception data is collected, and the compressed perception adaptive sparse algorithm is used in the data sorting center to compress the original data, and the data collection is completed. If no child node data is received, data collection ends. The data collection process is shown in Fig. 2.

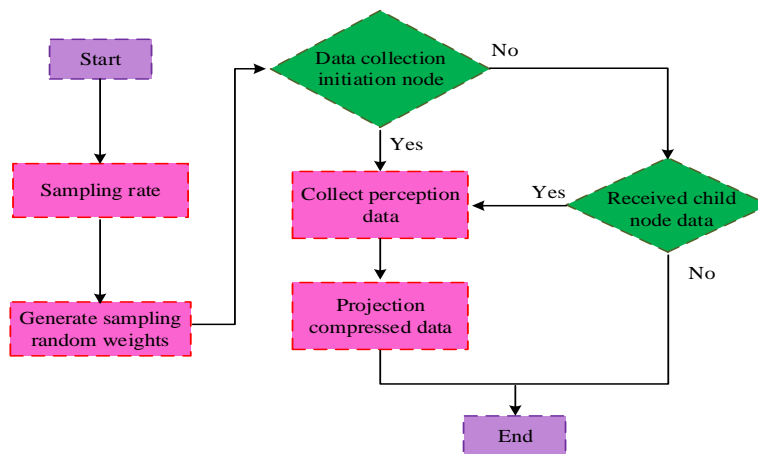

Fig. 2. Data collection flowchart.

The study adopts an adaptive sparse strategy based on compression perception for data collection. The data collection model is represented by Eq. (5).

$$f = BRx + v \tag{5}$$

In Eq. (5), f represents the observed signal. B refers to a random beta effort matrix. R is a sparse routing matrix. v represents the noise interference of the model. In data collection, there may be insufficient sparsity of the original signal. To obtain suitable sparse bases, the perception data are learned. The optimization process is represented by Eq. (6).

$$\min_{\Psi} \|X - \Psi S\|_F^2 \text{ s.t. } \forall i, \|S_i\| \leq K \tag{6}$$

In Eq. (6), Ψ refers to the sparse basis in the model that needs to be optimized. K refers to the sparsity of optimizing sparse bases. S refers to a sparse vector matrix. $\|\bullet\|_F$ refers to the Frobenius norm of a matrix. If only one sparse basis is optimized, the constraint isometry condition needs to be satisfied. If not, multiple measurements need to be taken. Therefore, low coherence is used to compensate for the deficiency. Then, optimization and update are carried out through covariance, represented by Eq. (7).

$$\min_{\Psi} \left\| \left(\Psi^T \Phi^T V \Phi \Psi + A \right) \right\|_F^2 + \eta \left\| \Psi^T \Phi^T V \Phi \Psi - I \right\|_F^2 \tag{7}$$

In Eq. (7), η refers to the equilibrium factor in the model. A refers to the variance matrix of sparse signals. V refers to the inverse matrix of noise variance. $\left\| \Psi^T \Phi^T V \Phi \Psi - I \right\|_F^2$ refers to meeting low coherence. In a successfully deployed WSN, there is a significant amount of

redundancy in the perception data collected from sensor nodes due to temporal and spatial correlations. Compression perception is a commonly used data collection technique. Therefore, the study adopts compression perception for data collection. The compression perception performance will improve with the increase of sample size, but the sparsity of sample data is uncertain. Fig. 3 shows a designed data collection framework to continuously update node sparsity.

B. Node Selection Based on Bayesian Compression Perception

The study adopts a method based on Bayesian compression perception adaptive sparsity to collect data. This can reduce the consumption of communication resources and ensure the reliability of data collection. However, this method ignores the performance differences of the nodes themselves. The WSN nodes produced by each company have different characteristics depending on the selected core processor, radio frequency communication chip, and expansion function. The sensor node mainly consists of four parts: sensing unit, processing unit, wireless transceiver unit, and power supply unit [24]. The differences in nodes can lead to a shortened network lifecycle. In this regard, the study adopts a method based on Bayesian compression perception to select nodes. Fig. 4 shows the composition of sensor nodes.

The research on data collection in WSN has been ongoing for many years and has achieved significant research results. However, sensor nodes still face issues such as imbalanced energy consumption, ineffective correlation measurement between nodes, and inability to perform effective spatial clustering. Therefore, when selecting sensor nodes, the study simplifies WSN. Because each sensor node is different, the sink node is affected by noise during the data collection process. Therefore, the model update is represented by Eq. (8).

$$g = \Phi x + a \tag{8}$$

Fig. 3. Data collection framework diagram.

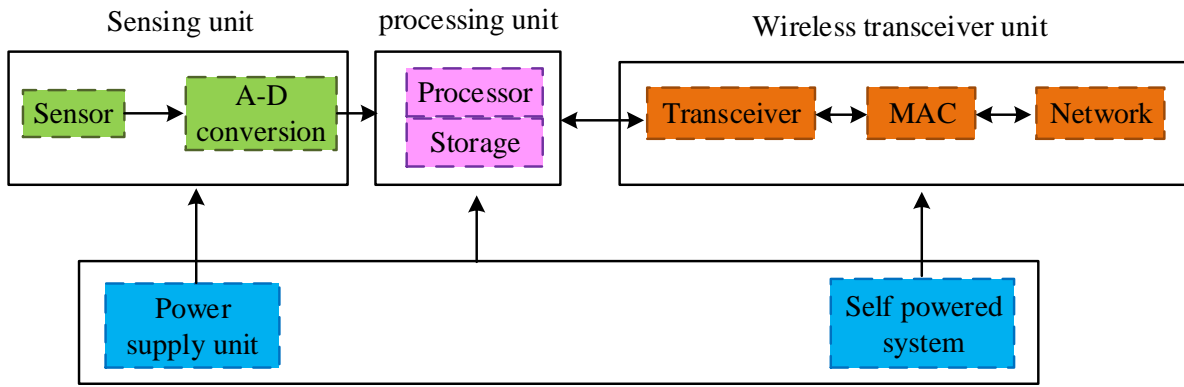

Fig. 4. Composition structure of sensor nodes.

In Eq. (8), a represents the noise vector measured by the model, x represents the data collected by each node, and g represents the measurement data. The model collects raw data without sparsity. Therefore, by utilizing the spatiotemporal correlation of data to transform the original data, sparse data can be obtained. The sparsity of the original data is represented by equation (9).

$$x = \Psi s = \sum_{i=1}^N \psi_i \cdot s_i \quad (9)$$

In Eq. (9), s refers to a sparse signal. x refers to raw data. Ψ refers to the sparse basis in the model that needs to be optimized. To better reconstruct the obtained data, assuming that the information of sparse basis and measurement matrix is known, Bayesian algorithm is used to reconstruct the measurement data. The posterior expectation of sparse signal is represented by equation (10).

$$\mu = \sum \Theta^T V^{-1} y \quad (10)$$

In Eq. (10), μ refers to the posterior expectation of the sparse signal. V refers to the inverse matrix of noise variance.

Θ refers to the perception matrix. The posterior covariance of sparse signals is represented by Eq. (11).

$$\Sigma = (\Theta^T V^{-1} \Theta + A)^{-1} \quad (11)$$

In Eq. (11), Σ refers to the posterior covariance of the sparse signal. A refers to the variance matrix of sparse signals. Θ refers to a perception matrix. In the framework of compression perception, selecting appropriate active sensor nodes is crucial for ensuring reconstruction performance when the data collection quality of each node is different. Bayesian compression perception utilizes prior knowledge to improve reconstruction performance, especially when there are differences in node quality. The node selection steps are as follows: first, all sensor nodes in the wireless sensor network obtain data sources and transmit them to the sink node through node selection. The sampled data is compressed, perceived, and reconstructed at the sink node. Then, the node selection is optimized based on the reconstruction information. Finally, the sink node distributes the optimized node selection information to various sensor nodes in the network through control signals, iteratively until the conditions are met. The architecture diagram for node selection is shown in Fig. 5.

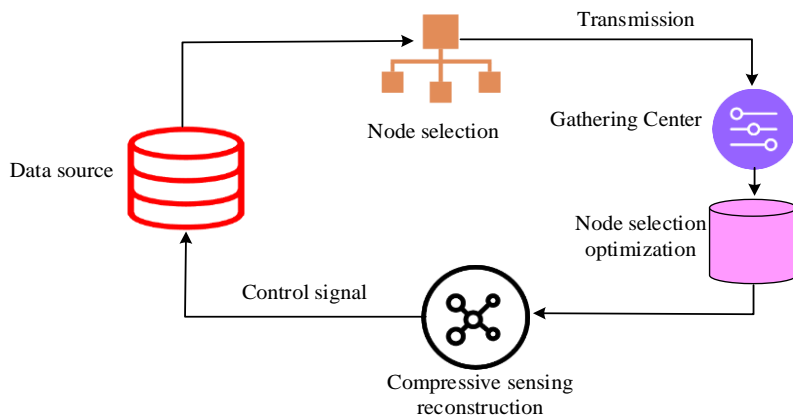

Fig. 5. Node selection framework diagram.

Assuming that the sink node provides complete information for hyperparameters and rewrites the mean and covariance, the observation matrix is an important parameter that affects the reconstruction effect. The reconstruction effect can be controlled by selecting different nodes. Mean square error is a commonly used indicator in machine learning to evaluate the model quality. It reflects the predicted and true values' error. This study uses mean square error to determine the reconstruction error, which is represented by Eq. (12).

$$MSE = \frac{\|\hat{x} - x\|_2^2}{\|x\|_2^2} \quad (12)$$

In Eq. (12), x represents the raw data. \hat{x} represents the reconstructed original signal. The WSN lifecycle generally refers to the energy consumption of a node or a specific area of nodes. In order to extend the lifecycle of WSN, it is necessary to reduce the computational complexity. The average network lifetime is represented by Eq. (13).

$$E(L) = \frac{\xi_0 - E(E_u)}{P_c + \rho E(E_t)} \quad (13)$$

In Eq. (13), P_c refers to constant continuous power consumption. ρ refers to the average rate of reporting data. ξ_0 refers to the starting total energy. $E(E_t)$ refers to the average transmission energy consumption of sensors.

$E(E_u)$ refers to the average idle energy during network downtime. The energy limitation of the node itself is represented by Eq. (14).

$$H_{i,i} = \frac{\varepsilon_i}{\mathcal{G}_i} \quad (14)$$

In Eq. (14), ε_i represents the energy stored by a node. \mathcal{G}_i represents the energy consumed by a node when transmitting information. The energy consumption of sending data packets from each node to the sink node is represented by Eq. (15).

$$E_{\delta_1}^i = E^e \delta_1 + \bar{E}_{\delta_1} \delta_1 \hat{r}^\gamma \quad (15)$$

In Eq. (15), δ_1 refers to the length of the data packet. \bar{E}_{δ_1} refers to the energy consumption required to achieve the target signal strength. E^e refers to the energy related to the receiving radio wave device. γ refers to the loss in the process of information dissemination. \hat{r} refers to the distance between nodes. To select active nodes, first, sink node sampling is performed. Then, Bayesian compression perception reconstruction is performed. Finally, it is determined whether the energy consumption of the node exceeds the limit. If exceeding this limit, the node selection is redone. If not exceeding this limit, the reconstructed original data are output. Fig. 6 shows the node selection process.

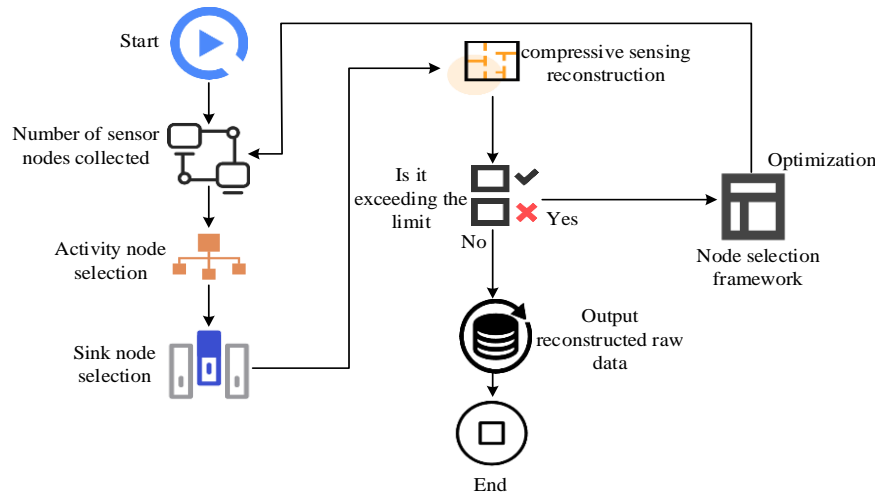

Fig. 6. Node selection flowchart.

IV. EFFECTIVENESS ANALYSIS OF DATA COLLECTION METHODS BASED ON DATA PERCEPTION AND POSITIONING TECHNOLOGY

A. Experimental Parameter Setting and Efficiency Analysis

To verify the effectiveness of the adaptive sparse strategy and node selection strategy, analysis was conducted on a simulation platform. Set a square network monitoring area with

a side length of $L=10$, and divide the monitoring area into 100 cells on average. Randomly deploy a sensor node in each cell, for a total of 100 sensor nodes. Deploy the sink node at the center position (5, 5) of the monitoring area, with an initial observation frequency of $M=50$. The length of the data packet is set to 20 bytes, the bandwidth is 2M/S, and the sparsity is 16. The simulation parameters and experimental environment settings are shown in Table I.

In the case of different sparsity, the reconstruction error of the adaptive sparsity strategy used in this study was compared with the reconstruction error of other methods. The balance factor was set to 0.6. Fig. 7 shows the statistical results. The reconstruction error decreased with increasing sparsity. The research method had the lowest reconstruction error. When the sparsity was 25, the reconstruction error curve tends to stabilize, and the minimum reconstruction error was 0.05. The reconstruction error of the overcomplete dictionary design method for sparse representation was slightly greater than that

of the method used in the study. When the sparsity was 30, the reconstruction error curve tends to stabilize, and the minimum reconstruction error was 0.06. The wavelet transform method's reconstruction error was the largest. When the sparsity was 30, the reconstruction error curve tended to stabilize, and the minimum reconstruction error was 0.49. The reconstruction error of the discrete cosine transform method was slightly smaller than the wavelet transform method's. When the sparsity was 35, the reconstruction error curve tended to stabilize, and the minimum reconstruction error was 0.42.

TABLE I. SAMPLE PARAMETER SETTINGS

Adaptive sparse strategy		Node selection		Experimental environment	
Parameters	value	Parameters	value	Project	Environment
Number of sensor nodes	100	Sparsity	16	CPU	11th Gen Intel(R) Core(TM) i7-11800H @ 2.30GHz
Sink point location	(5,5)	Sink node sampling number	50	GPU	NVIDIA GeForce RTX 3070 Laptop GPU
Monitoring area	10*10	Sink point location	(5,5)	Memory	16GB
Bandwidth	2M/S	Number of sensor nodes	100	Video Memory	8GB
Packet length	20bytes	/	/	Operating system	Windows 10
Observation frequency	50	/	/	/	/

Fig. 7. Reconstruction performance of four sparse bases.

The reconstruction error of node selection based on Bayesian compression perception was compared with the reconstruction error of other methods under different degrees of redundancy and sparsity. Fig. 8 shows the statistical results. In Fig. 8(a), the reconstruction error increased with the increasing redundancy. The research method had the lowest reconstruction error and the maximum reconstruction error was 0.31. The orthogonal matching tracking algorithm had the highest reconstruction error, with a maximum reconstruction error of 0.96. The reconstruction error of the error backpropagation algorithm was slightly lower than that of the orthogonal matching tracking algorithm's, with a maximum reconstruction error of 0.93. The reconstruction error of Jeffrey's prior algorithm was

higher than the research method's, with a maximum reconstruction error of 0.61. In Fig. 8(b), the reconstruction error increased with the increase of sparsity. The research method had the lowest reconstruction error and the maximum reconstruction error is 0.40. The orthogonal matching tracking algorithm had the highest reconstruction error, with a maximum reconstruction error of 0.98. The reconstruction error of the error backpropagation algorithm was slightly lower than that of the orthogonal matching tracking algorithm, with a maximum reconstruction error of 0.96. The Jeffrey's prior algorithm had higher reconstruction error than the research method, with a maximum reconstruction error of 0.82.

B. Quality Analysis of Data Collection Methods based on Data Perception and Positioning Technology

IoT signals are often affected by other noises during transmission, but this research does not consider noise interference in sensor networks. The reconstruction performance of the research adaptive sparse strategy was compared with other methods under different sampling quantities in Fig. 9. When the samples quantity reached 70, the reconstruction performance of different algorithms was basically the same in the two routing scenarios. The reconstruction performance decreased with increasing

sampling. The adaptive strategy had the best reconstruction performance. When the sampling quantity was 70, the reconstruction error curve tended to stabilize, and the minimum reconstruction error was 0.04. The reconstruction performance of the discrete cosine transform method was the worst. When the sampling quantity was 60, the reconstruction error curve tended to stabilize, and the minimum reconstruction error was 0.42. The reconstruction performance of the overcomplete dictionary design method for sparse representation was slightly inferior to the research method. When the sampling quantity was 60, the reconstruction error curve tended to stabilize, and the minimum reconstruction error was 0.13.

Fig. 8. Comparison of reconstruction performance of four algorithms.

Fig. 9. Reconstruction performance of sparse routing and dense routing.

The reconstruction performance of node selection based on Bayesian compression perception was compared with other methods under different balance factors. In the case of unreliable links, the reconstruction performance of the adaptive sparse strategy was compared with that of other methods in Fig. 10. Observing Fig. 10(a), it can be seen that when the balance factor is small, the reconstruction performance of node selection based on Bayesian compressive sensing is the best,

with a minimum reconstruction error of 0.09. When the balance factor is small, the reconstruction performance of genetic methods is the worst. The reason is that for some complex, high-dimensional, and nonlinear problems, genetic algorithms may have difficulty effectively searching for the optimal solution. At this time, the minimum reconstruction error is 0.47. When the balance factor is large, the reconstruction performance stability of the five algorithms is insufficient. In

Fig. 10 (b), the adaptive sparse strategy had better and more stable reconstruction performance, with a reconstruction error of 0.16. The reconstruction performance of the overcomplete dictionary design method for sparse representation was slightly inferior to the research method, with a reconstruction error of 0.22.

In the case of different numbers of nodes, the study compared the network lifetime and error rate of data collection using methods with the method proposed in study [24]. The

statistical results are shown in Fig. 11. Observing Fig. 11(a), it can be seen that the network lifetime of the wireless sensor network data collected by the method used in the study has been extended. When the number of nodes is 28, the network lifetime is 17, and the network lifetime has been extended by 30.8%. Observing Fig. 11 (b), it can be seen that the error rate of wireless sensor network data collection has been reduced in the study. When the number of nodes is 30, the error rate of data collection has been reduced the most, with an error rate of 29%. The error rate of data collection has been reduced by 12%.

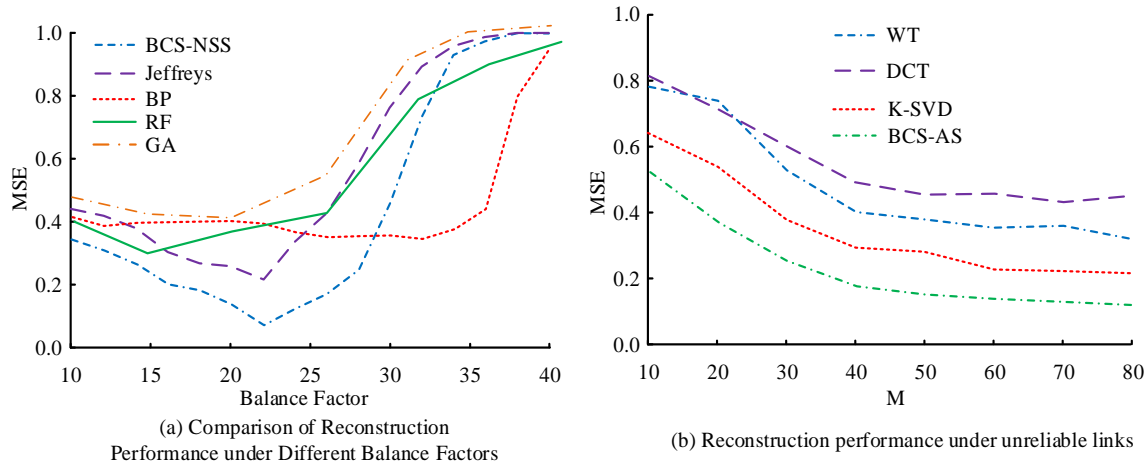

Fig. 10. Comparison of reconstruction performance of different methods.

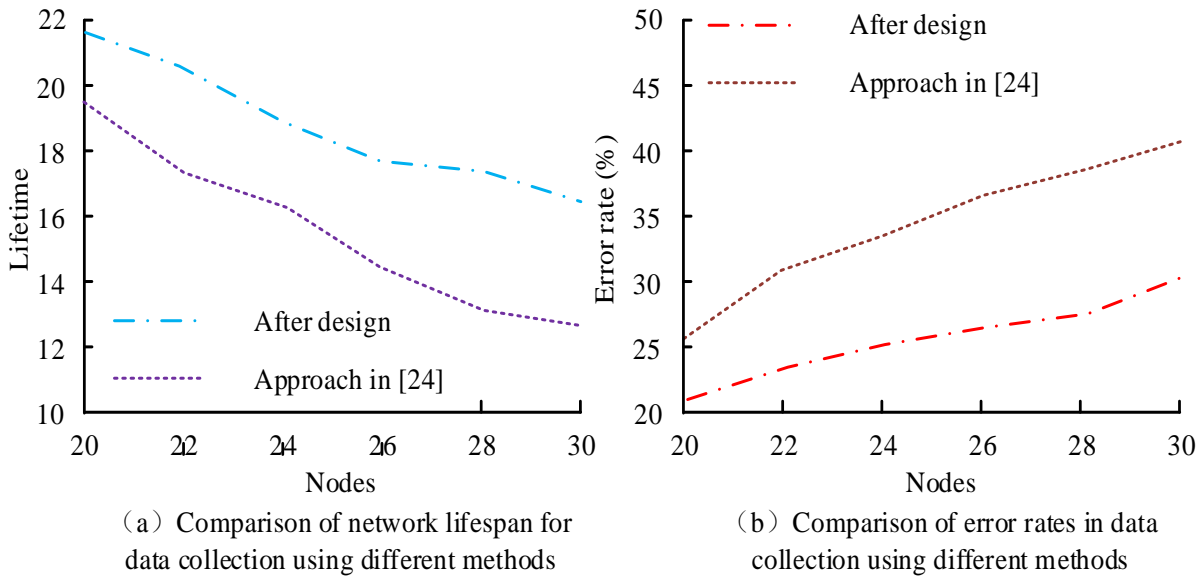

Fig. 11. Comparison of error rates and network lifespan of data collected by different methods.

The adaptive sparse strategy was compared with the discrete cosine transform method in terms of lifespan in sparse and dense routing. The reconstruction error and network lifetime of node selection based on Bayesian compression perception were compared with those of other methods under different numbers of nodes. Table II shows the statistical results. The lifespan of WSN with adaptive sparse strategy was longer than that of discrete cosine transform method. WSN had the longest lifespan under sparse routing. When the nodes were the same,

the reconstruction error of node selection based on Bayesian compression perception was minimized. When nodes were 28, the minimum reconstruction error of the strategy used in this study was 0.04. Under the same reconstruction error, the network lifespan of node selection based on Bayesian compression perception was longer. When the reconstruction error was 0.6, the longest network lifetime of the strategy used in this study was 28.

TABLE II. COMPARISON OF RECONSTRUCTION ERROR AND NETWORK LIFESPAN

Same number of nodes			Same reconstruction error		
method	Number of active nodes	Reconstruction error	method	Reconstruction error	Network lifespan
BCS-NSS	22	0.35	BCS-NSS	0.3	25
BCS-DSSR	22	0.55	BCS-DSSR	0.3	6
BCS-MA-DR	22	0.62	BCS-MA-DR	0.3	22

V. DISCUSSIONS

The proposed digital sensing technology has unique advantages in data collection in wireless sensor networks. The study in [15] uses an efficient aggregation method for multi hop clusters based on hybrid compressive sensing to collect data. By combining compressive sensing and routing protocols, although the effect is significant, it requires multiple compression and decompression operations on the signal, thus requiring a large amount of computing resources and time, and the computational cost is high. The method in study [16] achieves compressive matrix decomposition through random singular value decomposition, thereby achieving higher accuracy at lower sampling rates and reducing data transmission costs. However, stochastic singular value decomposition is based on random sampling, and its results are sensitive to the randomness of the initial sampling matrix, which may lead to instability and uncertainty in the results. The method proposed in study [17] can reduce the loss of data samples when transmitted wirelessly, but its applicability is limited. In contrast, when studying the collection of wireless sensor network data based on digital sensing technology, the selection of sensor nodes reduces the amount of data collected and extends the lifespan of the wireless sensor network. In the experiment, as the amount of data continued to increase, the minimum reconstruction error of the research method was 0.04, which was 0.42 lower than DCT and 0.14 lower than SVD. The proposed method achieves significant performance improvement while maintaining low error, making it suitable for large-scale wireless sensor network data collection.

In summary, the research on data collection based on data aware positioning technology reduces the amount of data collected and extends the lifespan of wireless sensor networks by selecting sensor nodes. The research has provided

theoretical support and practical guidance for wireless sensor network data collection, further improving the efficiency and accuracy of wireless sensor network data collection. And this method requires high-performance computer resources, so future research directions will focus on how to reduce the demand for computer resources in Bayesian compressive sensing methods.

VI. CONCLUSION

The development of IoT enables wireless communication between objects and automates data exchange. The foundation of IoT is wireless sensor technology. There is noise interference and abnormal or missing data in WSN, which leads to excessive consumption of communication resources and insufficient data reliability. The study proposes a data collection method based on data compression perception positioning technology. Firstly, a Bayesian compression perception-based method is adopted to select nodes to address the shortened network lifecycle caused by differences in node performance. Secondly, an adaptive sparse strategy based on Bayesian compression perception is adopted to collect data and reduce communication resource consumption. When nodes were 28, the minimum reconstruction error based on Bayesian compression perception node selection strategy was 0.04. When the reconstruction error was 0.6, the longest lifespan of the network based on Bayesian compression perception node selection strategy was 28. Under different sampling quantities, the adaptive strategy had the best reconstruction performance with a minimum reconstruction error of 0.04. When the balance factor was small, the reconstruction performance of node selection based on Bayesian compression perception was the best, with a minimum reconstruction error of 0.09. Compared with existing algorithms, the proposed method has been effectively applied in data acquisition, reducing energy consumption of wireless

sensor networks, extending their lifecycle, and improving the reconstruction performance of compressed sensing. However, Bayesian compressive sensing requires a prior distribution of known signals and has a high computational complexity, requiring a large amount of computing resources. Subsequent research will adopt other methods to optimize the Bayesian compressive sensing method, in order to avoid problems such as long computation time and large storage space.

Abstract—The application of machine learning, particularly through image-based analysis using computer vision techniques, has greatly improved the management of crop diseases in agriculture. This study explores the use of transfer learning to classify both spreadable and non-spreadable diseases affecting soybean, lettuce, and banana plants, with a special focus on various parts of the banana plant. In this research, 11 different transfer learning models were evaluated in Keras, with hyperparameters such as optimizers fine-tuned and models retrained to boost disease classification accuracy. Results showed enhanced detection capabilities, especially in models like VGG_19 and Xception, when optimized. The study also proposes a new approach by integrating an EfficientNetV2-style architecture with a custom-designed activation function and optimizer to improve model efficiency and accuracy. The custom activation function combines the advantages of ReLU and Tanh to optimize learning, while the hybrid optimizer merges feature of Adam and Stochastic Gradient Descent (SGD) to balance adaptive learning rates and generalization. This innovative approach achieved outstanding results, with an accuracy of 99.96% and an F1 score of 0.99 in distinguishing spreadable and non-spreadable plant diseases. The combination of these advanced methods marks a significant step forward in the use of machine learning for agricultural challenges, demonstrating the potential of customized neural network architectures and optimization strategies for accurate plant disease classification.

I. INTRODUCTION

Over 80,000 plant diseases are known to exist in the world. Crop diseases often harm crop plants, which can result in major economic and agricultural losses [1]. If a plant disease is induced by an environmental element and is not spread from one plant to another, it is referred to be abiotic, or non-infectious. Diseases classified as biotic or infectious are those brought on by pathogens like viruses, fungi and nematodes.

Pathogens that affect animals as well as humans mimic plant illnesses. Fungus, organisms that mimic fungal, bacterial, phytoplasmas, viral, viral vectors, nematodes and parasitic higher plants are examples of plant diseases.

In order to establish and maintain food security and revenue sources for a developing world, it is more crucial to safeguard plants against diseases. Severity of plant diseases can be reduced with the aid of early identification.

The first lettuce farms were established in ancient Egypt as it was the most widely consumed salad produce and has substantial economic worth. Lettuce is more susceptible to biotic than abiotic illnesses. The study highlights crucial and substantial diseases, such as downy mildew, which may spread swiftly to impact most plants in a crop. Lettuce diseases can cause significant damage and occasionally full crop loss [2]. Some diseases, such as downy and powdery mildews, can spread swiftly and harm the majority of the plants in a crop.

Diseases and insect pests are the main issues in soybean production. To get a broader perspective on spreadable and non-spreadable diseases, soybean plant is chosen. This calls for careful diagnosis and prompt handling to prevent the soybean crops from suffering significant losses. The world's soybean production is projected to be 333.67 million tonnes in 2019–2020 from a total area of 120.50 million hectares [3].

It is crucial to learn more about the spreadable and non-spreadable diseases that affect various plant parts, including the leaves, fruits, stems, nodes and roots. The banana crop fits best into this category because each part of the plant has a variety of uses, including medicinal properties for the stem and roots and maintaining the health of the soil. Additionally, with an output of 97.5 million tonnes, bananas are a significant fruit crop on a worldwide scale. It has a total yearly output of 490,710,000 hectares producing 16.91 million tonnes [4].

Bananas are an important fruit crop in India. They are a staple food for many people in the country and are also widely used in various dishes. Panama disease, also known as Fusarium wilt, is a serious threat to banana production worldwide. It is caused by a fungus that infects the root system of the banana plant, ultimately causing the plant to wilt and die. Aphids are a common pest that can also infect banana plants. They feed on the sap of the plant, which can weaken it and make it more susceptible to other pests and diseases. It is important for farmers to monitor their banana crops closely and take steps to prevent and control these pests and diseases to protect their yield.

Food security is at risk from plant diseases because they can harm crops, lowering food production and driving up food

prices. Leaf blight, septoria blight, powdery mildew and downy mildew, which can be fungal, are the main diseases impacting the lettuce crop. Bacterial rust and downy mildew are the diseases that affect soybeans, whereas weevil, soft rot, aphids, and few may affect bananas [5]. Fig. 1 and 2 shows the illnesses of lettuce and soybean.

Deep learning is a cutting-edge technique for object recognition and image processing that improves categorisation of numerous crop diseases [6]. One well-liked method in deep learning where pre-trained models are modified to perform a new job is transfer learning. Deep Transfer Learning (DTL) creates a applied novel framework for predictive analytics and digital image processing that is more accurate and has enormous potential for crop disease identification. A potential method for recognising diseases onsite is the DTL technique, which also offers a quick way to adapt created models to the constraints imposed by mobile applications [7]. This would be very useful in a real-world field scenario.

Fig. 1. Some major plant diseases found in lettuce plant dataset.

A variety of factors, including that of the high-definition camera, high efficient processing and many built-in accessories, enable automatic disease identification. The accuracy of the outcomes has increased because of the use of cutting-edge techniques like deep learning and machine learning. Our experimental results represent significant advances in the understanding of the severity of plant diseases. The paper is organised as follows for the following sections: Section I

Introduction, Section II Literature Review, Section III highlights Methodology that includes expanded dataset description, Augmentation and Activation functions, Section IV describes Performance evaluation. Performance reviews go into great detail, Section V is concerned with implementation, results are provided in tabular format and Section VI acts as a conclusion.

Fig. 2. Some major plant diseases found in soybean plant dataset.

II. LITERATURE SURVEY

N. Saranya et al. [8] have categorized many ailments that affect the leaves and fruits of the banana plant. Fuzzy c-means, histogram-based equalization and artificial neural networks all have important roles in the proposed approach. The image is divided using fuzzy c-means and the histogram is then utilized to transform it without losing any of the details of the banana plant. In this study, a better categorization strategy is recommended in order to deliver the best return.

Michael Gomez Selvaraj et al. [9] applied pixel-based banana classification using the Random Forest (RF) model utilizing integrated features of Vegetative Indices (VI) and Principal Component Analysis (PCA) to map banana under mixed-complex African settings. Gomez Selvaraj et al. provided higher & low-resolution aerial (UAV and satellite) photos with cutting-edge computer vision algorithms to achieve more than 90% accuracy under actual settings (Smart phone-based AI applications).

A high-definition camera is used to take photos of the early and intermediate phases of soybean disease and the photos are then expertly batched into uniform sizes. The picture

segmentation methods used by E. Miao et al. [10] include lab grayscale map, ultragreen feature approach, genetic algorithm and threshold segmentation. Next, the results are filtered using the median and corroded expansion. A Convolutional Neural Network (CNN) that uses a MultiLayer Perceptron (MLP) framework to execute supervised learning of the network and achieves an average recognition rate of 94.87% is seen in the soybean illness picture identification experiment.

Three disease groups of soybean leaves were examined by Sachin B. Jadhav et al. [11] bacterial blight, frogeye leaf spot, and septoria brown spot. The diseased leaf area is segmented using incremental K-means clustering. Color and texture data are recovered using the R, G, B color space and the Gray Level Co-occurrence Matrix (GLCM), respectively. SVM and K-Nearest Neighbors Algorithm (KNN) are used in a classification technique to identify the exact kind of leaf disease. The results demonstrate that the SVM classifier approach outperforms the KNN methodology with efficiencies of 87.3% and 83.4%, respectively.

Elham Khalili et al. [12] examined and compared six ML methods for identifying the ailment known as charcoal rot in their study that was published in science. Healthy plants were gathered from the stem and root of soybean plants during the ripening stage based on the maturity's symptomless qualities. R7 (Yellowing of the leaves and yellow pods at 50% growing stage) was chosen for sick plants based on physical criteria indicates the presence of bright grey and mycelium on the root and stem. Gradient Tree Boosting and Support Vector Machines performed better than Regularized Logistic Regression, MultiLayer Perceptron and Random Forest techniques.

Miao Yu et al. [13] used the OTSU technique, which decreases the effect of the background on the disease images. Using ResNet18 and RANet, the model's effectiveness in the test set was confirmed and assessed. The response time was 0.0514 seconds, the F1-value was 98.52, and the RANet average recognition rate was 98.49%. Compared to ResNet18, the identification rate increased by 1.15 percent, the F1-value increased by 1.17 and 0.0133 seconds were saved while identifying illnesses from images.

Lack of calcium makes tip-burn, which is common in lettuce plants cultivated indoors, worse. Photos of tip-burn lettuce were illuminated using white, red and blue LEDs, and these images served as the training, validation and testing datasets for a deep-learning detection method. The detection approach developed by Munirah Hayati Hamidon et al. [14] was based on three detectors: CenterNet, YOLOv4 and YOLOv5. YOLOv5 beat the other two models tested, with an accuracy of 84.1% mAP.

Positive and negative samples from each kind of weed and crop were chosen by Kavir Osorio et al. [15] and taken. There are just a few of weed characteristics that remain consistent, making identification difficult. The identification of the vegetation was done alternatively using multispectral bands. The R-CNN model distinguished itself for its accuracy in detecting the crop and showing the edges, making it a tactic that may be recommended for addressing problems like fruit detection. The RCNN and HOG-SVM-based algorithms were shown to be the most trustworthy using the Bland-Altman

approach. The YOLO strategy exaggerates the high levels of cannabis coverage in contrast to the other two.

According to J. Amara et al. [16], who used the LeNet architecture as a Convolutional Neural Network to classify the data, banana leaf disease may now be classified using deep learning. This strategy stabilized after 25 iterations. This research demonstrated its effectiveness in a variety of picture situations, including ones with a complex background and various sizes and orientations.

W. Liao et al. [17] proposed using the SVM classifier in a machine learning-based strategy for early identification of banana disease. Hyperspectral images taken at close range are utilized in this instance. When using spectral and morphological data, the classifiers' outputs have an overall accuracy of 96% for early detection, 90% for mid-detection, and 92% for late detection.

More research is being done to detect and classify the disease, not just for banana leaves but also for the majority of food crops including rice, maize, apple, cheerio and other well-known plants. Here are a few of these judgements.

A superior convolutional neural network should be used to classify apple plant and cherry plant diseases, according to [18].

In the extremely packed growing conditions of indoor settings, early diagnosis of tip-burns in lettuce is vital in order to reduce the cost of human identification and boost lettuce quality and production. Shimamura et al. [19] created a system for tip-burn identification in plant factories by using GoogLeNet to classify two different types of tip-burn from a single picture of lettuce.

The most recent Neuron Compute Stick pretrained Movidius of deep CNN model from Intel provided an accuracy rate of 88.46% for Mishra et al. [20]'s system for classifying and diagnosing maize leaf diseases. The system was implemented on a Raspberry Pi 3.

K-means segmentation and multiclass support vector machines were used by Kumar et al. [21] to identify and classify different plant leaf diseases (SVM-based classification). Compared to other approaches, the detection accuracy is much higher.

To eliminate manual feature stage modelling, Mazzia et al. [22] created an LC&CC deep learning model that blends Recurrent Neural Networks (RNN) with Convolutional Neural Networks (CNN).

Researchers Cetin et al. [23] used six different machine learning algorithms to analyze and classify six sunflower varieties (105 single seeds) based on their fatty acid and mineral composition, biochemical traits and physical characteristics. These algorithms included Decision Tree (DT), Random Forest (RF), Support Vector Machine (SVM), Multiple Linear Regression (MLR), Naive Bayes (NB) and MultiLayer Perceptron (MLP).

Sharif et al. [24] proposed a hybrid feature selection method, which included the principal components analysis score, entropy, skewness-based covariance vector and Multiclass-SVM (MSVM), produced true positive rates of 96.9% and

97.1% for the detection of anthracnose disease and melanose disease on citrus leaves.

Machine learning models including K-Nearest Neighbor (KNN), Support Vector Machine (SVM), and other machine learning models have been widely used as classifiers to find anomalous areas on crop leaves. With a detection rate of 90.5%, Lu et al. [25] used Fisher discriminant analysis to identify anthracnose crown rot in the early stages of affected strawberry leaves inside.

To detect early blight on potato leaves, Vijver et al. [26] used partial least squares discriminant and discovered a positive predictive value of 0.92. This study demonstrated that artificial intelligence can accurately identify aberrant leaves in a range of crops. Therefore, using machine learning algorithms to detect yellow and wilted lettuce leaves in hydroponic systems is encouraging.

III. METHODOLOGY

A. Dataset Description

Performance evaluation of existing transfer learning pretrained models for plant disease classification is done using the Lettuce, Soybean and Banana dataset. Non-Spreadable diseases caused by abiotic factors include herbicide injury which

turn leaves or leaf veins yellow or red. Calcium strengthens plant cell walls and salt burn is a result of the plant's inability to supply enough calcium for developing leaves during periods of rapid growth. The dataset for the proposed research consists of images of Lettuce plant and Soybean Plant infected by non-spreadable diseases and images affected by spreadable diseases. These images have been obtained from CrowdAI [27] and PlantVillage dataset [28]. The images have been augmented and brought up to 628 images for the former and 1845 images for the latter, as represented in Fig. 3 and 4. Each image maintains a fixed width and height of 256x256 pixels.

Two mobile phones and a UAV were used to take pictures of soybeans. Three groups make up the dataset: (I) photos of healthy plants, (II) pictures of plants harmed by caterpillars, and (III) pictures of plants harmed by *Diabrotica speciosa*. To meet our demands, the photos have undergone processing and augmentation [29].

The banana plant is vulnerable to bacterial, fungal, and viral diseases that can affect different parts of the plant. For research purposes, the PSFD-Musa dataset [30] was utilized, which contains pre-existing enhanced photos. Fig. 5 to 11 represent the dataset, showcasing the spreadable disease affected regions such as Node, Leaf, Banana, and Fruit.

The dataset includes images of leaves affected by diseases like Black Sigatoka, Panama, and Yellow Sigatoka (Fig. 5-7), with a total count of 1104. Stem diseases, namely Bacterial Soft Rot and Pseudostem Weevil, also have 1104 corresponding images. The Banana node is affected by Aphids (Fig. 8), and the Banana Fruit is affected by Scarring Beetle (Fig. 9), with 366 and 150 images obtained, respectively.

To enhance the model's efficiency and performance, self-captured healthy banana images were incorporated. Fig. 7 illustrates images of healthy nodes. Additionally, potassium deficiency, caused by abiotic factors, has an adverse impact on banana leaves (Fig. 8). The dataset also includes 150 images of spreadable diseases in banana fruit (Fig. 9).

In addition to the banana dataset, 740 photos of soybean plants infected with spreadable diseases (Fig. 10) and 1084 non-spreadable images (Fig. 11) were obtained for comparative analysis.

B. Augmentation

Convolutional Neural Networks (CNN) are widely used for image classification. However, the quality and quantity of training data significantly impact model performance. Insufficient or imbalanced data can lead to poor generalization. Techniques like oversampling or undersampling can address class imbalance [31]. Data augmentation, including affine transformations and color manipulation, is a popular method to increase dataset size. Classical approaches may not always improve accuracy or address overfitting effectively. Affine transformations include rotation, reflection, scaling, and shearing. Additional techniques like permutation rotate, random zoom, variation in shear, random crop, and flip can be used. After data augmentation and balancing, the dataset consisted of 200 augmented images per class [32].

C. Activation Function

An activation function is a mathematical function that is applied to the input of a neural network node or a layer of nodes. The activation function is used to introduce non-linearity into the network, which is necessary for the network to learn complex patterns in the input data. Without activation functions, a neural network would essentially be a linear model, which is limited in its ability to learn complex relationships.

Activation methods that are frequently employed based on a few desirable characteristics include:

1) *Nonlinear*: Whenever the activation function is nonlinear, it has been shown that a two-layer neural network is an excellent approximator of any function. The identical

activation function does not satisfy this condition. When many layers employ the same activation function, the network as a whole is equivalent to a single-layer model.

2) *Range*: Gradient-based training techniques have a tendency to be more stable when the activation function's range is finite, since only a small number of weights are significantly affected by pattern presentations. Since most of the weights are strongly affected by pattern presentations when the range is unlimited, training is often more effective. Short learning rates are often required in the latter scenario.

3) *Continuously differentiable*: For the purpose of allowing gradient-based optimization approaches, this property is desirable (ReLU is not continuous differentiable and has some challenges with it, but it is still achievable). Because the binary step activation function is not differentiable at zero and differentiates to zero for all future values, gradient-based techniques cannot advance with it.

4) *Monotonic*: A single-layer model's related error surface is always guaranteed to be convex when the activation function is monotonic.

5) *Approximates near the origin*: When activation functions have this property, the neural network can learn efficiently when its weights are initialized with low-level random values. If the activation function differs from identity near to the origin while initializing the weights, more care must be taken.

Each activation function has advantages and disadvantages, so we must be cautious when choosing one. Following are some frequent considerations to make while selecting an activation function:

1) When it comes to classification issues, sigmoid [33] functions (including softmax) and their combinations often perform better.

2) Due to the vanishing gradient issue, sigmoid and tanh functions continue to be avoided in hidden layers.

3) Tanh is typically avoided because of the dead neuron issue [34].

4) Because it produces superior results, ReLU activation function is frequently employed and is the default option (than sigmoid and tanh) [35].

5) However, the ReLU function should only be utilized in the buried layers (and not in the output layer).

6) In cases of regression issues, an output layer's activation function can be linear, however nonlinear activation functions are required for classification tasks.

7) The leaky ReLU function is the ideal option if we come into an instance of dead neurons in our networks.

8) For any kind of neural network, the ReLU activation function is presently the one that is most frequently employed for the hidden layers (but never for the output layer).

9) Swish activation should only be utilized for bigger neural networks with depths of more than 50 layers, even though it does not consistently beat ReLU in complicated applications [36].

10) The output (top-most) layer should be triggered by the sigmoid function for 2-class applications, as well as for multi-label classification.

11) The output layer must be triggered using the softmax activation function for multi-class applications.

12) A basic regression neural network should just employ the linear activation function in the output layer.

13) The tanh activation function is recommended for the hidden layer in Recurrent Neural Networks (RNN). By default, it is configured by TensorFlow.

14) In some circumstances, switching to a leaky ReLU might produce better outcomes and overall performance if ReLU is unable to deliver the desired results.

Some of the known Activation functions are:

1) *The sigmoid function*: Logistic regression and simple neural network implementation both use sigmoid functions. The fundamental activation units in machine learning are sigmoid functions. However, because of a number of limitations, it is simply not advisable to use complicated neural network sigmoid functions (vanishing gradient problem). Given that it is among the most frequently used activation functions, it serves as an excellent introduction for those who are naïve to data science and machine learning. Whilst the sigmoid function and its derivative are simple to use and help reduce the time required to develop models, there is a considerable downside of data lost since the derivative has a constrained range.

2) *Tanh function*: The tanh function partially addresses the drawback of the sigmoid function. Its key feature is that its curve is symmetric across the origin and has coefficients that range from -1 to 1 [34]. This does not, however, mean that the fading or bursting gradient problem does not occur. It does exist for tanh, however unlike Sigmoid, it is centered at zero, making it more ideal than Sigmoid Function.

3) *ReLU (Rectified Linear Units) and Leaky ReLU*: ReLU functions, as opposed to Logistic Activation functions, are currently used in the majority of Deep Learning applications, such as computer vision, natural language processing, speech recognition, deep neural networks, etc [35]. ReLU outperforms tanh or sigmoid functions in terms of application-level manifold convergence speed. Among the ReLU variations are Leaky ReLU, Parametric ReLU, Parametric Softplus (SmoothReLU), Noisy ReLU, and ExponentialReLU (ELU) [36].

4) *Softmax function*: The Softmax activation function which not only turns our output into a [0, 1] range but also

changes each outcome so that the sum of each is 1 [37], is extremely fascinating. Softmax produces probability distribution as a result. In logistic regression model (multivariate), Softmax is used for multi-classification while Sigmoid is employed for binary classification.

D. Mathematical Approach for the Considered Procedure

The field of machine learning relies heavily on mathematical principles and techniques to design, train, and optimize models that can make predictions or learn patterns from data. This mathematical approach enables us to create powerful algorithms capable of solving a wide range of tasks, from image recognition and natural language processing to financial predictions and recommendation systems.

At the core of the mathematical approach in machine learning is the idea of formulating the learning problem as an optimization task. The goal is to find the model's parameters that minimize a certain objective function, such as the mean squared error in regression tasks or the cross-entropy loss in classification tasks. This process involves using various mathematical tools to represent the model, compute gradients, and iteratively update the parameters to approach the optimal solution. Let's go through each of these layers, providing a brief introduction and their mathematical formulas:

1) *Convolutional Layer (Conv layer)*: Convolutional layers are the fundamental building blocks of Convolutional Neural Networks (CNNs). They are designed to automatically and adaptively learn spatial hierarchies of features from input data such as images. A convolutional layer applies convolutional operations to input data using learnable filters (kernels) to detect local patterns and features.

The output of a convolutional layer can be represented as follows:

Given an input feature map X with dimensions (height, width, channels), and a set of learnable filters W of size (filter_height, filter_width, input_channels, output_channels), the convolution operation can be represented as:

$$Y[i, j, k] = \sum \sum \sum X[p + i, q + j, r] * W[p, q, r, k]$$

Here,

- $Y[i, j, k]$ is the value of the output feature map at position (i, j) in the k-th channel.
- $X[p+i, q+j, r]$ is the value of the input feature map at position (p+i, q+j) in the r-th channel.
- $W[p, q, r, k]$ is the value of the learnable filter at position (p, q) in the r-th input channel and k-th output channel.
- The summation is performed over all spatial positions (p, q) of the filter and all input channels (r).

2) *MaxPooling Layer (MaxPooling)*: MaxPooling is a downsampling technique commonly used in CNNs to reduce the spatial dimensions of the feature maps while retaining the most important information. It works by dividing the input

feature map into non-overlapping regions and taking the maximum value within each region.

The output of a MaxPooling layer can be represented as follows:

Given an input feature map X with dimensions (height, width, channels), and a pooling window of size (pool_height, pool_width), the MaxPooling operation can be represented as:

$$Y[i, j, k] = \max(X[i * pool_{height} : (i + 1) * pool_{height}, j * pool_{width} : (j + 1) * pool_{width}, k])$$

Here,

- Y[i, j, k] is the value of the output feature map at position (i, j) in the k-th channel.
- The max function takes the maximum value within the pooling window.

3) *SeparableConv Layer (Depthwise Separable Convolution)*: The SeparableConv layer is an alternative to standard convolutions designed to reduce computation and model size while maintaining representational capacity. It splits the convolution operation into two steps: depthwise convolution and pointwise convolution.

The output of a SeparableConv layer can be represented as follows:

Given an input feature map X with dimensions (height, width, channels), a depthwise kernel DW of size (filter_height, filter_width, channels), and a pointwise kernel PW of size (1, 1, channels, output_channels), the SeparableConv operation can be represented as:

$$Y[i, j, k] = \sum \sum X[i + p, j + q, r] * DW[p, q, r] * PW[1, 1, r, k]$$

Here,

- Y[i, j, k] is the value of the output feature map at position (i, j) in the k-th channel.
- X[i+p, j+q, r] is the value of the input feature map at position (i+p, j+q) in the r-th channel.
- DW[p, q, r] is the value of the depthwise kernel at position (p, q) in the r-th channel.
- PW[1, 1, r, k] is the value of the pointwise kernel at position (1, 1) in the r-th input channel and k-th output channel.
- The summation is performed over all spatial positions (p, q) of the depthwise kernel and all input channels (r).

4) *GlobalAveragePooling2D Layer*: Global Average Pooling 2D is another downsampling technique used in CNNs, often as an alternative to fully connected layers at the end of the network. It computes the average value of each channel of the feature map, reducing the spatial dimensions to a single value per channel.

The output of a GlobalAveragePooling2D layer can be represented as follows:

Given an input feature map X with dimensions (height, width, channels), the Global Average Pooling operation can be represented as:

$$Y[k] = \left(\frac{1}{(height * width)} \right) * \sum \sum X[i, j, k]$$

Here,

- Y[k] is the value of the output for the k-th channel.
- The summation is performed over all spatial positions (i, j) of the feature map.

5) *Dense Layer (Fully Connected Layer)*: The Dense layer is the standard fully connected layer in neural networks. It connects every neuron from the previous layer to every neuron in the current layer. The Dense layer performs a linear transformation followed by an activation function.

The output of a Dense layer can be represented as follows:

Given an input vector X of size (input_units) and the weight matrix W of size (input_units, output_units), the Dense layer operation can be represented as:

$$Y = activation_function(X * W + b)$$

Here,

- Y is the output vector.
- activation_function is the non-linear activation function applied element-wise to the linear transformation.
- b is the bias vector of size (output_units).

6) *BatchNormalization layer*: BatchNormalization is a normalization technique applied to intermediate layers in neural networks to stabilize and accelerate training. It normalizes the activations of each layer's mini-batch, making the network more robust and less sensitive to the scale of the input.

The output of a BatchNormalization layer can be represented as follows:

Given an input feature map X with dimensions (batch_size, features), and learnable scaling and shifting parameters γ and β , the BatchNormalization operation can be represented as:

$$\mu = \frac{1}{batch_size} * \sum X$$

$$\sigma^2 = \frac{1}{batch_size} * \sum (X - \mu)^2$$

$$X_{normalized} = \frac{(X - \mu)}{\sqrt{\sigma^2 + \epsilon}}$$

$$Y = \gamma * X_{normalized} + \beta$$

Here,

- μ and σ^2 are the mean and variance of the mini-batch.

- $X_{normalized}$ is the normalized input.
- γ and β are learnable scaling and shifting parameters, respectively.
- ϵ is a small constant (usually a small value like $1e-5$) added for numerical stability.

7) *Flatten layer*: The Flatten layer is used to reshape the high-dimensional feature maps into a 1D vector, which is then fed into a Dense (fully connected) layer for further processing.

Let's consider an input tensor X with dimensions (batch_size, height, width, channels), where:

batch_size: The number of samples in the batch.

height: The height dimension of the feature maps.

width: The width dimension of the feature maps.

channels: The number of channels (depth) of the feature maps.

The Flatten layer reshapes the input tensor X into a 1D vector with size (batch_size, height * width * channels). This is

achieved by simply concatenating all the elements of each feature map in X into a single long vector.

$$Flatten_output = Reshape(X, (batch_size, height * width * channels))$$

Here, $Reshape(X, (batch_size, height * width * channels))$ represents the operation of reshaping the input tensor X into the specified dimensions.

IV. PERFORMANCE EVALUATION AND RESULTS

A. Model and Dataset Selection

On datasets for lettuce, soybeans and bananas, 11 Transfer Learning models have been used to identify and categorize disease occurrence. The dataset that was collected from web sources are treated as raw data and organized as indicated in Fig. 12 and 13.

The original dataset was reshuffled, and the resulting dataset is used to train the transfer learning models in Keras module. Divided 38 TL Keras models into 11 different groups, grouped them as families, and primarily selected a member from each group for further study.

Fig. 12. (a) Modification of Lettuce Dataset, (b) Modification of Soybean Dataset.

Fig. 13. Variety of banana dataset considered.

The bold models in Table I are chosen for research.

To retrain a transfer learning model, you will need to follow these steps:

1) *Choose a pre-trained model:* Start by choosing a pre-trained model that you want to use as the base for your model. There are many pre-trained models available in various libraries and frameworks, such as TensorFlow, PyTorch and Keras.

2) *Freeze the base model:* The pre-trained model will likely have many layers, and you will want to "freeze" the weights of these layers so that they are not updated during training. This will allow you to take advantage of the knowledge learned by the pre-trained model on a large dataset, while still training a new model that is customized for your specific task.

3) *Add new layers:* Next, you will want to add one or more layers to the model that you can train specifically for your task. These layers should be added on top of the frozen base model.

4) *Train the model:* Once you have added your new layers, you can compile and train your model using your own dataset. This will allow the model to learn task-specific features that are relevant to your problem.

5) *Fine-tune the model:* After training, you may want to fine-tune your model by unfreezing some of the layers in the base model and training them along with the new layers. This can help to further improve the performance of your model.

6) *Evaluate the model:* Once the model has been trained and fine-tuned, it is important to evaluate its performance on a validation set to ensure that it is not overfitting to the training data. You can use metrics such as accuracy, precision, recall and F1 score to evaluate the performance of your model.

7) *Tune hyperparameters:* You may need to tune hyperparameters such as learning rate, batch size, and number of epochs to optimize the performance of your model. This can be done using techniques such as grid search or random search.

8) *Deploy the model:* Finally, once the model has been trained and evaluated, it can be deployed in a production environment to make predictions on new, unseen data. This can be done using various deployment strategies such as containerization or serverless functions.

Maintaining a modest learning rate during fine-tuning is an important strategy to avoid over and under-distorting the CNN weights. The learning rate determines the step size at each iteration during the optimization process and a high learning rate can result in large weight updates that may cause the weights to diverge or oscillate. On the other hand, a low learning rate may result in slow convergence or getting stuck in local minima. A modest learning rate strikes a balance between these two extremes, allowing the model to converge towards an optimal solution without over-distorting the weights. The identification of both communicable and non-communicable diseases is done using Transfer learning techniques as shown in Fig. 14.

Fig. 14. Approach and analysis of the Transfer Learning Models for plant disease detection in Lettuce, Soybean and Banana.

V. IMPLEMENTATION AND RESULTS

The accuracy of 11 TL models selected from Table II, as well as average F1 score for each class belonging to both spreadable and non-spreadable kinds, are shown in Table III. Table IV considers the average F1 score and accuracies for the Lettuce dataset, which contains 7 classes for infectious diseases.

Accuracy is employed when True Positives as well as True Negatives are more necessary, but F1-score is employed when False Negatives but also False Positives are essential.

While F1-score is a superior measure when there are unbalanced classes, as in the example above, accuracy may be utilized when the class distribution is similar. Due to the uneven class distribution that characterizes the majority of real-world classification tasks, F1-score is a superior statistic to use when assessing the model.

A. What is ConvNext?

The science of computer vision has long employed residual networks like ResNets. Because of its smaller Residual Block design, it is considerably simpler to train deep neural networks employing skip connections. ResNet will serve as the beginning point because of their incredible accomplishment. The network will be gradually improved from this starting point, and after

each enhancement, its performance will be assessed using the dataset and compared to vision transformers.

1) *ConvNext*: A ConvNet that outperforms Vision Transformers in terms of accuracy, performance and scalability while having the structural simplicity of Convolutional Neural Networks.

B. Assessment of ConvNext

In comparison to its vision transformer contemporaries, the new ConvNet, termed ConvNeXt, is not only more accurate but also more scalable. The graph of Fig. 15 compares ConvNext models to their equivalent vision transformers in ImageNet-1K [38].

The Table V displays the accuracy of the 11 models that were trained on the Banana dataset for all 5 classes. The ConvNeXtXLarge model performs best by yielding the most accurate findings, but the baseline model, NASNetMobile, is inappropriate for datasets based on plants, as can be seen in Table V.

The outcomes of Transfer Learning models developed for three separate datasets—lettuce, soybean and banana under various categorizations, infectious and non-infectious illnesses, were covered in the section above. The behavior of the models trained on the same three datasets but combined is covered.

TABLE II. MODEL DESCRIPTION

Model	Description
Xception	It makes use of the Xception 71-layer deep convolutional neural network. More than one million pictures from the Imagenet dataset may be used to preload a network that has previously been pretrained. The pretrained network will categorize photos into far more than a thousand more object categories in addition to keyboards, mice, pencils, and other animals.
VGG_19	The total number of layers in the convolutional neural network VGG-19 is 19. More than one million pictures from ImageNet database may be used to preload a network which has previously been pretrained. The pretrained network will categorize photos into far more than a thousand more object categories in addition to keyboards, mice, pencils and other animals.
ResNet152	Detailed Retention Learning, recognizing images with ResNet-152. The bottleneck in TorchVision occurs at the second 3x3 convolution, as opposed to initial 1x1 convolution in the original work. ResNet V1 is the modification that improves accuracy.
InceptionV3	On ImageNet dataset, it has been demonstrated that InceptionV3 image recognition model achieves greater than 78.1% accuracy.
MobileNet	The MobileNet model is a network model that uses depthwise separable convolution as its fundamental unit. It has two layers in its depthwise separable convolution: depthwise convolution and point convolution.
Densenet169	The suggested model includes 4 convolutional layers, 2 maxpool layers, 1 fully connected layer, and three dense layers.
NasNetMobile	More than a million photos from the ImageNet collection were used to train the NASNet-Mobile convolutional neural network. There are more than 1000 different object categories which the network can identify in images, including keyboards, mouse, pens and other animals.
EfficientNetB0	The architecture EfficientNetB0 is launched. The output of this function is a Keras image classification model that can be trained using weights from ImageNet.
EfficientNetB1	The CNN construction and scaling approach EfficientNetB1 equally scales all depths, width and resolution parameters using a compound coefficient.
EfficientNetV2B2	It is a brand-new class of convolutional networks that train faster and more efficiently than older models. We develop this family of models by combining training-aware neural architecture search with scaling to jointly improve training speed and parameter efficiency. A search region that had been widened to include fresh processes like Fused-MBConv was utilized to hunt up the models. Our testing show that EfficientNetV2 models train up to 6.8 times faster than state-of-the-art models despite being much smaller.
ConvNeXtXLarge	ConvNeXT, is said to exceed Vision Transformers in terms of performance (ConvNet).

Fig. 15. Classification results for ConvNets and vision Transformers [38].

The accuracy achieved after combining all disease categories from the datasets of lettuce, soybean, and banana, which include both infectious and non-infectious conditions, is displayed in Tables VI through Table VIII.

EfficientNetV2B2 has the maximum accuracy of 95.81% from the Table VI, compared to a baseline accuracy of 56.38% from the NASNetMobile model.

C. What is EfficientNetV2?

The successor to EfficientNets is EfficientNetV2. EfficientNet is a family of models that was unveiled in 2019 and is optimised for FLOPs and parameter efficiency [39]. It makes use of neural architecture search to find the EfficientNet-B0 baseline model with the best possible accuracy and FLOPs trade-off. EfficientNets aggressively increase picture size, which results in high memory use and slow training. To overcome this problem, slightly altered the scaling rule and limited the maximum picture size to a lower amount. EfficientNetV2's technology, Deep learning models and training set both are becoming bigger and bigger. Efficiency in training is crucial in this situation. For instance, few-shot learning is demonstrated by the GPT-3 model, which has unheard-of model and training data volumes. However, retraining or enhancing the model is challenging because it takes weeks to train with thousands of GPUs. To construct this model, it combines scaling and training-aware Neural Architecture Search (NAS) to maximize training time and parameter effectiveness.

The findings of the models are remarkably comparable to those of the lettuce dataset, as can be seen from the Table VII, where EfficientNetV2B2 achieves a 93.97% accuracy while NASNetMobile achieves a baseline accuracy of 40.66%.

TABLE VIII. ACCURACY OF THE COMBINED DATASET (SPREADABLE + NON SPREADABLE) OF BANANA

Models	F1 Score	Accuracy(Banana)
Xception	0.9362	95.1865
VGG_19	0.8877	89.7714
ResNet152	0.9762	98.3153
InceptionV3	0.9408	95.9085
MobileNet	0.9677	97.1119
Densenet169	0.9746	98.0746
NasNetMobile	0.6562	65.3430
EfficientNetB0	0.9608	97.2323
EfficientNetB1	0.9685	97.7136
EfficientNetV2B2	0.8992	98.0746
ConvNeXtXLarge	0.9100	95.3069

The Table VIII makes it very evident that ResNet model has the maximum accuracy of 98.31% whereas NASNetMobile Baselines are at 65.34%.

D. What is ResNet?

ResNet was created with the goal of resolving computer vision issues. Deep residual networks that take advantage of remaining blocks to increase model precision. The concept of "skip connections," which is the foundation of the residual blocks, is the strength of this type of neural network.

1) 'Skip Connections' in ResNet: There are two ways that these skip connections work. The gradient is given a new shortcut to employ in order to address the issue of the fading gradient. Additionally, they give the model the capacity to pick up an identity function. This ensures that the performance of the model's top tiers is equal to or better than that of its lower layers. In conclusion, the residual blocks lets the layers acquire identity functions considerably more quickly. ResNet therefore decreases errors while boosting the efficiency for deep neural networks with far more neural layers. In other words, the skip connections integrate the outputs of older layers with outputs from stacked layers, enabling the training of networks that are far deeper than was previously possible.

Final point: ResNet, sometimes referred to as residual network, was a crucial development that changed how deep convolutional neural networks are trained for computer vision tasks. The venerable Resnet featured 34 layers with 2-layer bottleneck blocks, while more advanced models, like the Resnet50, used 3-layer bottleneck blocks that guarantee greater accuracy and faster training.

Tables VI to VIII shows the models in bold that are being examined for improvement of outcomes by modifying a hyperparameter, particularly the optimizer.

The optimizers that are considered for research work are:

- Adadelta
- Adagrad
- Adam

- Adamax
- Ftrl
- Nadam
- RMSprop
- SGD

2) *Stochastic Gradient Descent (SGD)*: This is a typical 'base' optimizer, and many others are variations on it [40],[41]. It is adjustable by varying the learning rate, momentum and decay.

a) *Learning rate*: The learning rate controls the magnitude of parameter updates at each iteration of the optimization algorithm. A higher learning rate allows for larger updates, potentially leading to faster convergence but also increasing the risk of overshooting the optimal solution. On the other hand, a lower learning rate results in smaller updates, which may slow down convergence but can help the model settle into a more accurate and stable solution.

b) *Momentum*: propels SGD in the desired direction while dampening oscillations. Essentially, it allows SGD to push past local optima, resulting in quicker convergence and reduced oscillation. A normal momentum value is between 0.5 and 0.9.

c) *Decay*: For the learning rate, you can provided a decay function. As training advances, this will alter the learning rate. Decay functions are- Time delay, Step delay and Exponential delay.

d) *Nesterov*: Nesterov momentum is a variant of the momentum method that provided better theoretical converge guarantees for convex functions. In practice, it is somewhat more effective than conventional momentum.

3) Adaptive learning rate optimizers

a) *Adagrad*: Adagrad is an optimizer with variable parameter-specific learning rates based on how frequently a parameter is altered during training [42].

b) *Adadelta*: Adadelta is an optimizer that dynamically adapts the learning rate during training without the need for a predefined initial learning rate. It uses a combination of the gradient information and a moving average of the past gradients to adjust the learning rate at each iteration, allowing for efficient convergence [43]. The learning rate in Adadelta is not explicitly set by the user but is internally calculated based on the algorithm's parameters and the gradient history.

c) *RMSprop*: RMSprop, like Adadelta, modifies the Adagrad technique in a very easy way to lessen its aggressive, monotonically declining learning rate [44].

d) *Adam*: Adam is an RMSProp optimizer update. It's essentially RMSprop with momentum [45].

e) *Adamax*: It is a first-order gradient-based optimization approach and a version of Adam based on the infinite norm. It is well suited to learning time-variant processes, such as voice data with dynamically changing noise circumstances, because to its capacity to alter the learning rate based on data features.

f) *Nadam*: Similarly, to how Adam is RMSprop with momentum, Nadam is Adam with Nesterov momentum.

4) *Ftrl*: "Follow The Regularized Leader" (FTRL) is an optimization technique created by Google in the early 2010s for click-through rate prediction [46]. It works well with shallow models with vast and sparse feature areas, this was discussed by McMahan et al. (2013). Both online L2 regularization (the L2 regularization described in the study above) and shrinkage-type L2 regularization are supported in the Keras version (which is the addition of an L2 penalty to the loss function).

The results of the cluster of models are not as linear as shown in Tables IX to XI, and the behavior of each model with its corresponding optimizer differs for different datasets.

The adamax optimizer dominates in every other model, whereas SGD optimizers have low efficiency rate due to its poor processing performance. SGD is a very fundamental technique that is seldom employed in applications nowadays. Another issue with the method is, its constant learning rate for each epoch. Furthermore, it is not particularly good at dealing with saddle points. Because of the frequent modifications in the learning rate, Adagrad performs better than stochastic gradient descent in general. It works well when dealing with sparse data. RMSProp produces comparable results to the gradient descent technique using momentum; the only difference is how the gradients are calculated. Finally, the Adam optimizer inherits the best aspects of RMSProp and other algorithms.

The Adamax optimizer provided a faster computation time, provided better results than other optimization techniques, it requires fewer tuning parameters. Adam is recommended as default optimizer for majority of applications as a consequence of all of this. Any application may have the highest chance of producing the finest outcomes if Adamax optimizer is used.

Finally, we discovered that even Adamax optimizer had certain drawbacks. In some circumstances, algorithms like as SGD may be more useful and perform better than the Adam optimizer. To pick the finest optimization method and obtain great results, it is critical to understand the needs and the type of data dealt with.

Since the performance of NASNet model with Adamax as optimizer, VGG19 model with Adagrad as optimizers and Xception model with Adamax as optimizer for Lettuce dataset NASNet model with Ftrl as optimizer, VGG19 model with Adagrad as optimizer and Xception model with Adamax as optimizer for soybean dataset and NASNet model with Adam as optimizer, Xception model with Adamax as optimizer for Banana dataset, although is highest with respect to other optimizer, yet its accuracies are incompatible for practical consideration.

Hence it is required to improve its performance.

One way to enhance performance is to train the model so that it is exclusively prepared for this dataset by initializing the weights to 0.

Why didn't the process initially explore retraining or fine-tuning the model from scratch?

Due to the small amount of data, creating new models from start would be a resource and time-intensive operation with no assurance of performance. These models were previously trained quite effectively. In order to improve performance efficacy in our case, it is thus preferable practice to load those pertained models and use the information that the two models have previously acquired in the course of their original work. Transfer learning and fine-tuning are commonly confused with one another since they are both parts of the same process. Many refer to the entire process as fine-tuning since we often do so after transfer learning.

However, fine-tuning involves more than just applied the weights from the pre-trained models. In order to adjust the model to the present job, it is also using prior information but freezing some layers while training the last layers at a slow learning rate. Convolution deep learning model results are shown to provide a better understanding of the entire process.

TABLE XII. ACCURACIES OF MODELS BEFORE AND AFTER RETRAINING WITH THE DATASETS

E. Concept of Underfitting and Overfitting

Why poor accuracy is viewed for few models over other models with various optimizers?

If a model adequately generalizes all new input data from the problem domain, it is considered to be a good machine learning model. Additionally, underfitting and overfitting are the main reasons why machine learning algorithms perform poorly [47].

F. Concept of Bias, Variance, Underfitting and Overfitting

1) *Bias*: Essentially, it is the error rate of the training data. Whenever the error margin is high, we say the bias is strong, while when it is low, the bias is low.

2) *Variance*: The variance is the difference in the error margin between the training and test sets of data. The variance is described as being high when it is large and low whenever

the difference between both the errors is small. Usually, we want to expand our model with the least amount of variance.

3) *Underfitting*: Underfitting is the term used whenever a statistical model as well as machine learning algorithm fails to capture the overall pattern of the data, i.e., when it performs well on training data but poorly on testing data. Its recurrence simply shows that model or method doesn't really adequately fit the data. It frequently happens when there are not enough data to build a solid model or when we try to build a linear model with too little non-linear data. Because its rules are too basic and flexible to be applied to such scant data, a machine learning model will probably make a number of inaccurate predictions under these circumstances. Underfitting may be avoided by utilizing more data and restricting the features through feature selection [48].

Underfitting, is when a model is unable to perform satisfactorily on the training dataset or generalize to new data.

G. Justifications for underfitting

- Low variance and high covariance.
- The used training dataset's size is insufficient.
- The model is rather basic.
- Training data has noise in it and is not being eliminated.

Methods to reduce underfitting

- Amplify model complexity.
- Boost feature count by doing feature engineering.
- Data noise should be removed.
- To achieve better outcomes, increase the period of training or the number of epochs.

1) *Overfitting*: An overfitted statistical model is one that cannot accurately predict events, based on test data [49]. When a model has been trained with a massive quantity of data, it begins to gain knowledge from the disturbance and incorrect data entries in the given dataset and when test data is used for testing, there is a lot of diversity. The model is unable to correctly recognize the data because of the overabundance of characteristics and distortion. Since these give machine learning algorithms greater freedom to build the model depending on the dataset, non-parametric and non-linear techniques are the primary sources of overfitting and can result in extremely illogical models [50]. Using a linear approach to analyze linear data is one strategy to avoid overfitting.

Overfitting, is a problem when the evaluation of machine learning algorithms on unknown data varies from the analysis on training data.

Overfitting has the following causes:

- Both variance and bias are high.
- The model is very sophisticated.
- The volume of training data.

Methods to reduce overfitting

- Expand the training data.
- Simplify the model.
- During the training phase usage of early stopping stay updated on the loss during the training period, and cease training as soon as it starts to rise.
- Regularization of the Ridge and the Lasso [51].
- To mitigate overfitting in neural networks, using a dropout technique.

H. How to Fit a Statistical Model Well?

When a statistical model makes predictions that are error-free, that is the ideal situation, it is said to be a good match with the data. This situation may exist anywhere between overfitting and underfitting. To understand the model, we need to look at how it performs over time as it learns from the training dataset.

As time goes on, the model would continue to learn, as a result, the model's accuracy just on test & training data will decrease over time. If the model is given an abnormally lengthy time to learn, the accumulation of junk and less important characteristics can make it more susceptible to overfitting. The model's performance will therefore suffer. In order to obtain a

good match, you must stop just as the error starts to grow worse. In both our concealed testing dataset & training datasets, the model is judged as being competent at this point.

I. How to find whether the model chosen is overfit or underfit?

When the validation accuracy increases after retraining and subsequently sharply decreases, the model is overfit. While in the event of underfit, there is just a slow, lower value rise in validation accuracy.

Models with excellent accuracy prior to retraining but significantly reduced accuracy after retraining are shown in Table XII. The validation accuracy and test accuracy in Table XIII are used to determine whether the model is overfit or underfit.

The model training details show that none of the models under consideration are overfit, but NASNetMobile model with Ftrl as optimizer for soybean dataset and NASNetMobile model with Adam as optimizer for banana dataset is underfit. This is because the mentioned model has good training accuracy but low validation and test accuracy making it underfit.

Also, the presence of overfit model does not affect the accuracies in present research case because of consideration of best fit model and early stopping criteria.

TABLE XIII. ACCURACIES OF MODEL WITH VALIDATION ACCURACIES

VI. PROPOSED METHODOLOGY

In the context of proposing a methodology for developing a high-accuracy convolutional neural network (CNN) model, particularly for tasks like image classification, the method integrates cutting-edge architectural principles from EfficientNetV2B2 with custom-designed elements, specifically a novel activation function and optimizer. Here's a detailed breakdown of the proposed methodology.

To further elucidate the rationale behind choosing the specific combination of ReLU and Tanh for the custom activation function and the integration of Adam and SGD characteristics in the custom optimizer, we can refer to the

previously discussed implementation and general principles in neural network optimization and activation functions as shown in Fig. 16.

A. Components of the Methodology

1) Base Architecture (EfficientNetV2):

- EfficientNetV2B2 [52] is chosen as the foundational architecture due to its state-of-the-art performance in image classification tasks.
- It utilizes a compound scaling method that uniformly scales the depth, width, and resolution of the network, making it highly efficient and effective.

Fig. 16. Proposed methodology.

2) Custom Activation Function:

- A novel activation function is introduced to potentially improve the learning process.
- The function, custom activation, is a combination of ReLU and Tanh functions. ReLU ensures non-saturation of gradients for positive values, enhancing learning speed, while Tanh provided output normalization, potentially aiding in stabilizing the learning process.

3) Custom Optimizer:

- Developing a custom optimizer aims to enhance the training efficiency and convergence rate.
- The optimizer combines elements of Adam (adaptive learning rates) and SGD (stochastic gradient descent), attempting to utilize the benefits of both.

4) Integration and Training:

- The EfficientNetV2B2 base model is loaded with pre-trained ImageNet weights to leverage transfer learning, accelerating the training process and improving initial accuracy.
- The top layers of the model are replaced with custom layers, including Global Average Pooling and Dense layers, utilizing the custom activation function.
- The model is compiled with the custom optimizer, and categorical cross-entropy is used as the loss function, suitable for multi-class classification tasks.

5) Training Strategy:

- Initially, the EfficientNetV2B2 base layers are frozen to preserve the pre-trained features, and only the custom top layers are trained.

- Subsequently, fine-tuning can be performed by unfreezing some of the top layers of the base model and continuing the training, allowing for refined feature extraction tailored to the specific dataset.

6) Evaluation:

- The model's performance is evaluated using accuracy metrics on a validation dataset.
- Regular checkpoints and monitoring are employed to track the training progress and prevent overfitting.

B. Integration of Concepts Based on Previous Results

The decision to combine these specific elements from ReLU, Tanh, Adam, and SGD is not only based on their individual strengths but also on empirical observations from previous implementations:

1) *ReLU and Tanh*: The combined use of ReLU and Tanh in various architectures has shown promising results in terms of faster convergence and improved accuracy, as these functions complement each other's properties.

2) *Adam and SGD*: Similarly, the integration of Adam's adaptive learning rate and SGD's generalization capabilities aims to create a more robust and efficient optimizer. This is based on observations where models trained with Adam initially show rapid improvement but sometimes fail to achieve the level of generalization that SGD can provide.

3) Outcomes:

- **Enhanced Model Performance:** By integrating the architectural efficiency of EfficientNetV2 with the novel elements of the custom activation function and optimizer, the model has demonstrated remarkable performance in image classification tasks. Notably, this approach has achieved a remarkable accuracy of 99.96%, positioning

it at the forefront of current image classification models. This high level of accuracy indicates an exceptional ability of the model to correctly classify images, minimizing both false positives and false negatives.

- **Superior F1 Score:** Alongside accuracy, the model has achieved an F1 score of 0.99. The F1 score is a more complex metric that considers both precision and recall, providing a more holistic view of the model's performance. An F1 score of 0.99 implies that the model not only accurately classifies the positive cases but also maintains a high rate of successfully identifying true negatives. This balance is crucial in scenarios where both types of classification errors carry significant consequences.
- **Improved Learning Dynamics:** The custom activation function and optimizer have played a pivotal role in enhancing the training process. These custom elements have contributed to improved training stability and accelerated convergence speed, enabling the model to quickly adapt and optimize its performance. The combination has been instrumental in achieving the high accuracy and F1 score, underlining the effectiveness of these custom components in handling complex learning tasks.

VII. CONCLUSION

This paper focuses on the use of transfer learning for the identification of spreadable and non-spreadable plant diseases. The study considers three different plant types, namely lettuce, soybean, and banana, and addresses the classification of the most prevalent diseases in these plants. The diseases are categorized into spreadable and non-spreadable diseases, treated as distinct classes in the analysis.

To evaluate the classification accuracy of different models, a comparative research approach is employed. The performance of 11 transfer learning models available in Keras are assessed on separate datasets for spreadable and non-spreadable diseases. Additionally, the models are evaluated on a combined dataset that includes five different portions of the plants, comprising both healthy and diseased parts. Early stopping criteria are set at a minimum of 20 to 30 epochs with a patience of 6 for comparison. It is observed that the metrics and accuracy of the models vary depending on the dataset being used. However, some of the selected models did not exhibit the anticipated high accuracy after training on the datasets.

To improve the model performance, various techniques such as optimizing the models and retraining them from scratch can be employed. These strategies aim to enhance the accuracy and effectiveness of the classification models for identifying spreadable and non-spreadable plant diseases. The available optimizers in Keras are taken into consideration in order to increase accuracy, that includes SGD, RMSprop, Adam, Adadelta, Adagrad, Adamax, Nadam, and Ftrl. However, this strategy only worked for higher models (like EfficientNet models, ConvNeXt); smaller models (like VGG-19, Xception) showed less improvement. The paper's major goal was to select a lower model since it is less complicated to train for and has a smaller width. Improving them suggests an upgrade to the

foundational CNN model, making the study more flexible. With certain models, there is a rapid fall in accuracy, leading it to be considered as either underfit or overfit. In the current instance, the NASNetMobile model is underfit, and situations of overfit are not evident because of the early stopping approach. VGG_19 model with Adadelta as optimizer without retraining and Xception model with Adamax as optimizer when retrained from scratch, outperform in terms of classification metrics for the datasets under consideration.

In addition to these strategies, the paper proposed a novel methodology focusing on the integration of an EfficientNetV2-style architecture with a custom-designed activation function and optimizer. The custom activation function, a hybrid of ReLU and Tanh, aims to enhance learning dynamics by combining the benefits of non-saturation (from ReLU) and output normalization (from Tanh). The custom optimizer, blending elements of Adam and SGD, is designed to achieve a balance between adaptive learning rates and effective generalization. This proposed methodology, especially with the EfficientNetV2's efficient scaling and advanced architecture, is expected to yield even higher accuracy and robustness in classifying plant diseases. Notably, this approach has achieved remarkable performance with an accuracy of 99.96% and an F1 score of 0.99 in the classification tasks, setting a new standard in the field and underscoring the effectiveness of combining advanced neural network architectures with innovative custom components for complex classification challenges.

VIII. FUTURE WORK

Moving forward, several key areas offer promising opportunities to extend and enhance the research presented in this study. One significant direction is the expansion and diversification of the dataset. By including a broader range of plant species, diseases, and environmental conditions, the models could be made more robust and generalizable across different agricultural contexts. Additionally, incorporating data from various geographical regions and employing data augmentation techniques could help address issues of overfitting and improve the model's performance on smaller or imbalanced datasets.

Integrating real-time data from environmental sensors is another avenue that could significantly enhance the predictive accuracy of the models, especially in relation to both biotic and abiotic plant stressors. By developing models capable of adapting to dynamic environmental conditions, the relevance and effectiveness of AI-driven solutions in agriculture could be substantially improved. Moreover, refining the custom activation function and optimizer introduced in this study remains an important task. Testing these components across different deep learning architectures and applications, such as pest detection or crop yield prediction, could assess their versatility and broader applicability.

Ethical considerations and societal impacts also warrant close attention. As AI-driven plant disease identification systems are deployed, it is crucial to address potential ethical issues, such as data privacy, fairness, and the implications for small-scale farmers. Moreover, the societal impacts, including potential job displacement and the need for upskilling agricultural workers,

should be carefully considered to ensure responsible and equitable deployment of these technologies.

Finally, exploring the scalability of the proposed models for large-scale farming operations is essential, particularly in terms of computational efficiency and resource constraints. Investigating cloud-based or edge-computing solutions could facilitate real-time disease detection in remote or resource-limited settings. Collaborative, multi-disciplinary research involving AI experts, agronomists, plant pathologists, and agricultural economists will be critical in developing holistic solutions that effectively address the complexities of plant disease management.

CONFLICTS OF INTEREST

The authors declare no conflict of interest.

FUNDING STATEMENT

This research did not receive any specific funding or financial support.

ETHICAL STATEMENT

This research was conducted in accordance with ethical principles, including informed consent, confidentiality, and adherence to relevant guidelines.

AUTHORS' CONTRIBUTION

Conceptualization: Asha Rani K P and Gowrishankar S jointly conceived and designed the research project.

Methodology: Asha Rani K P developed the methodology for the study.

Validation: Asha Rani K P and Gowrishankar S collectively validated the results and ensured their accuracy.

Formal Analysis: Asha Rani K P conducted the formal analysis of the data.

Investigation: Asha Rani K P and Gowrishankar S carried out the investigation and collected the necessary data.

Resources: Asha Rani K P and Gowrishankar S provided the required resources for the project.

Data Curation: Asha Rani K P curated and prepared the dataset for analysis.

Writing—Original Draft Preparation: Asha Rani K P wrote the initial draft of the manuscript.

Writing—Review and Editing: Gowrishankar S critically reviewed and Asha Rani K P edited the manuscript.

Visualization: Asha Rani K P created the visualizations used in the paper.

Both the authors have substantially contributed to the work reported and have approved the final version of the manuscript.

DATA AVAILABILITY STATEMENT

Images used for the study are obtained from CrowdAI [27] and PlantVillage dataset [28].

Design and Application of Intelligent Visual Communication System for User Experience

Chao Peng

School of Art and Design, Henan Industry and Trade Vocational College, Zhengzhou, Henan 450000, China

Abstract—The design and application of visual communication system should be human-oriented, but currently this is often ignored by designers, resulting in poor user experience of visual communication. In order to improve the experience effect of visual communication system, combined with the existing computer technology, this paper proposes an intelligent visual communication system for user experience. First, for the problem of extracting multimodal features of users, considering the characteristics of different modal data, long and short-term memory networks are used to extract features with contextual information, and multi-scale convolutional neural networks are used for visual modality to extract low-level features from video frames. In the cross-modal stage, the low-level features in the source modality are used to enhance the target modality features. Then, for the personalized recommendation problem of users, a graph information extractor is constructed based on the graph convolutional neural network to fuse the recommended user-item bipartite graph node neighborhood information and generate a dense vector representation of nodes, which can enhance the recommendation effect in the form of incorporating the graph information representation in the deep recommendation model with Transformer as the sequence feature extractor. The proposed method is experimentally validated to shorten the response time and improve the performance of the system, which can increase the user experience of the visual communication system. The system designed in this article is user experience oriented, combined with Multimodal Features and intelligent recommendation algorithms, effectively meeting the personalized needs of users and has certain practical significance.

Keywords—Visual communication system; user experience-oriented; multimodal features; recommendation algorithm

I. INTRODUCTION

Visual communication was first used in the 1920s and refers to a design activity that conveys visual information by means of all visual media. Visual communication design is defined as a design that uses visual symbols to communicate information. Visual communication is included in design, which is also a purposeful and creative human practice. However, visual communication is different from other designs in that its primary function is to transmit information, which is different from product design and environmental design, where the use of perception is the main focus [1]. It is different from the transmission of abstract concepts that is done by language, and it involves a wide range of fields.

Visual communication enables the exchange of ideas and information between individuals and individuals. Vision is a

physiological term. Vision is created by the action of light, the cells in the visual organ become active and excited, and the external visual content is processed by the visual nervous system to form vision. Through vision, human beings can perceive the size of external objects, the color of light and dark, color and the movement and stillness of objects, and in the process of perception, they can obtain various types of information that are important for the existence of the body. Vision is the most important of the five senses of human perception, and at least 80% of natural information in the natural environment is obtained through vision.

From the external form of visual communication, any act of communication must be carried out by means of physical symbolic media loaded with information, and these media must be visible. In the past, the most important medium of visual communication design was print, and the form of bearing was mainly two-dimensional plane [2].

Visual communication design is composed of three basic elements: text, logo and illustration. In order to communicate their thoughts and feelings and necessary information, humans have gradually developed language. The medium of spoken language is the beginning of the transformation and development of our communication behavior and the most fundamental medium in the progress of our social communication activities [3]. However, oral language has certain limitations. The first is the limitation of distance, because dialogue can only exist in close communication; the second is the constraint of time, because the oral language is not easy to record and store since there is no more export.

The visual communication system is a way for people to communicate through seemingly, using visual language to spread information. And the application of computer technology is to retouch and process the pictures. Nowadays, although people's living standards are improving, many people are busy with their lives and rarely have time to enjoy various scenery. In this case, the advantages of the visual tradition system emerge [4]. People do not have to go out to enjoy the scenery of various regions, which not only saves people's time but also satisfies their diverse visual experience. The relationship between visual communication among people, nature and society is shown in Fig. 1.

The visual communication system is an art form created by treating text, pictures, and colors as basic elements, and using advanced computer graphics software to process these elements so as to achieve a good artistic presentation effect, transforming a single performance into a more acceptable and favorite art form [5]. Nowadays, professional graphic image

processing software such as Photoshop software, CAD series. This software will be based on the needs of visual communication design, text and other elements of the processing, to achieve a good visual communication effect.

Fig. 1. Visual communication in the relationship between human, nature and society.

The application of these calculations in the visual communication system is discussed below: 1) Packaging design; 2) Advertising interface design; 3) Image processing technology. Nowadays, people like to use cell phones to take pictures, and in the process of taking pictures, the role of graphic image processing technology should not be underestimated, such as PS technology [6].

Computer technology is a way to use computer technology to modify, adjust and present. To achieve its function, it is necessary to build a specific scene of graphic description and create virtual optical effects with the help of light simulation technology, which is very closely related to computer geometry design. For computer graphics image processing technology, its data information is mainly from the subjective and objective world, the focus of image processing is to enhance the presentation of graphic images, which includes geometric image transformation, texture enhancement, color conversion and so on. At the same time, computer processing is based on digital signals, and it is widely used in the fields of medicine and aviation.

Based on the above background, this paper proposes an intelligent visual communication system for user experience in order to better improve the experience of visual communication system and combine with computer technology. Firstly, for the problem of multimodal feature extraction of users, an emotion recognition algorithm model with multimodal feature fusion is proposed, and each module and component of the proposed network model is introduced in detail. Then, for the user personalized recommendation problem, a new model architecture is designed by combining graph neural network with Transformer model to improve the recall of recommendation matching model. It is experimentally verified that the method in this paper has advantages in speed and performance.

The main research content of this article is as follows: First, for the problem of extracting multimodal features of users,

considering the characteristics of different modal data, long and short-term memory networks are used to extract features with contextual information, and multi-scale convolutional neural networks are used for visual modality to extract low-level features from video frames. In the cross-modal stage, the low-level features in the source modality are used to enhance the target modality features. Then, for the personalized recommendation problem of users, a graph information extractor is constructed based on the graph convolutional neural network to fuse the recommended user-item bipartite graph node neighborhood information and generate a dense vector representation of nodes, which can enhance the recommendation effect in the form of incorporating the graph information representation in the deep recommendation model with Transformer as the sequence feature extractor.

II. RELATED WORK

A. The Development Status of Visual Communication System

Visual communication system usually refers to the sender of information using visual symbolic elements to convey various information to the audience of information design, referred to as visual design visual communication includes two basic concepts, visual symbolic elements refers to what our eyes can see and can express the certain nature of things symbolic elements [7]. Visual communication design is also known as graphic design. The expressive design that we convey to the viewer's eyes and then shape the relevant content is collectively called visual communication design.

At this stage of analysis, the main content of visual communication design is still graphic design, professionals used to call it graphic design, visual communication design [8]. There is no great difference in the scope of design between graphic design and graphic design at this stage, and the relationship between them is a progressive one in terms of conceptual scope, not a contradictory and opposing relationship.

The study of non-planar elements of visual communication design is to break through the purely one-dimensional space to think and express around graphics, text and layout, and to advocate that all factors related to our design works should be included in the designer's scope of thinking and expression [9]. Visual communication design in the new era is not only about human vision, but also involves the sense of hearing and even touch.

In the context of the rapid development of computer media, visual communication technology, with its unique and innovative design images and language, has been gradually applied to the field of computer media, contributing to the development of the media. Visual communication technology is a kind of design activity that transmits and presents information to people through visual symbols, which are mostly expressed in the form of images [10]. Therefore, image design and processing is of great value in visual communication analysis, especially image fusion technology, which is very important for clear and complete presentation of visual images.

Computer graphic image processing techniques and visual communication systems are difficult to divide using standard

lines in many aspects. The commonality between the two is reflected in the basic professional curriculum, color and pattern design, which can be said to converge between them. The aesthetics, design methods, design concepts and development backgrounds are the same, and there are also similar concepts in the arrangement of lines and surfaces [11]. In addition, the design techniques produced by both are based on the same design techniques, use and depth of exploration. In this condition, the interpolation of the two can be better realized.

Many visual image fusion related research results have appeared. Some researchers use visual weight map for image fusion, decompose multi-scale images using cross bilateral filters, calculate visual weight values at different decomposition layers, and complete image fusion by integrating the results of weight value calculation, but the quality of fusion still needs further improvement. Recently, some researchers use adaptive PCNN to extract image information and fuse images by inverse NSCT, and use different fusion strategies to fuse images several times to increase the fusion accuracy, which has better fusion quality but longer computation process [12]. There are also researchers who enhance the infrared image based on the guiding filter, inject the infrared image information into the visible image effectively, complete the image fusion, and post-process the image to enhance the fusion effect, the process is more complex and time-consuming.

At this stage, the society is developing in the direction of diversification, and in the future, the use of computer processing technology and visual communication design will gradually expand, it is necessary to discuss and study the problems of technology application in depth, and under this condition, propose effective solutions to promote the application of technology to obtain a better visual communication effect.

B. Application of Multimodal Features in Recommendation Algorithm

The essence of recommendation algorithm is to connect users and items in a certain way, and search and recommendation should be divided into at least two stages: recall and sorting. In the recall phase, because of the large amount of data processed, fast speed, simple models and few features are required.

Due to the need of business scenarios, online evaluation is likely to be the evaluation of multi-objective fusion results. The evaluation of offline experiments on search ranking focuses on two aspects: efficiency evaluation and effectiveness evaluation. Efficiency evaluates response time and space consumption. Effectiveness is comparing the ranking results with the standard results. The evaluation metrics include: accuracy, recall, F-value, average accuracy [13]. The accuracy of the system can be evaluated according to three different paradigms. The first is that the recommendation algorithm can be used as a rating prediction model, predicting the user's rating for all the subject matter that did not produce an action. The second is to view the recommendation algorithm as a classification problem.

All of these algorithms currently have the following drawbacks: the recommended items are very similar to the items previously purchased by the user, the recommended results can only cover a small portion of the items, and they cannot explore the user's changing interests [14]. With the increasing popularity of posting contents on social platforms, people will post images, texts and videos on microblogs and other platforms to exchange their thoughts and express their emotions.

Based on this scenario, we propose to extract information from multiple modalities to give personalized recommendations through sentiment computing. A novel DNN approach is proposed to exploit the features and class relationships in video classification by fusing speech, video, and text modalities using a joint architecture for video classification. The classification performance is improved by imposing regularization based on the trajectory paradigm on the specially tailored fusion and output layers and exploiting the commonality shared among semantic classes, however, the feature representation and classification models are not learned jointly [15].

Multimodal learning refers to learning information from each of the multiple modalities and enabling the exchange and transformation of information from each modality. Multimodal deep learning refers to building neural network models that can perform multimodal learning tasks. The prevalence of multimodal learning and the heat of deep learning have given multimodal deep learning a vivid vitality and development potential. The fusion architectures are divided into joint architectures, coordination architectures and codec architectures according to the different ways of feature fusion. The fusion methods include three model-independent methods, early, late and hybrid, and two model-independent methods, multi-core learning and image model. Modal alignment has been the difficulty of multimodal fusion technology, and the two commonly used methods are display alignment and implicit alignment.

As a technique that enables machines to possess more human intelligence, multimodal deep learning is expected to gain significant momentum in the future. The next step can be to further investigate the insufficiently researched issues such as semantic conflict of modalities, multimodal combination evaluation criteria, and modal generalization ability, to deeply explore the difficult issues such as cross-modal transfer learning and non-convex optimization, and to promote the application of this technology in some new areas of deep learning [16]. In order to better capture the inter-modal relationships, this paper proposes to adopt a model-independent approach. A weighted sentiment feature fusion model based on is proposed, thus providing support for the later calculation of sentiment similarity.

Based on the above analysis, it can be concluded that traditional methods suffer from poor clarity after image reconstruction or excessive redundancy in visual information feature extraction, resulting in unsatisfactory extraction results, low extraction efficiency, and long training time. Therefore, considering the characteristics of different modal data, this paper uses long short-term memory networks to extract

features with contextual information, and uses multi-scale convolutional neural networks to extract low-level features from video frames. In the cross modal phase, low-level features in the source modality are used to enhance the target modality features, Integrating graph information representation into deep recommendation models to enhance recommendation performance. The experimental verification shows that the proposed method can shorten response time, improve system performance, and enhance the user experience of visual communication systems.

III. ALGORITHM DESIGN

A. User Multimodal Feature Extraction

The model proposed in this section implements feature fusion of three modalities: image, acoustic and text. For the features of different modalities, a suitable deep neural network is selected for low-level feature extraction, and then the cross-modal attention mechanism proposed in this paper is used for feature fusion.

With the progress of machine learning and deep learning, machines that can achieve learning cognition and express emotions in complex real-world environments are often more versatile and effective in human-computer interaction-related research in artificial intelligence applications, which makes the role of affective computing more and more important. The purpose of this paper is to learn effective modal representations for feature fusion of textual, acoustic and visual multimodal data by using a cross-modal attention mechanism approach. The model structure of this paper is shown in Fig. 2.

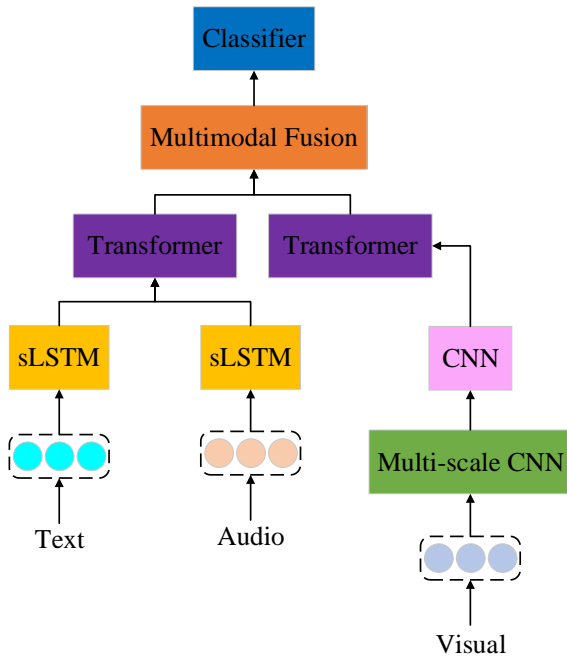

Fig. 2. Multi-modal feature fusion model.

The algorithm process is divided into four steps:

Step 1. In this paper, we use multimodal signals to detect emotions in videos, and use three modal data as the input of the model. The inputs include three low-level feature sequences from transcribed text, acoustic and visual modalities.

Step 2. Given the different characteristics of each modal feature, different neural networks are used to extract the features.

Step 3. After getting the different modal feature vectors, they are divided into two groups, text-acoustic and acoustic-visual.

Step 4. The output results of the two Transformer networks are spliced to obtain the fused features, and finally the prediction results are obtained through the fully connected network.

The advantages of LSTM networks in processing temporal data are: global processing and memory units. By processing data with time- or space-dependent characteristics, global information containing context-dependent information is obtained, and memory units are used to control the retention and removal of key historical information, enabling long- and short-term memory functions [17]. Therefore, it is more reasonable to use LSTM networks to capture the feature information of contextual cues. The textual feature vector obtained by using a one-way long and short-term memory network to capture temporal features, is calculated as follows:

$$t_i = sLSTM(T_i; \theta_i^{lstm}) \quad (1)$$

Since speech is highly random and correlated between adjacent frames, it is mainly reflected in the phenomenon of co-articulation when speaking, where words with connections before and after have an impact on the currently spoken word. Therefore, in this paper, for acoustic modality, the same LSTM network is used for feature extraction, and the acoustic feature vector is obtained and calculated as follows:

$$a_i = sLSTM(A_i; \theta_i^{lstm}) \quad (2)$$

For visual features, it is necessary to segment the video to obtain each video frame containing key feature information, sample it, and then use the face images in all video frames as the output information of acoustic modality. Therefore, for the visual modality considering the size of the input image data and the performance of the experimental equipment in this paper, MSCNN is applied and a set of feature maps are obtained, calculated as:

$$G_a^{MSCNN}(V, \theta) = \{v_a | a \in \Omega\} \quad (3)$$

Where V denotes the input features.

For the different characteristics of the dataset, the first two are regression tasks, i.e., dichotomous tasks, and the commonly used loss functions are L1 Loss (Mean absolute loss, MAE) and L2 Loss (Mean Square Error, MSE). The MAE is calculated with absolute error as the distance, and is computed as shown below:

$$MAE = \frac{1}{n} \sum_1^n |y_i - \hat{y}_i| \quad (4)$$

MSE is also often used as a regular term, but because of the presence of the squared term, the gradient tends to explode when the predicted value differs significantly from the target value. Therefore, this paper uses MAE as the loss function and also introduces a varying learning rate.

B. User Recommendation Algorithm Design

Recommendation system is a research direction closely integrated with industrial applications, and the research of recommendation system from the academic point of view has certain limitations, therefore, the research on it needs to focus on the sub-problems of the recommendation task, or simplify the complex scenario, and optimize the sub-structure of the whole system from a certain point of view.

With the development of new neural network structures and efficient information extractors in recent years, the problem is solved by introducing graphical neural networks and Attention mechanism. Therefore, this chapter will introduce recommendation models based on graphical neural networks and Transformer structures, and show the effect of their application on classical datasets of recommendation systems and comparative experiments [18]. In addition, although the timestamps of interactions are introduced in the training process to constitute sequential information, it is necessary to distinguish this approach from intra-session recommendation, where individual sessions occur for a short period of time, while this model faces a long time span of data, which is still essentially using relatively static data for matching user preferences and item traits.

The core of the recommendation model proposed in this section is shown in Fig. 3, which incorporates information from the graph perspective of user-item interaction and applies an efficient feature extractor Transformer structure in order to obtain an effective method for item characterization with certain industrial practical capabilities.

Compared with graph embedding methods, the biggest advantage of graph neural networks in recommender system construction is their ability to be trained as part of an end-to-end model for collaborative filtering based on the introduction of graph structure. It is possible to use both node information and graph structure information.

The way node information is updated in a graph neural network is divided into two parts, i.e., message construction and message delivery. In each layer of GNN, messages can be passed along the edges of the graph. Each node receives messages from its neighbors and uses appropriate aggregation and mapping functions to construct new messages, which are used as node information in the next layer and also represent the new node features aggregated to the neighboring nodes' information. The message construction part mainly consists of the F mapping function, and the Sigma aggregation function. The Sigma function can be replaced by any aggregation function, and the F mapping function can be set as a single layer neural network:

$$M_i^r = F\left(\sum M_u^{r-1}, M_i^{r-1}\right) \quad (5)$$

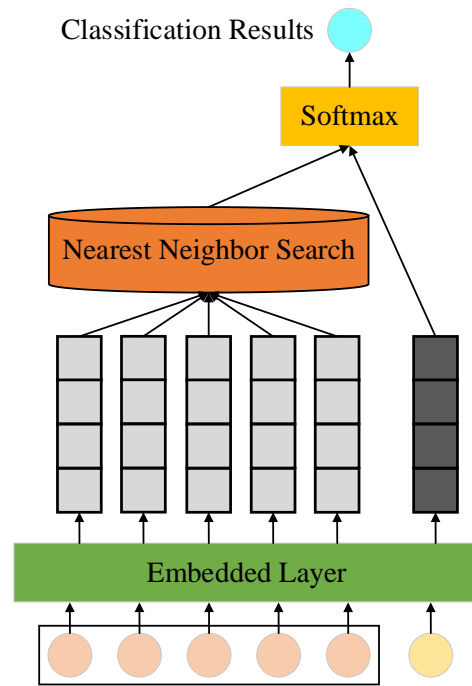

Fig. 3. Recommended model.

The difference between item-based and user-based recall algorithms lies in the pre-calculation of which of the two representations is used for nearest neighbor search. For most of the recommendation scenarios including movies and e-commerce, the recommended items are often relatively fixed, while the users are in constant high-frequency dynamic changes, and for large-scale e-commerce sites, the size of the users may be more than 10 times the size of the items.

The graph neural network structure used in the model is GCN, which uses the adjacency matrix, the degree matrix and the hidden feature matrix of the current layer to obtain the connection relationship between the nodes and the node features, and iteratively updates the node features:

$$H^{(l+1)} = Leaky\ Relu\left(D^{-\frac{1}{2}}AD^{-\frac{1}{2}}H^{(l)}W^{(l)}\right) \quad (6)$$

where the node hidden feature matrix H is the X-feature matrix in layer 0, the input layer.

In the training phase, the integrated features will be interacted with the candidate items, also embedded via items, in order to train the model parameters through a binary classification task. In the online service phase of the matching model, this feature tensor will be used as the retrieval target to obtain the matching result set by performing a K-NN nearest neighbor search from the full set of candidate items.

IV. EXPERIMENTS

A. Experiment of Feature Extraction

Simulating pulse neural networks using computers requires powerful computing power. This article relies on the hardware devices listed in Table I for experiments:

TABLE I. HARDWARE TABLE OF DEVELOPMENT ENVIRONMENT

Development Environment	Parameter
GPU	V100S 32GB x 4
CPU	Intel(R) Xeon(R) Gold 6240R
Memory	38GB
Disk	7TB

The experiments first require setting hyper-parameters based on previous experience, and then tuning the parameters. The trainable parameters are obtained by back propagation, and the hyper-parameters must be set before building the entire network architecture. Each hyper-parameter related to the network structure needs to be specified first. For hyper-parameters such as discard rate and number of heads in the cross-modal attention module, a basic grid search method is performed in this paper. When the verification performance reaches a steady state, the learning rate is decayed by a factor of 10, making it more likely that the model will converge to a locally optimal solution, and the experimental results are cross-validated by a factor of 10. Two metrics, accuracy and F1 score values, are used to evaluate the performance of the algorithm model.

In order to fully verify the performance of the model proposed in this paper, the baseline models for experimental comparison are representative and recent algorithmic models with excellent performance. The baseline models are basically as follows: 1) EF-LSTM: a traditional network model using early fusion network and late fusion. 2) RMFN: a recurrent multi-stage fusion network that decomposes the fusion problem into multiple stages, each stage focusing on a subset of multimodal signal on a subset of the signal to achieve specialized and efficient fusion. 3) MFM: A multimodal decomposition model optimized for the joint generation of discriminative objectives for multimodal data and labels.

Table II gives the results obtained from the baseline model and the model proposed in this paper in the dataset, where the higher values of evaluation metrics Acc and F1 scores are better, and the comparison with the evaluation metrics Acc and F1 scores of different baseline models is used to demonstrate the optimal performance of the multimodal feature fusion sentiment recognition model proposed in this paper. In order to display the comparison results more intuitively, the best data shown in each column are bolded. It can be obtained that the sample recognition accuracy reaches 91.38%, the accuracy reaches 88.64%, and the average accuracy reaches 87.18%. The recognition accuracy of happy, angry and neutral emotions is the highest.

TABLE II. COMPARISON OF FEATURE EXTRACTION EFFECT OF EACH MODEL

Model	Acc	F1	Average
EF-LSTM	85.26%	83.72%	82.57%
RMFN	87.49%	86.43%	83.49%
MFM	90.54%	86.81%	85.36%
Ours	91.38%	88.64%	87.18%

Taking the Last.FM and Movielens datasets as examples, the distribution of the number of model training interactions is shown in Fig. 4. Although the overall interaction data scale is above 10M, the interaction volume has an obvious long-tail effect, which leads to the fact that the interaction volume of most items cannot meet the training scale of the model, which is reflected in the training results, only a very small number of items can be fully trained in a short time, and the overall training speed is slow. Therefore, negative sampling was introduced to expand the data in the training. When the negative sampling ratio is set to 5, that is, whenever a positive interaction is put into the training set, 5 samples of items that have not been interacted with the user will be collected at the same time, and during training, these 5 negative samples will be processed negatively, which greatly increases the training efficiency.

Fig. 4. Experimental results of model training interaction.

B. Personalized Recommendation Experiments

In the personalized recommendation experiments for users, the datasets used are: 1) Amazon-Music: containing 125,998 shopping reviews generated by 5,453 users and 65,833 items, with an interaction density of 0.35%. 2) Amazon-App: containing 341,784 shopping reviews generated by 18,328 users and 32,684 items, with an interaction density of 0.57%. The interaction density was 0.57%. 3) Movielens movie rating dataset, which contains user ratings of movies from the Movielens movie rating website collected by GroupLens.

The comparison methods are: 1) Popular+ClASS(PopClass): a dynamic recommendation strategy based on popularity, which introduces the consideration of user preference categories. 2) DeepWalk: a classical graph embedding technique, which constructs a sequence of nodes by random wandering on an undirected graph and applies (3) YoutubeDNN: In the matching phase, YoutubeDNN tries to use the information of items that users have interacted with and additional auxiliary information such as time information to input into the deep neural network as the user's representation, and then train the network through the multi-category classification task of videos. The steps can be broken down into two phases: network pre-training and model service.

The hit rate performance of our model and the comparison algorithm are shown in Table III. Since the Amazon-Music dataset is the sparsest, it indicates that there is incomplete training and therefore the overall hit rate is lower than the other datasets. In DeepWalk, the overfitting may be caused by the sparsity of the training data, but the graph-based embedding method is able to achieve the best hit rate performance based on a simple structure. However, the graph-based embedding method is able to achieve excellent performance based on a simple structure, which fully illustrates the importance of using the graph structure information in the field of recommendation recall.

In contrast to Transformer-Encoder, which also extracts sequence information, it should be noted that although this model achieves a good hit rate level, in industrial applications, the recall of target items by a single method only reflects a limited perspective of the recall strategy, and multiple fusion recall is needed in conjunction with business scenarios.

TABLE III. EXPERIMENTAL RESULTS OF HIT RATE OF EACH MODEL

Model	Amazon-Music	Amazon-App	Movielens
PopClass	13.25%	8.56%	4.52%
DeepWalk	24.63%	6.49%	12.61%
YoutubeDNN	22.84%	7.54%	10.84%
Ours	27.38%	11.27%	15.06%

Fig. 5. Experimental results of each model under different implicit vector dimensions.

The experimental results of each model with different implied vector dimensions are shown in Fig. 5. It can be seen from the figure that the larger the implied vector dimension of the model, the better the performance of the model, because the larger the implied vector dimension, the more information the nodes contain, the finer the granularity of the representation of the user's interest, and thus the deeper and finer the granularity of the user's interest preference can be captured, and the recommendation effect will be better. However, due to the

nature of the neural network structure, the implicit vector dimension increases the time and space complexity of the model, so the implicit vector dimension should be set to balance performance and resource consumption.

V. CONCLUSION

In order to improve user experience, this paper proposes an intelligent visual communication system oriented to user experience, and applies user experience to the algorithm design of the visual communication system to realize the design and application of personalized visual communication. First, for the user multimodal feature extraction problem, based on the cross-modal attention mechanism in its module, the target modal features are enhanced by including low-level features from other modalities. The output of multiple attention heads in it enhances the representational capability of the network and further better improves the effect of modal fusion. Then, for the personalized recommendation problem, the Transformer is used as the main structure of the sequence feature for extractor to replace the DNN in the base model, and the graph convolutional neural network module with end-to-end graph learning capability is combined with the dense vector representation of items in the recommendation matching stage to improve the hit rate of the matching algorithm. It is experimentally verified that the method in this paper achieves a large performance improvement on three different datasets compared with other advanced network models.

Although convolutional neural networks have developed relatively maturely in the field of visual recognition, capturing subtle changes in visual images that are difficult to detect, efficiently extracting facial expression features, and effectively utilizing these features are key issues; Meanwhile, how to fully consider the changes in key facial features, as well as the fusion of global and local features, is also a major key factor in the process of facial expression recognition. Although the paper proposes a visual feature recognition method based on convolutional neural networks to address the above issues, which has improved the recognition accuracy to some extent, our work still has some shortcomings and needs to be improved and perfected in the following aspects in the future.

Firstly, for static image recognition, due to the limitations of the dataset itself, the accuracy of recognizing certain expression categories is still lacking. Therefore, future work will focus on training and validating the proposed method on datasets with more evenly distributed expression labels.

Secondly, the method proposed in this article has not yet been applied to datasets collected in real environments. Future work will train and validate the method using datasets collected in real environments.

Finally, for the local collection end, when performing facial expression recognition, only one person's facial image can be recognized, and the problem of storing expressions when multiple people appear simultaneously has not been solved; For online management, we hope to achieve real-time facial expression collection on web pages in the future to reduce costs.

Synchronous Update and Optimization Method for Large-Scale Image 3D Reconstruction Technology Under Cloud-Edge Fusion Architecture

Jian Zhang^{1*}, Jingbin Luo², Yilong Chen³

Guangdong Power Grid Co., Ltd, Guangzhou 510030, China^{1, 2}

Guangdong Power Grid Co., Ltd, Guangzhou Power Supply Bureau, Guangzhou 510000, China³

Abstract—Aiming at the problems of limited bandwidth and network delay in the traditional centralized cloud computing mode during large-scale image processing of transmission and distribution digital corridors, a synchronous updating and optimization method for large-scale image 3D reconstruction technology under cloud-edge fusion architecture is proposed. Based on the cloud-side fusion architecture, the image data of the transmission and distribution corridor is preprocessed, feature extraction is performed by deep learning, synchronous updating is performed by using the cloud-side cooperative network, and matching and 3D reconstruction are performed according to the order of the point cloud data; given the dynamically changing characteristics of the image data in the cloud-side fusion environment, the incremental learning is combined with the continuous learning and synchronous updating of the model parameters, to realize the adaptive updating mechanism. The research method utilizes the advantage of cloud-edge fusion architecture to distribute the computational tasks to the cloud and edge, realizing parallel processing and load balancing, and improving the accuracy and efficiency of 3D reconstruction. The experimental results show that the research method in this paper has an image feature point matching rate as high as 96.72%, a lower network latency rate, and a higher real-time performance, which provides strong technical support for the optimization of the transmission and distribution digital corridor 3D reconstruction technology.

Keywords—Cloud-edge fusion; cloud-edge collaboration; 3D reconstruction; synchronized update

I. INTRODUCTION

With the in-depth promotion of intelligent transformation in the power industry, 3D reconstruction technology is widely used in the construction of digital corridor models, and the study of 3D reconstruction technology with efficient synchronization performance is of great significance to enhance the construction and management efficiency of transmission and distribution corridors. The study in [1] designed a point cloud data extraction process based on tilt photography technology, combined with the optical distortion problem for 3D modeling of transmission lines, which can quickly obtain the target shape, but the throughput of remote image communication is not high and the transmission rate is low. The study in [2] fuses transmission line channel information based on visible image sequences, sets the model

geometry through standardized mapping space, establishes mapping relationship with power line point cloud data and images, and constructs 3D reconstruction model under the constraint relationship function, but the technique lacks double-ended synchronous communication system and centralized network information processing efficiency is not high. The research in [3] introduces the cloud-side cooperative function to realize the global resource sensing and cooperative scheduling of star-earth fusion network, and combines the arithmetic network technology to provide a new technical path for the synchronous transmission of large-scale image 3D reconstruction. The study in [4], on the other hand, provides a comprehensive overview of the development history of image 3D reconstruction technology, evaluation methods and datasets. Image 3D reconstruction techniques have made remarkable progress, from early geometric model-based methods to today's advanced algorithms based on deep learning, the accuracy and efficiency of reconstruction have been continuously improved. However, current 3D reconstruction techniques still face many challenges. On the one hand, the synchronized processing of large-scale image data puts forward extremely high requirements on computational resources and storage capacity, which are often difficult to be met by traditional centralized architectures. On the other hand, images from different data sources differ in quality, angle, illumination, etc., how to effectively fuse these images for accurate 3D reconstruction is still a difficult problem. Therefore, this paper provides new ideas and methods to solve the difficulties in large-scale image 3D reconstruction. By fully utilizing the advantages of cloud-edge fusion architecture, it can effectively integrate computational resources, improve reconstruction efficiency and accuracy, and meet the urgent needs of image 3D reconstruction in different fields. Innovative use of cloud computing and edge computing technology for organic combination, cloud-edge cooperative network can effectively improve the double-end communication throughput, providing powerful technical support for large-scale image 3D reconstruction. At the same time, the 3D reconstruction algorithm is optimized and improved by combining deep learning to improve the reconstruction accuracy and efficiency, providing a more efficient technical path and solution for the 3D reconstruction of transmission and distribution corridors, which improves the efficiency accuracy and enhances the robustness of large-scale image reconstruction from the technical level.

II. TRANSMISSION AND DISTRIBUTION DIGITAL CORRIDOR IOT CLOUD EDGE CONVERGENCE ARCHITECTURE

A. Cloud-edge Fusion Network Architecture

The transmission and distribution of digital corridor image 3D reconstruction system mainly adopts the cloud-edge fusion system architecture, including three key components: cloud center, edge domain, and edge nodes (see Fig. 1).

Cloud Center. The cloud center is the core of the whole architecture, responsible for processing and fusion of multi-dimensional data of the system, which can support massive 3D reconstruction image and data storage as well as synchronous data-parallel update. The cloud center aggregates the edge nodes and resource pools through the high-speed network and provides big data applications for the system through deep learning and association algorithms [5].

Edge domain. The edge domain is the "bridge" connecting the cloud center and edge nodes, with the function of data processing and forwarding. It is deployed in each key position of the transmission and distribution corridor according to the actual needs, and acquires real-time corridor information by collecting sensor data, video streams, etc., extracts key features and information through preliminary pre-processing, and then transmits them to the cloud center to realize "data in the cloud" [6].

Edge node. Edge nodes are multi-dimensional sensing front-end devices deployed at the site of transmission and

distribution corridor, with the ability to data acquisition, processing, and execution of control commands. The front-end node acquires the image, temperature, humidity, and other environmental information of the corridor in real time, adjusts the parameters of the equipment to carry out special operations, and sends the front-end information to the cloud center through the convergence of the edge domain.

B. Cloud Data Center Structure Optimization

Large-scale image three-dimensional reconstruction technology requires parallel processing of massive data, the cloud data center should take large-capacity, high-speed, and stable equipment to optimize the system hardware structure. The cloud data server cluster selects Dell PowerEdge R430 dual-channel rackmount servers with powerful computing capability and scalability, which can meet the needs of large-scale data processing and computing. AS13000 storage system is selected to provide high-capacity, highly reliable storage with data redundancy and backup functions to prevent data loss and ensure data security and fast reading [7]. The switch model is S5130S-28S-EI, which ensures a high-speed and stable network connection and supports the transmission and exchange of large amounts of data. The NGFW4000-UF firewall with a wide coverage domain is selected to guarantee the security of the Cloud Edge Convergence network, preventing external attacks and intrusions, reducing the risk of data loss, and ensuring the stability and efficiency of data transmission. Fig. 2 shows processor architecture.

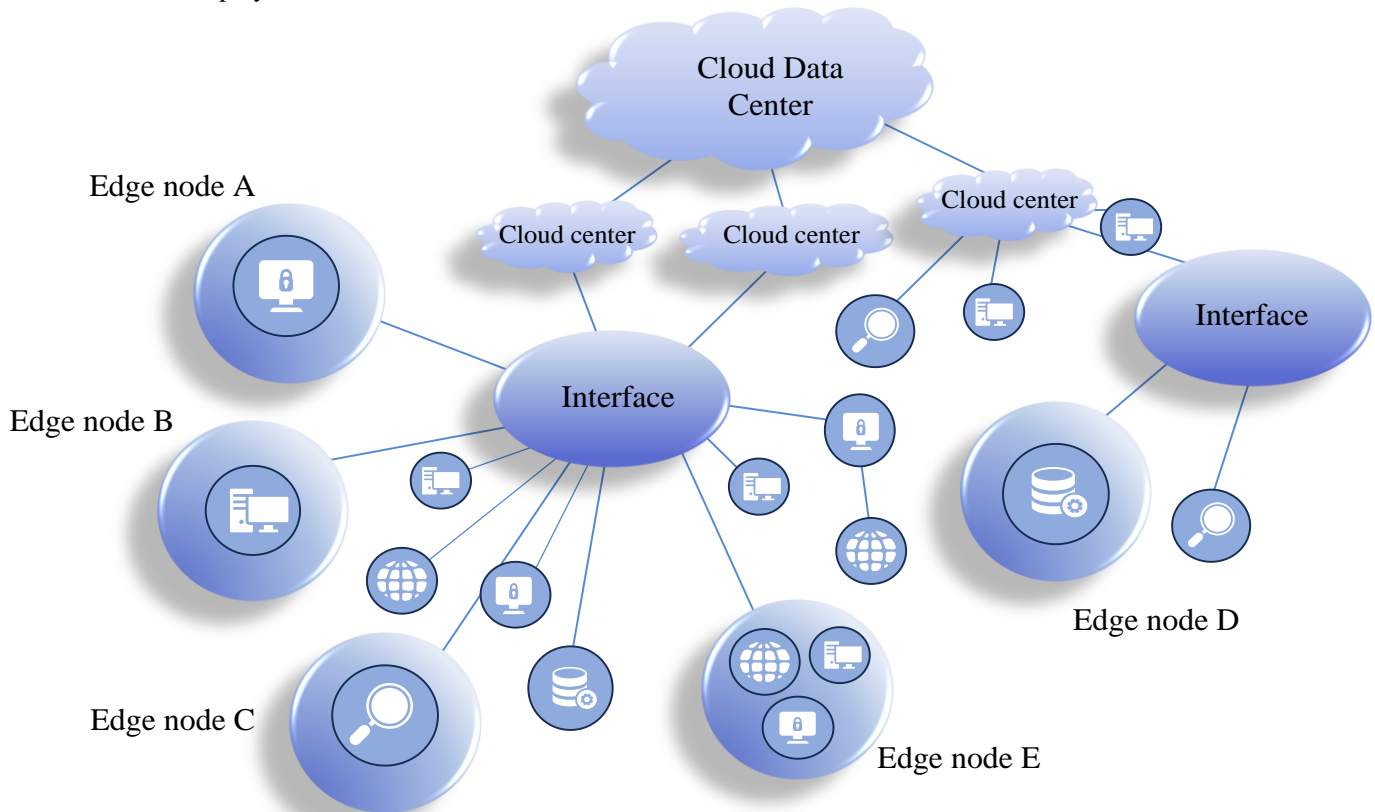

Fig. 1. Cloud edge converged network architecture.

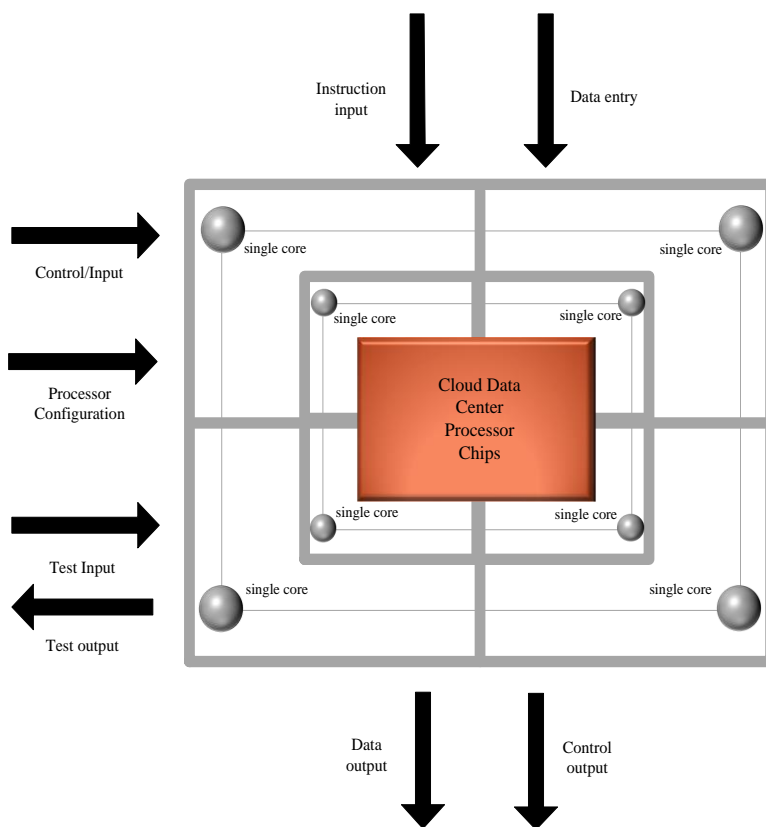

Fig. 2. Processor architecture.

C. Edge Node Structure Optimization

The front-end edge devices mainly include the SICK LMS111 high-precision laser distance sensor, ON Semiconductor MT9V034 high-definition image sensor, DHT11 temperature and humidity sensor, ADXL345 acceleration sensor, which can detect the distance of the transmission and distribution corridor, image, temperature and humidity and motion status [8]. The core terminal equipment of the edge domain is the Lenovo tower server, which is

rugged and suitable for complex environments, and can aggregate massive data in the domain for transmission and pre-processing. Moxa EDS-408A-MM-SC switches provide real-time synchronized edge network connection for the system, which is characterized by high bandwidth and low latency and supports a variety of communication protocols with strong adaptability to guarantee the high efficiency and stability of the edge domain network. Fig. 3 shows edge-core server CPU architecture.

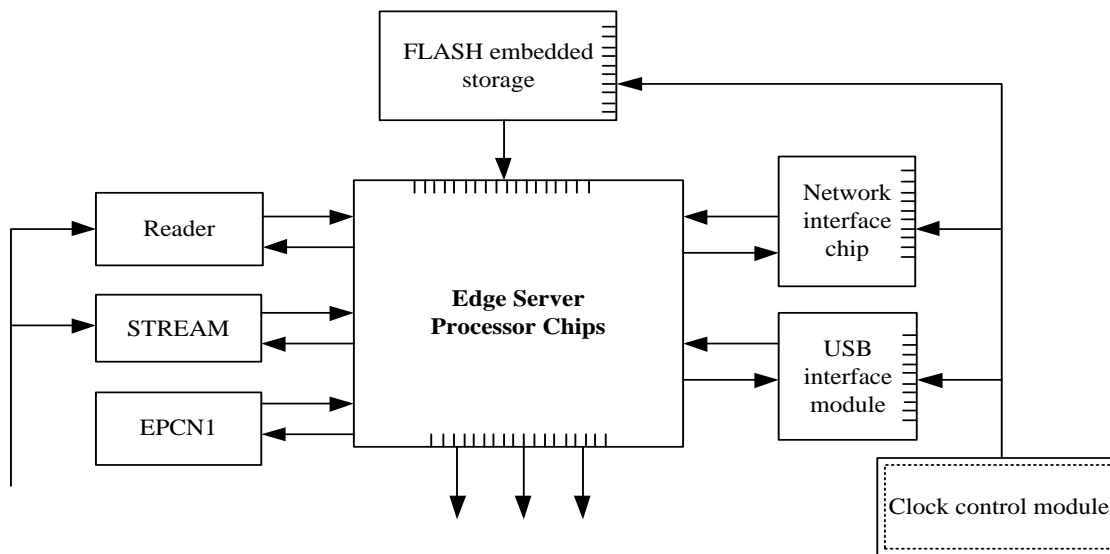

Fig. 3. Edge-Core server CPU architecture.

III. OPTIMIZATION OF IMAGE 3D RECONSTRUCTION TECHNIQUE BASED ON CLOUD EDGE FUSION

A. Non-Sampling Transform Fusion

Aiming at the complex reality of transmission and distribution corridors, non-sampling directional filters are installed at the front end, which can perform filtering operations on signals or images in a specific direction to extract and enhance the signal features in a specific direction while suppressing the interference and noise in other directions, which has important applications in the field of three-dimensional image reconstruction and other fields [9]. Firstly, the image is decomposed at the second level according to the directional component to obtain the quadrant sampling formula:

$$\begin{cases} S_l(i) = 2 * [i / 2] - 2^{l-3} + 1 \\ S^p(i) = 2 * I_0^{p-3} - I_3^{S_l(i)} \end{cases} \quad (1)$$

In the formula, $S_l(i)$ and $S^p(i)$ are the quadrant filter function formulas for random pixel points i in the horizontal and vertical directions, respectively, l is the horizontal quadrant parameter, p is the vertical quadrant parameter, and I is the matrix threshold of the sampling points. The decomposition is performed iteratively for three or more times according to the above steps, and the source image is decomposed into low-frequency sub bands and high-frequency sub bands, which are normalized by wavelet transform. The low-frequency sub band signals are average weighted according to the low-frequency criterion:

$$\begin{cases} P_l = \sqrt{\frac{1}{LP} \sum_L \sum_P [f(i, j) - f(i, j-1)]^2} \\ P_p = \sqrt{\frac{1}{LP} \sum_L \sum_P [f(i, j) - f(i-1, j)]^2} \end{cases} \quad (2)$$

$$P_s = \sqrt{P_l^2 + P_p^2} \quad (3)$$

In the formula, P_l and P_p are the spatial row and column frequencies of the low-frequency sub band averaged and weighted, respectively, and P_s is the low-frequency spatial frequency criterion. The high-frequency sub band signals are regionally energy maximized according to the high-frequency criterion:

$$\begin{cases} E_l(i, j) = \sum_1^{i-1} \sum_1^{j-1} W(i, j) [l(i+L, j+P)]^2 \\ E_p(i, j) = \sum_1^{i-1} \sum_1^{j-1} W(i, j) [p(i+L, j+P)]^2 \end{cases} \quad (4)$$

In the formula, $E_l(i, j)$ and $E_p(i, j)$ are the energy maxima of the high-frequency sub band pixel point (i, j) in the horizontal and vertical regions of space, and W is the regional energy weighting coefficient. The transform fusion is performed by the filtered dual channel, so that the source image is finely preprocessed at the edge end. Fig. 4 shows convolutional neural network workflow visualization.

Fig. 4. Convolutional neural network workflow visualization.

B. Edge Detection Constraints

For the source image collected by the infrared laser equipment, there is an edge variability problem, to further guarantee the authenticity of the fused image, the edge image information needs to be evaluated constraints. The richness of the image elements is evaluated through the entropy formula:

$$R = \sum_{H=1}^{i=0} P_i \ln P_i \quad (5)$$

In the formula, R represents the entropy value of image

pixel content richness, H is the image resolution grayscale, and P_i is the distribution frequency of pixel point i . The image normalized mean weight δ is introduced for standard deviation calculation to evaluate the image grayscale clarity level:

$$\Delta C = \sqrt{\sum_{L=1}^{i=0} \sum_{P=1}^{j=0} [f(i, j) - \delta]^2 / lp} \quad (6)$$

The larger the standard deviation calculation results,

indicating that the fusion image grayscale dispersion value is higher, the worse the fusion effect, the authenticity and relevance do not meet the standard, need to repeat the above

steps of convolution iterative optimization [10]. Fig. 5 shows grayscale test of edge image.

Fig. 5. Grayscale test of edge image.

C. Feature Point Extraction Matching

The preprocessed image information at the edge end is transmitted to the cloud data center for source data archiving in real time via the edge domain network. For the image of the transmission and distribution corridor edge points, line points, corner points, bright spots, dark spots, and other key feature points for localization and extraction, through the Gaussian function convolution to generate three-dimensional scale space:

$$K(x, y, z) = G(x, y, z) \times (x, y) \quad (7)$$

In the formula, $K(x, y, z)$ is the 3D scale space mapping coordinates of the image 2D coordinates (x, y) and $G(x, y, z)$ is the Gaussian function convolution coordinate parameter. The Gaussian difference is utilized to detect the three-dimensional spatial coordinate point poles:

$$J(x, y, z) = (G(x, y, z\beta) - G(x, y, z)) * (x, y) \quad (8)$$

According to the calculation results, the three-dimensional spatial discrete extreme points are extracted, and then the feature points are localized by three-dimensional quadratic function fitting to eliminate the edge points with poor stability [11]. Due to the existence of dynamics in the real-time monitoring of cloud edge fusion, the gradient method is used to carry out a balanced and stable simulation of the moving

structure of the feature points in a specific direction, and the description of the baseline feature direction is obtained as:

$$D(x, y) = \sqrt{(K(x+1, y) - K(x-1, y))^2 + (K(x, y+1) - K(x, y-1))^2} \quad (9)$$

$$Dir(x, y) = \tan^{-1} \left(\frac{K(x, y+1) - K(x, y-1)}{K(x+1, y) - K(x-1, y)} \right) \quad (10)$$

In the formula, $D(x, y)$ denotes the gradient value of the feature point and $Dir(x, y)$ denotes the spatial reference direction of the feature point. The feature points are extracted from the 3D reconstructed spatial point cloud to generate a descriptor. The descriptor contains the local geometric information of the feature point, and the SIFT (Scale Invariant Feature Transform) algorithm is used to generate the feature point description vector:

$$M(x_i, y_i) = Dir(x, y) * \Delta T(x_i + y_i) \quad (11)$$

In the formula, $M(x_i, y_i)$ is the dynamic scale description vector in the reference direction and ΔT is the 3D coordinate mapping dynamic time difference. Based on the description vector, dynamic image 3D point cloud reconstruction can be performed, which utilizes the camera position and point cloud information to project each pixel point of the image into the 3D space [12].

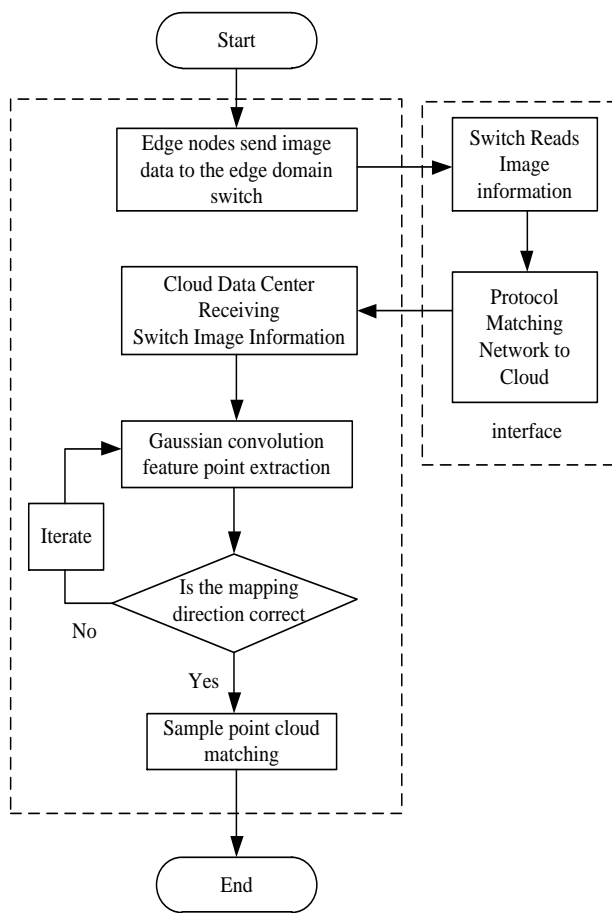

Fig. 6. Cloud edge collaborative feature point extraction process.

D. Point Cloud Synchronized 3D Reconstruction

Based on the basic geometric structure and moving position described by the feature point vectors, the key feature points with high edge dispersion are extracted to construct a sparse point cloud for localization and reconstruction in 3D space [13]. However, the sparse only contains a small number of salient feature points, which cannot accurately describe the 3D details of the transmission and distribution corridor, and further dense point cloud reconstruction is required [14]. First, the data collected by the edge devices are synchronously transmitted to the cloud data center, and the sparse point cloud is arranged from near to far according to the camera positional distance to obtain the feature-matching initialization sequence:

$$A(w) = \left\{ w_i \mid w_i \in w_m, n(w) \cdot \frac{O(w)O(w_i)}{|O(w)O(w_i)|} > \cos \alpha \right\} \quad (12)$$

In the formula, $A(w)$ is the set of sequence images, w_i denotes the image i , $O(w)$ is the center point of the surface of the fused image, $O(w_i)$ is the center of the focused light of the camera of the fused image, and α is the maximum value of the angle between the largest edge point within the image and the center of the camera. Face sheet expansion is performed on the neighboring images in the sequence:

$$Q(w) = \{ Q_i(x', y') \mid w \in Q_i(x, y), |x - x'| + |y - y'| = 1 \} \quad (13)$$

In the formula, (x, y) and (x', y') are the corresponding point clouds of neighboring image facets. To ensure the authenticity of the extended image, the facets with anomalies in the extended fusion are filtered, and the neighboring image facets are screened by the consistency test:

$$|Q'(w)|(1 - hid^*(w)) < \sum_{w_i \in W(w)} 1 - hid^*(w) \quad (14)$$

In the formula, $hid^*(w)$ is the grayscale consistency test function. If the tested image facets satisfy the above conditions, it means that the two image facets have large differences and are not suitable for extended reconstruction. Based on the consistency fusion test, the dense point cloud can accurately capture the key geometric structures in the corridor, and the processed dense point cloud data is converted into a 3D mesh model using the Power Crust algorithm [15]. Fig. 6 shows cloud edge collaborative feature point extraction process.

A set of discrete extreme values highlighted in the image is extracted as the simulation center axis, the point cloud is linearly estimated and regionally divided, adjacent points are connected to generate a Voronoi diagram, the extreme points

of each cell Voronoi diagram are extracted, i.e., the feature points of each region that are farthest away from the sampling points, and the weighted computation is performed to get the description of the reconstruction of the three-dimensional Power diagram [16]:

$$U_{pow(x, \varphi_{o,u})} = U^2(o, x) - \eta^2 \quad (15)$$

In the formula, $U_{pow(x, \varphi_{o,u})}$ is the weighted stereo Power map distance description of the extreme point, U is the

distance of the extreme point from the sampling center, $\varphi_{o,u}$ represents a sphere with O as the center and a radius of u , and η^2 is the reconstruction weighting value. Each region of the image features a point cloud in turn for three-dimensional reconstruction, to get the three-dimensional framework, comprehensively improve the image's three-dimensional reconstruction accuracy (see Fig. 7). The texture information in the original image is extracted and mapped onto the surface of the 3D model, which makes the transmission and distribution corridor model more realistic and vivid and can effectively enhance the realism of the digital model [17].

Fig. 7. 3D reconstructed view of point cloud.

IV. SYNCHRONIZED UPDATE OF 3D RECONSTRUCTION DATA FOR CLOUD EDGE COLLABORATIVE IMAGES

A. Dynamic Estimation of Feature Points

The transmission and distribution corridor monitoring equipment is subjected to remote manipulation for displacement, and the images need to be evaluated for feature point motion. Assuming that the equipment moves at the same speed as the pre-set parameters, the dynamic estimation model is expressed as:

$$\begin{bmatrix} v_{\gamma 1} \\ v_{\gamma 2} \\ v_{\gamma 3} \\ v_{\gamma 4} \end{bmatrix} = \frac{1}{r} \begin{bmatrix} 1 & 1 & long_n \\ -1 & 1 & -long_n \\ -1 & 1 & long_n \\ 1 & 1 & -long_n \end{bmatrix} \begin{bmatrix} v_x \\ v_y \\ v_z \end{bmatrix} \quad (16)$$

In the formula, v_{γ} represents the angular velocity parameter of the device moving different gears, $long_n$ is the distance of the device running for one week, v_x and v_y are the moving speeds of the device in the x and y directions, and r is the radius of the McNamee wheel [18].

The time difference variable Δt of the dynamic image facets is calculated to recognize the dynamic position of the sequence image feature points, and the displacement coordinate variable is extracted to be fused with the 3D

reconstruction data:

$$dt_{ni} = \text{LinarInterp} \left((x_i, y_i), \frac{long_{ni+1} - long_{ni}}{\Delta t} \right) \quad (17)$$

Through dynamic estimation, the synchronized transmitted images can be analyzed and compared in a more detailed way, and the optimal data can be selected for fusion and three-dimensional reconstruction to reduce the distortion of information due to light and shadow and noise in the moving process.

B. Incremental Learning Synchronization Update

After the initial reconstruction of the 3D image, continuous optimization of the 3D reconstructed data is achieved by incremental learning allowing the 3D model to continuously learn from and update new data while retaining knowledge of the existing data [19]. The edge network transmits new image or scan data to the cloud data center and continuously adds new image frames using the Incremental SFM (Structure for Recovery of Motion) algorithm to 3D map the real-time data onto the existing 3D knowledge [20]:

$$\tilde{R}(x, y, z | \Delta t) = \sum_{N'} y_n \log \frac{\exp(o_i)}{\sum_{N'} \exp(o_i)} \quad (18)$$

In the formula, $\tilde{R}(x, y, z | \Delta t)$ represents the cross entropy of 3D reconstructed feature points under uniform

synchronization conditions, $\exp(o_i)$ and $\exp(o_i)$ represent the original feature point center position and the incremented feature point center position, respectively. The dynamic synchronization data is introduced to iterate the network weights λ to calculate the extra data loss existing in the synchronization process:

$$loss(\tilde{R}^t) = \frac{1}{2} \sum_{|\tilde{R}^{t-1}|}^{i=1} \lambda (\tilde{R}_i^{t-1} - \tilde{R}_i^t)^2 \quad (19)$$

It solves the problem of data synchronization inconsistency in 3D reconstruction through incremental learning, and supports long-time continuous learning and optimization to eliminate image data discrepancies and improve the consistency and accuracy of large-scale image 3D reconstruction (see Fig. 8).

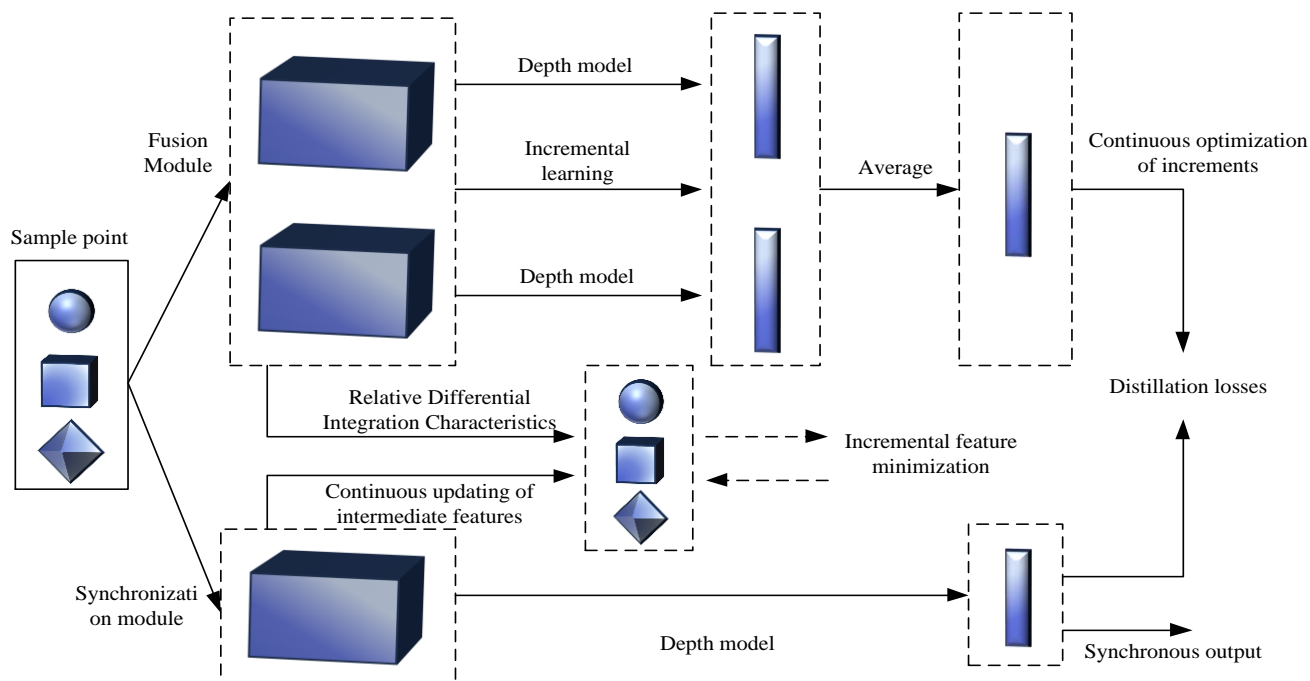

Fig. 8. Incremental learning synchronization mechanism.

V. EXPERIMENTAL RESEARCH

To verify the application effectiveness of large-scale image 3D reconstruction technology based on cloud edge fusion architecture and the optimized performance of cloud edge data synchronous update technology, a comparison experiment is designed for image acquisition and 3D reconstruction of transmission and distribution corridors. The experimental cloud data center equipment is selected from Dell Power Edge R430 dual-channel rack servers, and the edge core equipment is selected from Lenovo tower servers, with a unified setup of 8Mbps upstream broadband, and the collected images of transmission and distribution corridors are visualized using MATLAB software, to carry out comprehensive technical evaluation of the network latency state, matching performance, and reconstruction time of the large-scale image three-dimensional reconstruction method. A comprehensive technical evaluation is carried out.

A. Synchronization Update Network Latency Evaluation

The changing dynamics of the synchronization update network state of the image transmission from the front-end device to the system host computer is shown in Fig. 9.

According to the above figure, it can be seen that the data throughput of the cloud edge network based on cloud edge fusion technology is larger, the average throughput is always above 20000 Kbps, and the highest throughput can reach 42000 Kbps. The centralized cloud communication technology used for tilt photography has an average network throughput of about 10000 Kbps to 20000 Kbps due to the lack of a two-end synergistic mechanism. The larger the network throughput, the faster the synchronization and updating speed for large-scale images, so the image synchronization transmission delay time of the cloud-side cooperative network is the shortest, with a maximum of no more than 85 ms and a minimum of only 19 ms, which is significantly better than the other two methods in terms of synchronization transmission speed.

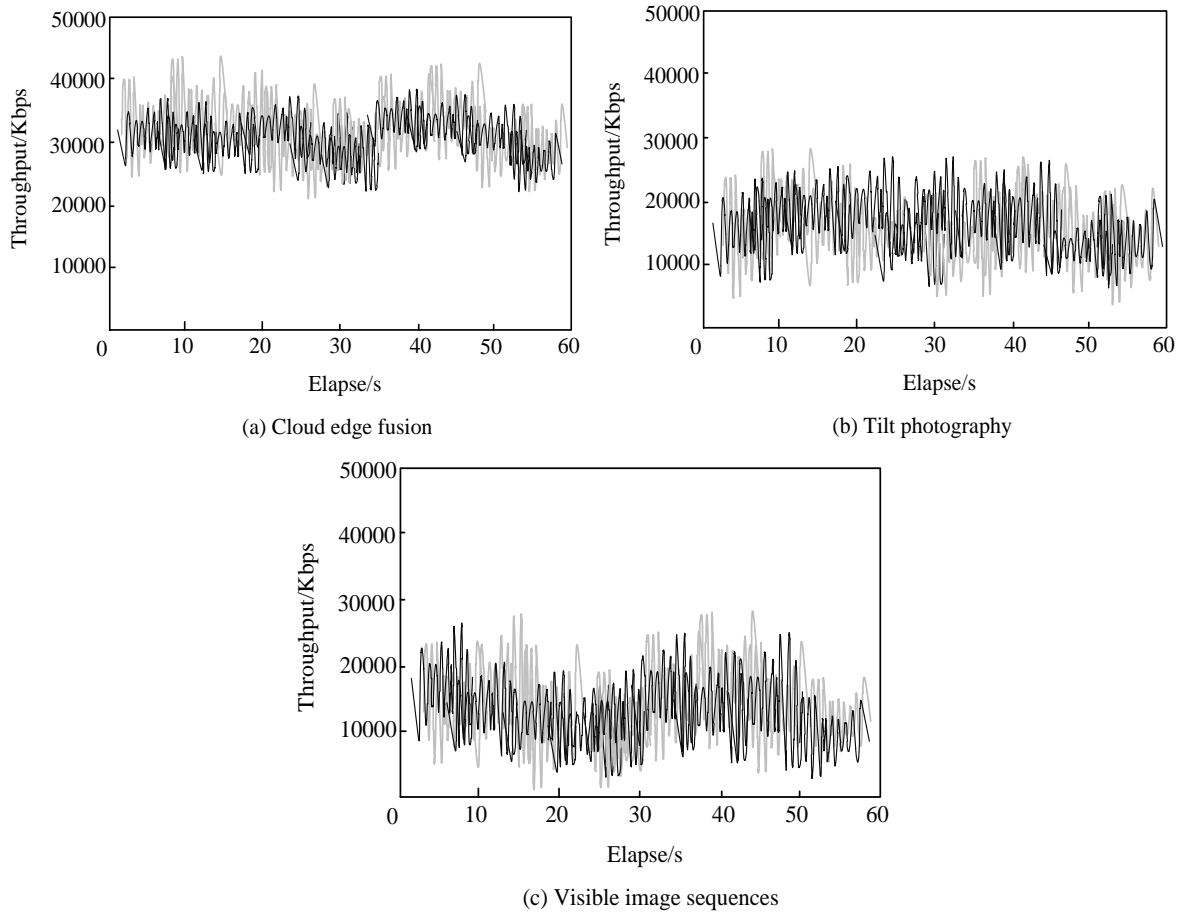

Fig. 9. Network communication throughput.

Fig. 10. Network synchronization delay.

B. Image 3D Reconstruction Time Evaluation

To check the processing time of large-scale image 3D reconstruction stages, 50, 100, 200, and 300 images are fused

and reconstructed respectively, and the time required for each stage is statistically shown below.

TABLE I. STATISTICS OF 3D RECONSTRUCTION DURATION FOR CLOUD-EDGE FUSION

Number of images	Duration of the first phase(min:s)	Point cloud upload time(min:s)	Duration of the second phase (min:s)	Total processing time (min:s)
50	01:48	02:15	03:23	07:26
100	03:21	03:46	06:58	14:05
200	10:17	07:31	09:18	27:06
300	21:39	17:28	19:42	58:49

TABLE II. STATISTICS ON THE DURATION OF 3D RECONSTRUCTION FOR TILT PHOTOGRAPHY

Number of images	Duration of the first phase (min:s)	Point cloud upload time (h:min:s)	Duration of the second phase (min:s)	Total processing time (h:min:s)
50	06:28	04:10	04:33	15:11
100	11:45	25:26	07:12	44:23
200	25:59	1:09:41	21:37	1:57:17
300	40:27	1:25:58	31:02	2:37:27

TABLE III. STATISTICS OF 3D RECONSTRUCTION DURATION OF THE VISIBLE IMAGE SEQUENCE

Number of images	Duration of the first phase (min:s)	Point cloud upload time (h:min:s)	Duration of the second phase (min:s)	Total processing time (h:min:s)
50	07:18	12:15	06:23	25:55
100	15:21	35:33	13:08	64:02
200	31:37	1:17:21	24:14	2:13:11
300	56:32	1:37:05	39:42	3:33:19

The data in Tables I to III show that cloud-edge fusion uses a cloud-edge cooperative network with a higher synchronization rate, and the time taken in the image point cloud upload phase is much lower than that of the tilt photography and visible sequence techniques. When the number of fused reconstructed images is 300, the first stage of image feature extraction and preprocessing of cloud edge fusion takes 21:39 min, point cloud uploading takes 17:28 min, and the second stage of point cloud reconstruction takes 19:42 min. The total processing time of the whole stage of 3D reconstruction of cloud edge fusion is only 58:49 min, whereas tilt photography requires a total time of 2:37:49 min. The total processing time

for the whole phase of 3D reconstruction is only 58:49 min, while the total time required for tilt photography is 2:37:27 h, and the total time used for the visible light sequence is 3:33:19 h. Thus, it can be seen that the cloud-edge fusion technology not only has good network synchronization performance but also has obvious advantages in image feature extraction and point cloud reconstruction functions.

C. Reconstruction Matching Performance Evaluation

It is verified that the cloud-edge fusion 3D reconstruction technique has good network synchronization performance, and further evaluation of its matching performance is still needed.

Fig. 11. 3D reconstruction of the visualized image.

Completing the 3D reconstruction of the transmission and distribution digital corridor, the statistics of the number of matches, the number of matching points, the success rate of

matching, and the length of time taken for the three methods of identification are shown in the following Table IV.

TABLE IV. COMPARISON OF THREE-DIMENSIONAL RECONSTRUCTION MATCHING PERFORMANCE

Methodologies	Number of matches/times	Match Points/Each	Match rate/%	Timing
Cloud Edge Fusion	5981	3925	96.72	1 h 11 min
Oblique photography	25883	1098	80.35	3 h 05 min
Visible Image Sequence	30768	875	72.64	3 h 58 min

According to the data in Table IV, it can be seen that for 3D reconstruction of the same transmission and distribution corridor image, the cloud-edge fusion technique takes the shortest time and carries out the least number of matches, but successfully recognizes and matches the greatest number of point clouds, with a total of 3925 matching points identified, and the matching success rate is as high as 96.72%. In summary, the cloud-edge fusion 3D reconstruction technique has efficient synchronization efficiency of the cooperative network and also has a good application effect in the point cloud recognition and matching function, which has significant advantages over other methods.

VI. DISCUSSION

The research results show that the synchronous update and optimization method for large-scale image 3D reconstruction technology based on cloud-edge fusion architecture has significant application advantages. On the one hand, the architecture can efficiently integrate cloud and edge computing resources, dynamically allocate them according to the task demand, hand over the computationally intensive work to the cloud, and the edge end is responsible for data acquisition and pre-processing, which greatly improves the resource utilization rate. On the other hand, the edge end can perform local preliminary processing of image data, reducing the time delay of transmission to the cloud. The synchronous update mechanism gives the technology adaptability and flexibility to adapt to changing image data and application scenarios, and the cloud-edge convergence architecture can be flexibly expanded and deployed according to actual needs to meet the needs of different scales and types of applications.

The author believes that the technology has great potential for development and has a bright future. In the future, it can further explore smarter resource allocation strategies and synchronized update mechanisms, improve the degree of system automation and efficiency, and achieve more innovative breakthroughs by combining advanced technologies such as artificial intelligence and 5G communication. In addition, research on data security and privacy protection should be strengthened to ensure the safe storage and transmission of large-scale image data under the cloud-side convergence architecture, so as to bring more efficient, accurate, and reliable image 3D reconstruction solutions to many fields.

VII. CONCLUSION

Aiming at the problem of three-dimensional reconstruction of power transmission and distribution corridors, this paper optimizes the design of large-scale image three-dimensional

reconstruction technology and its synchronous update performance under the cloud-edge fusion architecture, and mainly completes the following research: Establish the transmission and distribution digital corridor IoT cloud-edge fusion network architecture, optimize the cloud data center and edge node structure; Optimize the accuracy of cloud-edge fusion 3D reconstruction point cloud matching by using non-sampling filtering, edge checking, and Gaussian convolution; Enhance the synchronous updating performance of cloud-edge cooperative networks through dynamic evaluation of feature points and incremental learning algorithm.

It can be seen through experiments that the cloud-edge fusion 3D reconstruction technology can realize accurate image 3D reconstruction in a short time, the information synchronization update delay rate is low, and the processing time is shorter. Although the results of this paper have the above advantages, there are still some shortcomings: Cloud edge fusion technology requires higher compatibility equipment configuration, higher application costs, and relatively greater technical difficulties; 3D reconstruction software for image fusion detail processing and model training balance control is insufficient, there are still errors and distortion. Future research needs to be deepened from the above perspectives to comprehensively improve the efficiency and accuracy of the application of cloud edge fusion 3D reconstruction systems.

The Application of Anti-Collision Algorithms in University Records Management

Ying Wang^{1*}, Ying Mi²

Archives of the Party and Administration Office, North China Electric Power University, Baoding, 071000, China¹
Department of Economic Management, Baoding Vocational and Technical College, Baoding, 071000, China²

Abstract—University records management has grown in importance as a result of the quick growth of big data, artificial intelligence, and other technologies. However, university archives management is prone to data loss, redundancy, and errors. Moreover, the use of scientific management systems and algorithms can effectively improve such problems. To create an effective and secure archive management system and run simulation tests, the study suggests an RFID-based archive management system and uses nested random time slot ALOHA (RS0) and binary tree (BT) anti-collision algorithms to solve the collision problem between tags in the created system. The test results showed that the average query coefficient, recognition efficiency, and communication volume of the proposed algorithm were 1 and 1.2 times, 95% and 90%, 50 Bit and 180 Bit in two scenarios, continuous and uniform, respectively. 0.91% and 3.92%, 24.21% and 31.14% of the system CUP and memory occupation were achieved when the number of clients was 10 and 100, respectively. The average response time of the system was 0.112s and 1.244s when 100 and 1000 users were accessed, respectively. The information extraction accuracy of the system was 94% at 1000 accessed users. This suggests that the approach used in the study can significantly improve the operational effectiveness of the records management system and the accuracy of information extraction, as well as provide technical support for improving the university records management system.

Keywords—Anti-collision algorithms; archive management systems; information networks; RFID technology

I. INTRODUCTION

The number of archives has greatly increased as the twenty-first century has progressed due to the growth in both students and faculty in higher education. As a result, many schools have established electronic information-based records management systems [1-2]. Additionally, radio frequency identification technology can be extensively employed in the gathering and extraction of archival information, among other things, due to its benefits of high recognition efficiency and long usage time [3]. However, one of the key issues with radio frequency recognition technology is the collision problem. In this technology, the collision problem is further broken down into collisions between readers and collisions between tags. In most cases, it is the collision between tags that is encountered. While common RFID tag anti-collision algorithms are effective in improving the system's automatic identification performance, they also have several shortcomings. In high collision situations, each time slot or query will be subject to a significant amount of duplication, which can lead to a reduction in system efficiency or lag. Additionally, these algorithms are not well-suited for big data applications. When

the data volume is very high and the number of tags exceeds the system's processing capacity, the system may experience performance issues and substantial delays [4-6]. The standard anti-collision technique is therefore no longer able to satisfy the requirements of archive management in the big data era. Therefore, to maintain the security, integrity, efficiency, and accuracy of archive management, it is important to upgrade the conventional anti-collision algorithm. Based on this background, it is proposed that when a tag collision occurs, a little time slot is first released to handle the tags that have collided. Depending on the number of tags that have collided, the nested random time slot ALOHA (SR) algorithm and the nested choice binary tree (BT) anti-collision algorithm are used to process them in anticipation of further improving the recognition efficiency and accuracy of the system.

II. OVERVIEW

Data management of archives is one of the key issues in the construction of universities today. The huge number and variety of types of archives in universities require a standardized management system to ensure the security, integrity and accuracy of archives management as well as the efficiency and accuracy of archives access. Numerous specialists have studied data management extensively in this area. Uka K. K. et al. created an online system for document sharing and data management at higher education institutions. The programme was a decentralized cloud-based file management and sharing programme. The results showed that the proposed system was able to enable file sharing, replication and data management permission transactions between accessing users in higher education institutions [7]. To make viewing of platform picture data more safe, Gamido et al. created an image file management system. The system was encrypted and kept on the server, and image files were encrypted using the AES technique to give the file owner more security. The outcomes demonstrated that the encryption of image files on the server was successful, and the technique for exchanging images was now reliable and efficient [8]. Veena et al. constructed a hybrid image and document archiving system in order to increase the volume of document storage and make document retrieval more efficient. The system used a client-server architecture, which utilized Opencv to identify objects in images and Tesseract to identify text in images and generate labels. The results showed that the system could be used to store and retrieve large numbers of documents [9]. Zhou et al. proposed a metadata service approach to the problem of dealing with large amounts of data requiring long, continuous and uninterrupted data access. The strategy made

use of a novel shared storage pool and main-standby fault-tolerant design. The outcomes demonstrated that the method significantly decreased the average recovery time of the data service and enhanced the availability of the file system [10]. In the context of currently utilized distributed file systems that differentiate between the file system and network layers, Zhu et al. proposed a distributed persistent memory file system with RDMA support. The system introduced self-identifying remote procedure calls and offered direct access to a shared pool of persistent memory. The results demonstrated that the file system outperformed other distributed file systems by several orders of magnitude [11].

The anti-collision algorithm, which is extensively employed in many sectors, can significantly enhance the system's automatic recognition performance. Choi et al. proposed an anti-collision algorithm for mobile robots to address the problem that robots were prone to collision during the distribution process. The algorithm will reset a new path and motion when the robot collides. The outcomes demonstrated that the system could successfully prevent a robot-robot collision [12]. The multi-tag collision problem in RFID systems was addressed by the hybrid ALOHA and tree algorithm (HAMT) proposed by Zhou et al. For tag recognition, the method employed the DFSA algorithm. The outcomes demonstrated that the algorithm's recognition efficiency could increase to about 0.72 [13]. For the collision problem of RFID tag detection in the Internet of Things, Qiu et al. suggested an improved group adaptive query tree technique (IGAQT). The approach fixed the issues with the original algorithm's temporal complexity and communication overload. The outcomes demonstrated that the proposed strategy had a significantly higher recognition efficiency [14]. For the RFI multi-tag collision avoidance problem, Qu J et al. offered an adaptive frame-time slot ALOHA collision avoidance algorithm based on IGA. The algorithm counted the amount of tags before grouping them to identify tags. According to the findings, the algorithm was approximately 71% efficient, which is 90% more effective than the conventional ALOHA algorithm [15]. To address the collision issue, Jing C et al. devised an anti-collision method based on blind source separation (BSS). FastICA, PowerICA, ICA_p, and SNR_MAX were among the BSS algorithms that were

used to separate and test the mixed signals in RFID systems. The ICA_p method had the best overall performance among the aforementioned algorithms, according to the results [16].

From the research of numerous scholars mentioned above, anti-collision algorithms have been widely applied in multiple fields, most of which are applied in the Internet of Things, robot path research, and other fields. Few scholars have combined anti-collision algorithms with data archive management systems. Therefore, this research innovatively introduces anti-collision algorithms, a widely used technology in fields such as the Internet of Things, into university archive management systems, thus filling the technical gap in RFID tag recognition in this field. At the same time, the existing anti-collision algorithms are improved and optimized, and a combination scheme of nested SR algorithm and BT anti-collision algorithm is proposed. This scheme has shown significant advantages in reducing tag collisions, improving recognition efficiency and accuracy, and providing new ideas and methods for the application of RFID technology in the field of records management.

III. DESIGN OF AN RFID-ANTI-COLLISION ALGORITHM BASED ARCHIVE MANAGEMENT SYSTEM FOR UNIVERSITIES

This chapter first elaborates on the functions and design scheme of a university archives management system based on RFID technology. In response to the issues of data loss, redundancy, and errors that are inherent to university archives management, a nested SR algorithm and BT anti-collision algorithm have been developed to enhance the efficiency and accuracy of tag collision recognition, mitigate the risk of collisions between tags, and ultimately improve the operational efficacy of the university archives management system.

A. Model Design of RFID Technology-based University Archive Management System

In colleges and universities, there are many distinct kinds of records management, and each college has various records management requirements. The basic functions required for a general university records management system are shown in Fig. 1.

Fig. 1. Basic functions of university archives management system.

The basic operations of the university's records management system, including record entry, record storage, record retrieval, record approval, record borrowing, and statistical analysis, are shown in Fig. 1. According to the different needs of major universities for records management, the corresponding functions can be added or deleted. According to the needs of general universities for archive management systems, a network connection structure of university archive management systems based on RFID technology is studied and designed, as shown in Fig. 2.

As shown in Fig. 2, the network structure of the system uses a reader to first read the file information collected by the antenna, a WEB server to send it to the database server for backup, and a terminal server to implement file information management for students and teachers [17]. Four key components make up the function of the file management system developed for the project, which are shown in Fig. 3.

As demonstrated in Fig. 3, the archive management system designed in the study mainly includes four modules: user management, archive management, information collection and arrangement, and database management. The user management module mainly focuses on the access rights of different users to the archives. The database module mainly backs up and destroys the archives. The information collection and arrangement module mainly collects and processes information from different sources of archives. The archive management mainly manages the information of archives such as access, borrowing and returning, and whether they are in place. The database module is used for backing up and destroying the archives. The information collection and arrangement module is used for collecting and processing information from different sources. The archives management module is used for managing the information on access, borrowing and returning, and whether the archives are in place [18]. Six major divisions and fourteen subsections have been created based on the needs of the system's users to better serve their needs. The specific structure of the system functions for the management of archives by users is shown in Fig. 3.

As shown in Fig. 4, the basic functions of archive management in the university archive management system include user rights management, organization management, classification management, archive management, and borrowing management. According to the different user rights, the system divides users into three categories: system administrator, file administrator, and ordinary user. The system administrator has the highest authority and can perform all the functions of the system and modify the user rights to modify the file information. The file administrator is responsible for the daily maintenance of the system. Ordinary users can only query their own file information. The study employs a three-tier architecture for the software system structure in order to meet the many functional needs of the users and to make the management system convenient and effective with lower running costs. Fig. 5 shows the exact technical design of this system.

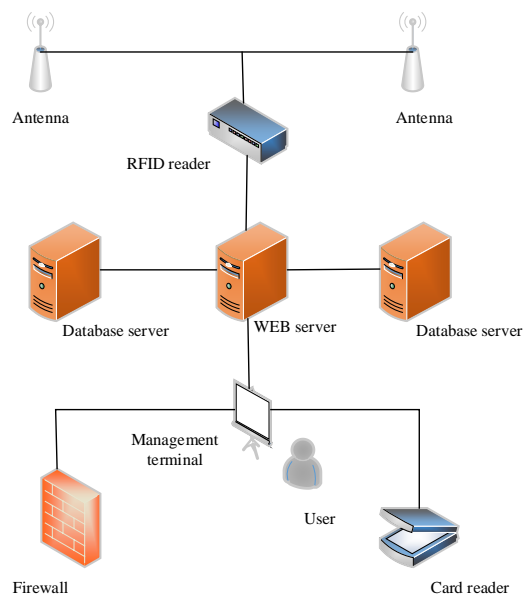

Fig. 2. System for managing university archives connections to the internet.

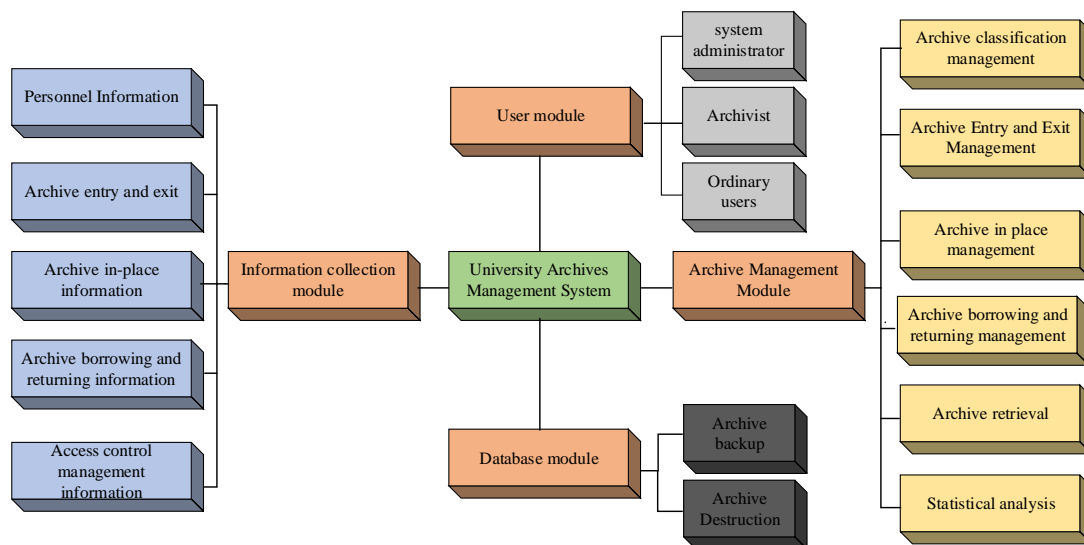

Fig. 3. System for managing university archives, showing its functional structure.

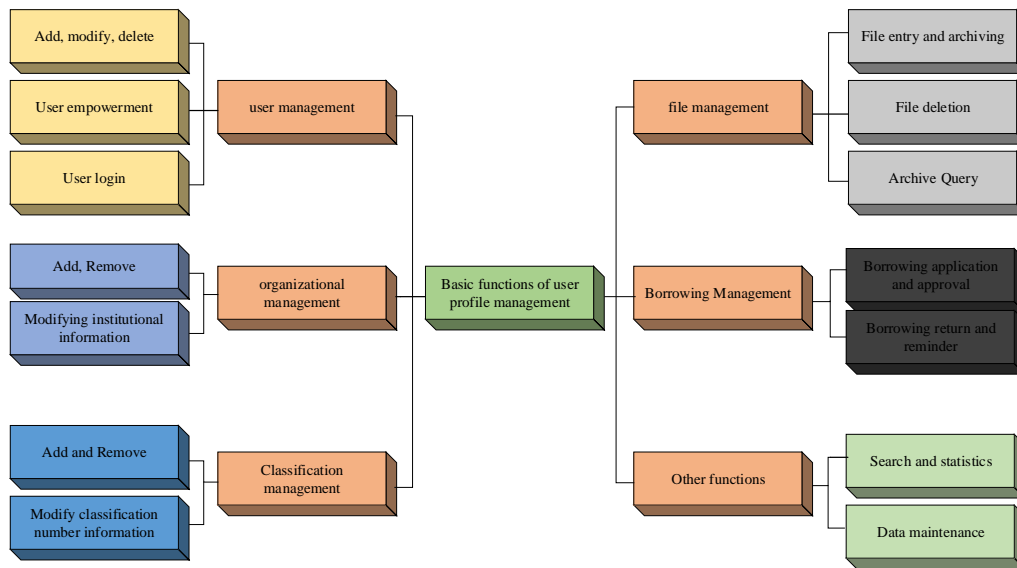

Fig. 4. Schematic representation of the fundamental file management operations carried out by users.

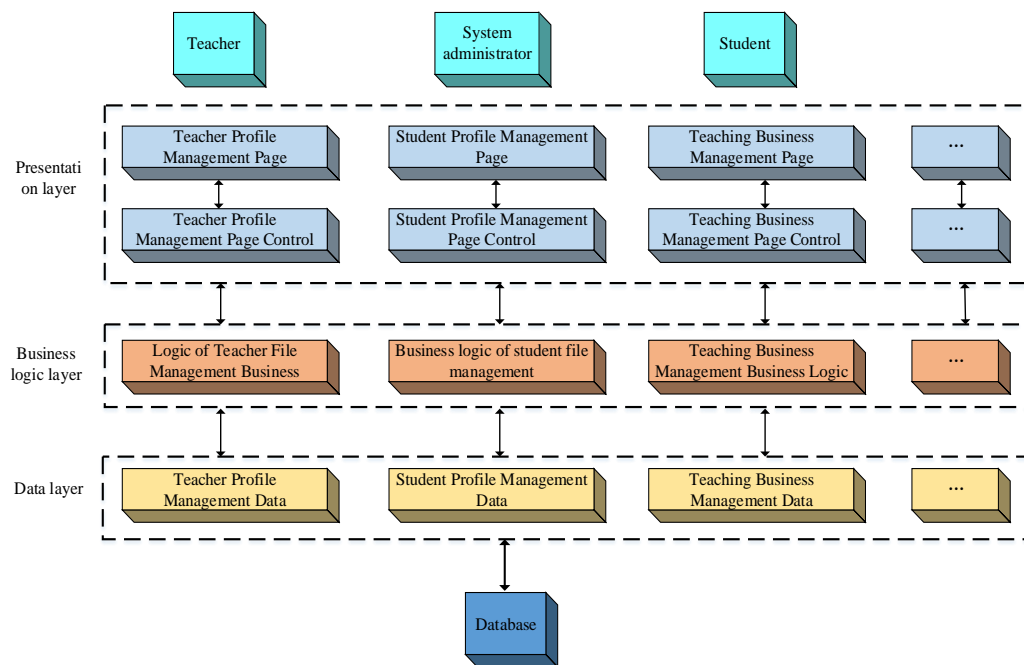

Fig. 5. Technical architecture of university archives management system.

Fig. 5 illustrates the three-layer B/S architecture used by the university file management system, with the presentation layer serving as the user operation interface via which users can manage, query, and alter files as needed. The business logic layer is the system operation logic processing, the main function of which is to parse the information sent by the user operation interface and execute the parsed instructions, and then send the instructions to the data layer. The data layer serves as the system's data processing layer. Its primary function is to filter out the necessary data in accordance with the instructions from the business logic layer, after which it sends the data back to the business logic layer for processing before sending it to the presentation layer for the users to see. Then, according to the needs of this file management system,

the corresponding running tools and development environment are selected, as shown in Table I.

TABLE I. OPERATING CONDITIONS AND TOOLS OF ARCHIVE MANAGEMENT SYSTEM

Database	MYSQL
B/S architecture development tool	Eclipse

B. Design of Improved Anti-Collision Algorithms Based on RS and BT

The university's RFID-based file management system has a sizable number of tags. When data is transmitted between

these tags and the reader, collision of data information is likely to occur, resulting in failure of information transmission [19]. There are two situations in which data information transmission collision occurs, as shown in Fig. 6.

Fig. 6(a) shows a tag-to-reader collision, which is caused by a tag being unable to accept command requests from multiple readers at the same time. A tag-to-tag collision is depicted in Fig. 6(b), where a single reader is unable to extract the data from several tags at once. While the former collision scenario can be avoided by adjusting transmit power, the latter scenario requires strengthening the anti-collision algorithm. The ALOHA-based algorithm and the tree-based algorithm are the two anti-collision algorithms between tags that are most

frequently utilized. ALOHA algorithms include the pure ALOHA algorithm (PA algorithm), the time slot ALOHA algorithm (SA algorithm), and the frame time slot ALOHA algorithm (FSA algorithm) [20]. The FSA algorithm decomposes the recognition process into separate recognition frames. Since the FSA algorithm can break down the recognition process into individual frames and utilize the time slot ALOHA algorithm one at a time, this method has greater recognition accuracy. The SR algorithm is devised since the amount of time slots per frame cannot be altered. This algorithm has the ability to change the total number of time slots in a recognition cycle and allow unrecognized tags to select a different time slot. The algorithm flow is shown in Fig. 7.

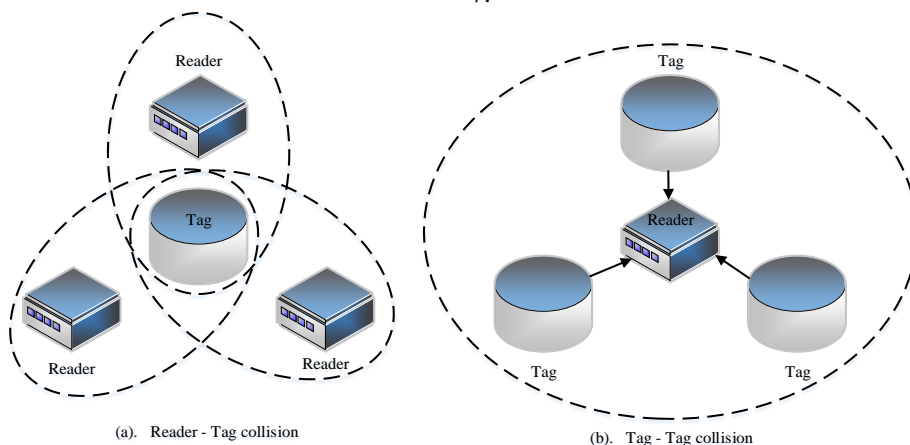

Fig. 6. Collision situation.

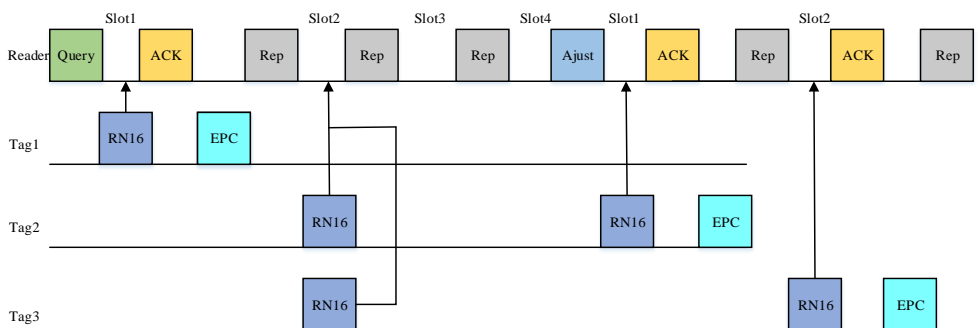

Fig. 7. SR algorithm flowchart.

The SR algorithm's main flow is depicted in Fig. 7. The reader transmits a command to the tag with the parameter Q , which the tag receives and uses to create a random number as the response command when the time period is up. Finally, the reader sends a separate instruction and moves on to the following time slot based on the corresponding amount of tags. The success rate of a specific tag identification in a particular time slot of the cycle is displayed in Eq. (1).

$$P_e = C_n^1 \frac{1}{2^Q} \left(1 - \frac{1}{2^Q}\right)^{(n-1)} \quad (1)$$

In Eq. (1), Q is the parameter in the command. n is the total number of tags. When the reader accepts signals from several tags at the same time, the probability of collision

between tags is shown in Eq. (2).

$$P_i = C_n^i \left(\frac{1}{2^Q}\right)^i \left(1 - \frac{1}{2^Q}\right)^{(n-i)} \quad (i \geq 2) \quad (2)$$

Let the total number of time slots be 2^Q , then the total expected value of tag collisions over the entire recognition cycle is calculated as shown in Eq. (3).

$$E_0 = n \left(1 - \frac{1}{2^Q}\right)^{(n-1)} \quad (3)$$

In Eq. (3), E_0 is the total expected value of collisions for a given cycle of tags, based on which the algorithm efficiency

of SR can be calculated in Eq. (4)

$$\eta_{SR} = \frac{n \left(1 - \frac{1}{2^q}\right)^{(n-1)}}{2^q} \quad (4)$$

In Eq. (4), η_{SR} is the efficiency of SR algorithm. The tree structure-based collision prevention algorithms include the BT algorithm, the query algorithm (QT algorithm), and the spanning tree algorithm. Fig. 8 displays the schematic diagram of the BT anti-collision algorithm among them.

Fig. 8. Schematic diagram of binary tree anti-collision.

As shown in Fig. 8, the algorithm starts with a counter for each reader and tag, each with a value of 0. The tag then sends a message to the reader, and the reader adjusts the value of the counter according to the message to drive the algorithm. Finally, the algorithm terminates when the reader's counter value reaches 0. The formula for the h level of the binary tree, which has 2^k cycles at the h level, is given in Eq. (5).

$$\begin{cases} S_{BT}(n, h) = 2^h \left(1 - \frac{1}{2^h}\right)^n \\ A_{BT}(n, h) = n \left(1 - \frac{1}{2^h}\right)^{(n-1)} \\ H_{BT}(n, h) = \sum_{h=0}^{\infty} 2^h \left[1 - \left(1 - \frac{1}{2^h}\right)^{(n-1)} - n \frac{1}{2^h} \left(1 - \frac{1}{2^h}\right)^{(n-1)} \right] \end{cases} \quad (5)$$

In Eq. (5), $S_{BT}(n, h)$ is the number of idle cycles. $A_{BT}(n, h)$ is the number of readable cycles. $H_{BT}(n, h)$ is the number of collision cycles for the h layer. In this algorithm, the number of queries $L(n)$ and the amount of communication $S(n)$ for the reader to recognize the tag are shown in Eq. (6).

$$\begin{cases} L(n) = n(\log_2 n + 1) \\ S(n) = Y \lceil n(\log_2 n + 1) \rceil \end{cases} \quad (6)$$

Based on the basic properties of bifurcation numbers, the total period identified by the algorithm can be obtained as

$1 + H_{BT}$. Both of these algorithms are common anti-collision algorithms for handling tag collisions, but both have shortcomings, so the study proposes a sub-nesting algorithm to improve them. In the event of a collision between tags when a command is sent in the SR algorithm, the reader processes the tag directly into the subsequent time slot, thereby bypassing the tag that collided. To address this problem, the study proposes that instead of going to the next gap immediately after a collision occurs, the colliding tag is processed first and the SR algorithm is nested with SR. Let the number of time slots to be released by this algorithm be m , and the SR nested SR algorithm is analyzed by the formula, the probability of success of identifying a tag per time slot in this algorithm is shown in Eq. (7).

$$Pe_1 = \left(1 - \frac{1}{m}\right)^{(m-1)} \quad (7)$$

Since there is a m time slot, the expectation of successful tag recognition at m is expressed in Eq. (8).

$$E_1 = m \left(1 - \frac{1}{m}\right)^{(m-1)} \quad (8)$$

In contrast, the traditional SR algorithm's expectation of successful tag recognition in m time slots is shown in Eq. (9).

$$\frac{n}{2} \left(1 - \frac{1}{2^q}\right)^{(n-1)} \quad (9)$$

Therefore, the nested SR algorithm label recognition success expectation optimization rate can be obtained as shown in Eq. (10).

$$\eta = \frac{\frac{n}{2} \left(1 - \frac{1}{2^q}\right)^{(n-1)}}{m \left(1 - \frac{1}{m}\right)^{(m-1)}} \times 100\% \quad (10)$$

Moreover, for the improvement of the BT algorithm, the study uses the SR nested BT algorithm to improve it. Let the number of tags to be recognized be L , the depth of the binary tree is $\lceil \log_2^L \rceil$, combined with the traditional BT algorithm, Eq. (11) can be used to determine the time required to recognize the tags and the formula for calculating expectations.

$$\begin{cases} E_A = \sum_{a=1}^{\lceil \log_2^L \rceil} \left(1 - \frac{1}{2^a}\right)^{L-1} \\ T_A = \sum_{a=1}^{\lceil \log_2^L \rceil} 2^a \end{cases} \quad (11)$$

In Eq. (11), E_A is the expectation of successful tag recognition. T_A is the time taken to recognize the tag. The efficiency of the algorithm can be obtained from the

expectation and the time taken. Next, the SR nested SR algorithm and the SR nested BT algorithm are compared. Let the total number of tags identified by the SR nested BT algorithm be E_A and the time taken be T_A . For the same usage time, the total number of tags identified by the SR nested SR algorithm is E_{SR} , and the tag identification expectation is given in Eq. (12).

$$E_{SR} = T_A \left(1 - \frac{1}{T_A}\right)^{(T_A-1)} \quad (12)$$

The label recognition expectations according to the two algorithms are compared in size using the do-quotient method, as shown in Eq. (13).

$$\lambda = \frac{T_A \left(1 - \frac{1}{T_A}\right)^{(T_A-1)}}{\sum_{a=1}^{\lceil \log_2^L \rceil} \left(1 - \frac{1}{2^a}\right)^{L-1}} \quad (13)$$

The time used in Eq. (13) can be brought in with the time used in Eq. (10) and calculated to give Eq. (14).

$$\lambda = \frac{\sum_{a=1}^{\lceil \log_2^L \rceil} 2^a \left(1 - \frac{1}{\sum_{a=1}^{\lceil \log_2^L \rceil} 2^a}\right)^{\left(\sum_{a=1}^{\lceil \log_2^L \rceil} 2^a\right)-1}}{\sum_{a=1}^{\lceil \log_2^L \rceil} \left(1 - \frac{1}{2^a}\right)^{L-1}} \quad (14)$$

According to Eq. (14), it is concluded that the SR nested SR algorithm has more tag recognition when $L \geq 5$ and the SR nested BT algorithm has more tag recognition when $L < 5$ [21]. Based on this conclusion, the nested RS and BT anti-collision algorithm flow is shown in Fig. 9.

The upgraded algorithm's reader delivers a command with a Q value, as seen in Fig. 9, which kick-starts the cycle of tag recognition. Each tag receiving the command randomly generates its own tag number and selects a corresponding time slot. When there is no tag response, the reader issues a command to move on to the next time slot. When there is one tag response, the reader issues a command to read and write the tag before moving on to the next time slot. Moreover, when there are multiple tag responses, the reader issues a nested BT algorithm command if there are $L < 5$ or $L \geq 5$ tag collisions, respectively.

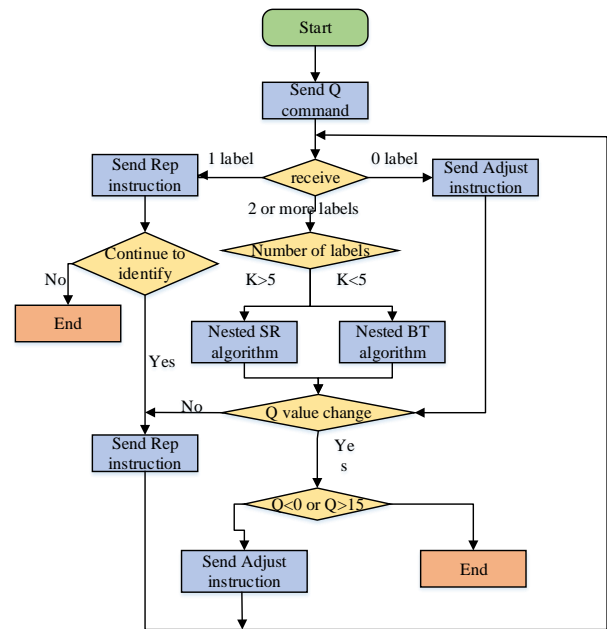

Fig. 9. Flow diagram of nested RS and BT anti-collision algorithm.

IV. PERFORMANCE ANALYSIS AND SIMULATION APPLICATION OF RFID-BASED ANTI-COLLISION ALGORITHM FOR ARCHIVE MANAGEMENT SYSTEM

This chapter mainly elaborates on the performance of nested RS and BT anti-collision algorithms and the design of file management system detection experiments.

A. Performance Analysis of Nested RS and BT Anti-Collision Algorithms

The study divides the tag identity codes into two distribution scenarios—continuous and uniform—to test the effectiveness of the recommendation algorithms developed in this study. The performance of the five QT algorithms, DBS algorithm, RS algorithm, BT algorithm, nested RS and BT algorithms are simulated and tested in these two scenarios respectively. Table II displays the experimental parameter settings.

TABLE II. EXPERIMENTAL PARAMETER SETTINGS

Number of readers	1
Label length	100
Transfer rate	100kbps
Number of labels	4~2048
Software	Matlab
Number of experiments	100

The average number of queries for each algorithm is first tested in two distribution scenarios for the tag identity code. The results of which are shown in Fig. 10.

Fig. 10. Average query times of different algorithms in two scenarios.

As shown in Fig. 10(a), the average number of queries for the five algorithms in the continuous scenario is shown. It can be concluded that the average query counts of the three algorithms, nested RS and BT algorithms, RS algorithm and BT algorithm, remain stable. Therefore, the average number of times to identify a tag is 1, 1.2 and 1.5 times, respectively. The average query count of DBS algorithm increases with the number of tags. The average query count of QT algorithm decreases with the number of tags. The average number of

inquiries for the five methods in the uniform scenario are shown in Fig. 10(b). It can be concluded that the DBS algorithm and QT algorithm query counts vary similarly to (a). The RS algorithm and BT algorithm both have the same average query count of 1.7. The nested RS and BT algorithms have the lowest query count of 1.2. The average recognition efficiency of the various algorithms is then tested in two distribution scenarios of tag identity codes, and the specific results are shown in Fig. 11.

Fig. 11. Average recognition efficiency of different algorithms in two scenarios.

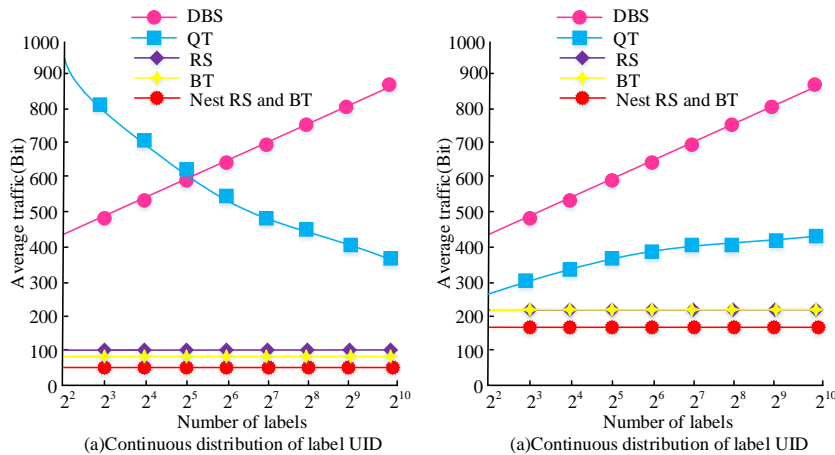

Fig. 12. Average traffic of different algorithms in two scenarios.

As shown in Fig. 11(a), the average recognition efficiency of the five algorithms in the continuous scenario is shown. As can be shown, the average recognition efficiency of the three algorithms—nested RS and BT algorithms, RS algorithm, and BT algorithm—remains stable as the number of tags increases, at 95%, 64%, and 78%, respectively. The average recognition efficiency of the DBS algorithm and QT algorithm is constantly changing, with the highest being around 50%. Fig. 11(a) shows the average recognition efficiency of the five algorithms in the uniform scenario. As can be observed, the average recognition efficiency of the BT algorithm stays constant at 62%, whereas that of the nested RS and BT + RS algorithms varies between 90% and 55%, respectively. The average recognition efficiency of the DBS and QT algorithms is similar to the case in (a), with a maximum of 50%. Finally, the average communication of the various algorithms is tested in two distribution scenarios of tag identity codes, and the specific results are shown in Fig. 12.

As shown in Fig. 12(a), the average communication volume of the five algorithms in the continuous scenario is shown. It can be concluded that the average communication volume of three algorithms, namely nested RS and BT algorithm, RS algorithm, and BT algorithm, remains stable, with 50, 100, and 80 Bit, respectively. While the average communication volume of the QT algorithm is inversely

proportional to the number of tags and has a minimum communication volume of 400 Bit that of the DBS method is proportionate to the number of tags and has a minimum communication volume of 430 Bit. Fig. 12(b) shows the average communication volume of the five algorithms in the continuous scenario. The average communication volume of the five algorithms is shown in Fig. 12(b). The average communication volume of the nested RS and BT algorithms, RS algorithm and BT algorithm remains stable but increases slightly to 180, 220 and 220 Bit respectively. The average communication volume of the DBS algorithm is the same as in scenario (a). The average communication volume of the QT algorithm increases slowly to a minimum of 280 Bit and uniform distribution scenarios.

B. Simulation Application Analysis of a File Management System Based on Nested RS and BT Anti-Collision Algorithms

To further verify the system designed by the research in practical applications, a university is selected to conduct simulation experiments with the research system. To provide a point of comparison, a traditional campus network file management system and a card-based file management system are also set up. The number of clients is set to 100, and the CPU occupancy and memory occupancy of the three systems are first tested. The results are shown in Fig. 13.

Fig. 13. CPU usage and memory usage of three systems.

As shown, Fig. 13(a) shows the change of CPU occupancy with client growth for the three systems. Fig. 13(b) shows the change of memory occupancy with client growth for the three systems. It can be concluded that the CPU occupancy and memory occupancy of the study system are smaller than those of the other two systems throughout the client growth. When the number of clients is 10, the CPU occupancy of the research system is 0.91% and the memory occupancy is 24.21%, while the CPU occupancy and memory occupancy of the other systems are as low as 0.97% and 25.13%. When the number of clients is 100, the CPU occupancy of the research system is 3.92% and the memory occupancy is 31.14%, while the CPU occupancy and memory occupancy of the other systems are as low as 5.98% and 32.13%. The average response time of the three systems is then evaluated once more, with the lowest values being 5.98% and 32.12%. Fig. 14 displays the average findings from 100 tests on the three systems' average reaction times with 100, 500, 1000, and 2000 users.

Fig. 14 shows that when the number of users increases, the average response time of the three algorithms increases as well. The average response time of the three systems is roughly the same at 0.112 seconds when there are 100 users being accessed? The average response time of the studied system is 1.244 seconds, which is 0.723 seconds faster than the card-based archive management system campus network archive management system and 1.036 seconds faster than the campus network archive management system. However, as the total amount of users increased, the difference in average response time between the three systems grow increasingly larger. When the number of access users reaches 2000, the studied system's average response time is 1.244 seconds. Finally, the accuracy of archive information extraction is tested for the three systems. A total of 1,000 users are permitted to access the system at any given time, with the system operating continuously for a period of either 12 or 24 hours per day. The results are shown in Fig. 15.

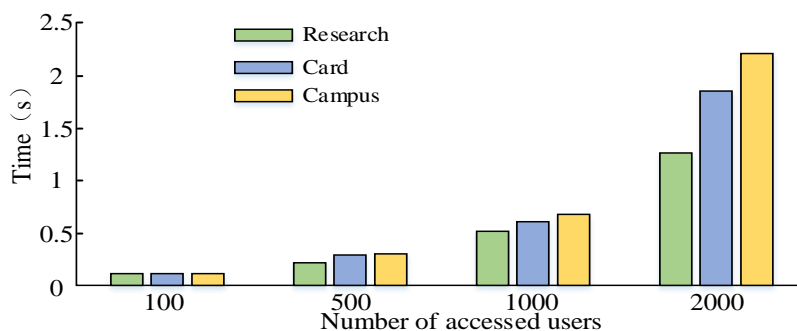

Fig. 14. Average response time of three systems.

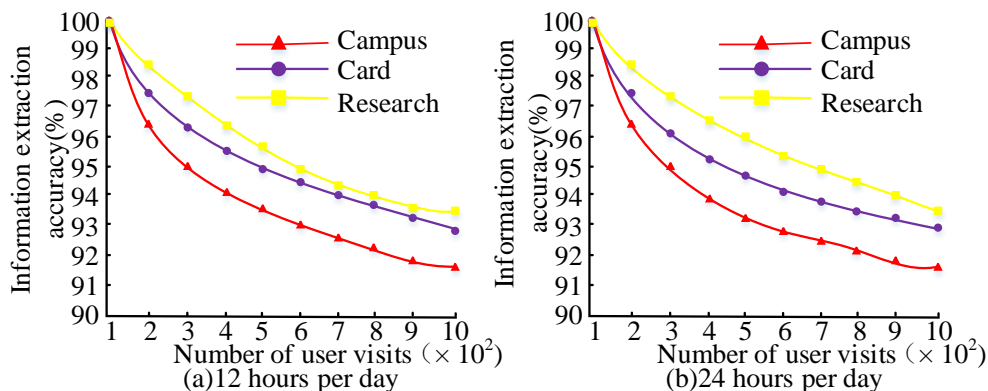

Fig. 15. Accuracy of extracting archive information for three systems.

Fig. 15(a) depicts the correlation between the number of users visiting the archives and the accuracy of information extraction from the archives for the three systems operating for 12 hours each day. It is clear that for all three systems, information extraction accuracy is high when the number of access users is low. The accuracy rate starts to decline as the user base grows, but the research system ages the least quickly. When the number of users is 1000, the accuracy of the research system algorithm is 94%, while the other two algorithms are accurate up to 93%. Fig. 15(b) shows the accuracy of archive information extraction versus the number of users accessed for the three systems running for 24h a day. The comparison shows that there is only a slight difference between the two scenarios. The duration of operation of all systems does not affect this result. In conclusion, it is clear that the research system offers quick performance, excellent information correctness, and minimal memory utilization for managing university records.

V. DISCUSSION

Research on the effective integration of RFID technology, Internet big data and artificial intelligence technology is an important trend in the field of Internet of Things. Internet big data provides a rich database for RFID system, while AI technology further improves the intelligence level of RFID system through data analysis, prediction and optimization. This technological integration can not only improve the efficiency of university archives management, but also improve the system's adaptability and decision-making ability. In the process of RFID tag recognition, nested random slot ALOHA and binary tree anti-collision algorithms were

introduced and optimized, significantly improving the efficiency and accuracy of tag recognition. The combination of these two algorithms not only leveraged the advantages of the random slot ALOHA algorithm in reducing collision probability, but also utilized the characteristics of the binary tree algorithm in quickly locating and solving collision problems. This dual optimization of recognition efficiency and communication volume is achieved through the effective integration of these two algorithms. From the test results, this study outperformed other algorithms in terms of average query coefficient, recognition efficiency, and communication volume, which fully demonstrated the effectiveness and superiority of the proposed algorithm. Especially in continuous and uniform scenarios, its performance advantages were more pronounced, which was crucial for stability and reliability in practical applications. This study is of great significance for fields such as university archive management that require high-precision and high-efficiency record management.

VI. CONCLUSION

An archive management system based on RFID technology was researched, designed and implemented, effectively integrating big data and artificial intelligence technologies to improve the intelligence level of archive management. The study introduced nested SR and binary tree anti-collision algorithm into the archive management system to solve the collision problem in the RFID tag recognition process. The test results showed that in both continuous and uniform scenarios, the proposed algorithm outperformed other algorithms in terms of average query coefficient, recognition efficiency, and communication volume, with values of 1.2

times and 1.2 times, 95% and 90%, and 50Bit and 180Bit, respectively. In practical application testing, when the number of clients was 10 and 100, the CPU and memory occupancy of the research system were 0.91% and 3.92%, 24.21% and 31.14%, respectively. At different numbers of clients, the CPU and memory usage of the system remained at a low level, indicating high resource utilization and the ability to meet the needs of large-scale file management. When accessing 100 and 1000 users, the average response time of the research system was 0.112 seconds and 1.244 seconds, respectively. The average response time of the system was short. Especially in high concurrency access scenarios, it still maintained good response speed and improved user experience. When accessing 1000 users, the information extraction accuracy of the research system was 94%. This indicated that the method could reduce recognition practice, improve recognition efficiency, and have high recognition accuracy. However, this method has not fundamentally solved the label collision problem, and the optimization level of information extraction accuracy is not obvious, which needs further improvement. Future research should concentrate on the fundamental resolution of the RFID tag collision issue. This should be achieved through the implementation of innovative algorithms and technological solutions, which will significantly enhance the accuracy of information extraction. Furthermore, continuous optimization of system performance is essential to guarantee the efficiency, accuracy, and stability of the archive management system.

Advancements in Deep Learning Architectures for Image Recognition and Semantic Segmentation

Abstract—This paper focuses on using Convolutional Neural Networks (CNNs) for tasks such as image classification. It covers both pre-trained models and those that are built from scratch. The paper begins by demonstrating how to utilize the well-known AlexNet model, which is highly effective for image recognition due to transfer learning. It then explains how to load and prepare the MNIST dataset, a common choice for testing image classification methods. Additionally, it introduces a custom CNN designed specifically for recognizing MNIST digits, outlining its architecture, which includes convolutional layers, activation functions, and fully connected layers for capturing handwritten numbers' details. The paper also guides starting the model, running it on sample data, reviewing outputs, and assessing the accuracy of predictions. Furthermore, it delves into training the custom CNN and evaluating its performance by comparing it with established benchmarks, utilizing loss functions and optimization techniques to fine-tune the model and assess its classification accuracy. This work integrates theory with practical application, serving as a comprehensive guide for creating and evaluating CNNs in image classification, with implications for both research and real-world applications in computer vision.

Keywords—Convolutional Neural Networks (CNNs); AlexNet; image classification; transfer learning; MNIST Dataset; Custom CNN Architecture; deep learning; model training and evaluation; neural network optimization; activation functions; feature extraction; machine learning; pattern recognition; data preprocessing; loss functions; model accuracy

I. INTRODUCTION

Convolutional Neural Networks (CNNs) have revolutionized the field of deep learning, proving particularly effective in tasks such as image classification. Their ability to automatically learn hierarchical feature representations from raw input data makes them highly suitable for processing images and videos across various applications. This paper focuses on leveraging CNNs for image classification tasks, examining both pre-trained models and those constructed from scratch.

A landmark advancement in CNN architecture is AlexNet, which gained prominence during the 2012 ImageNet Large Scale Visual Recognition Challenge (ILSVRC). Developed by Alex Krizhevsky, Ilya Sutskever, and Geoffrey Hinton, AlexNet utilizes a deep architecture consisting of multiple convolutional layers followed by fully connected layers. As depicted in Fig. 1, the model's layered structure enhances its capacity to learn complex patterns in images while employing ReLU activation and dropout techniques to prevent overfitting. This efficiency in feature extraction and classification establishes AlexNet as a

powerful tool for image recognition tasks, especially through the application of transfer learning.

Fig. 1 illustrates the architecture of AlexNet, highlighting the convolutional and fully connected layers that work in tandem to enhance learning and mitigate overfitting. Following the introduction of AlexNet, numerous custom CNN architectures have been developed to address specific challenges in image classification. One such architecture, designed for the MNIST dataset, focuses on recognizing handwritten digits. This dataset is a standard benchmark in image classification and contains a diverse set of examples for evaluating model performance. The architecture of the custom CNN includes essential components, such as convolutional layers for feature extraction, activation functions to introduce non-linearity, and fully connected layers to classify the extracted features. Fig. 2 illustrates sample images from the MNIST dataset, demonstrating the variety of handwritten digits that the model aims to classify.

Fig. 1. A pioneering architecture in convolutional networks for AlexNet.

Fig. 2. MNIST dataset samples.

Fig. 2 showcases samples from the MNIST dataset, illustrating the diversity of handwritten digits that the custom CNN model is designed to recognize. To facilitate the practical implementation of these models, this paper will outline the steps required to load and prepare the MNIST dataset for training. It will provide a detailed explanation of the custom CNN architecture, covering its layers and functionality, as well as guidance on initiating the model, running it on sample data, reviewing outputs, and assessing the accuracy of predictions.

Additionally, the paper will explore training techniques for the custom CNN, emphasizing the importance of loss functions and optimization methods in fine-tuning model performance. By comparing the custom CNN's accuracy with established benchmarks, this study seeks to provide valuable insights into the practical applications of CNNs in image classification tasks.

TABLE I. SUMMARY OF KEY CNN ARCHITECTURES

Architecture	Year	Main Features	Applications
AlexNet	2012	8 layers, ReLU, Dropout	Image Classification
VGGNet	2014	Deep layers, small filters	Image Classification
ResNet	2015	Residual connections	Various
Inception	2015	Inception modules	Various

Table I summarizes key CNN architectures, highlighting their respective features and applications, emphasizing their role in advancing image classification techniques. By integrating theoretical foundations with practical applications, this work serves as a comprehensive guide for creating and evaluating CNNs in image classification, contributing valuable knowledge for both research and real-world applications in computer vision.

A. Problem Statement

The advent of Convolutional Neural Networks (CNNs) has significantly advanced the field of image classification and computer vision. However, despite their effectiveness, several challenges persist in achieving optimal performance across various applications. This paper addresses the following key problems within the context of CNN architectures:

1) *Scalability and generalization*: Deep learning models like AlexNet have shown remarkable performance on benchmark datasets such as ImageNet. However, transferring these models to different or more complex datasets often requires careful tuning and adaptation. The challenge lies in designing CNN architectures that not only excel in specific domains but also generalize well to a wide range of applications and data variations.

2) *Model complexity and efficiency*: Deep CNNs often involve numerous layers and parameters, leading to high computational and memory requirements. For instance, the AlexNet model, despite its success, is known for its substantial resource demands. The challenge is to develop CNN models that balance complexity and efficiency, optimizing both performance and resource utilization.

3) *Feature extraction and classification*: The ability of CNNs to extract meaningful features from raw input data and

accurately classify them remains a critical challenge. This includes ensuring that the convolutional layers effectively capture relevant patterns and that the subsequent fully connected layers provide accurate classification results. The problem is exacerbated in cases where input data is noisy or contains complex variations.

4) *Training and optimization*: Training CNN models involves optimizing a large number of parameters, which can be computationally intensive and prone to issues such as overfitting or underfitting. Efficient training strategies, including proper choice of loss functions, optimizers, and regularization techniques, are crucial to achieving high-performance models.

5) *Benchmarking and performance evaluation*: Comparing the performance of different CNN architectures on standard benchmarks, such as the MNIST dataset, requires robust evaluation metrics and methodologies. The problem is to ensure that performance assessments are accurate and reflective of the models' real-world applicability.

In this paper, we aim to address these challenges by exploring and comparing various CNN architectures, including AlexNet and a custom CNN model for MNIST classification. We seek to provide insights into their strengths and limitations, propose strategies for enhancing their scalability and efficiency, and offer recommendations for overcoming common obstacles in CNN-based image classification tasks.

B. Research Questions

1) How do different Convolutional Neural Network (CNN) architectures, such as AlexNet and custom-designed models, perform in terms of accuracy and efficiency when applied to various image classification tasks?

2) What are the key factors that influence the scalability and generalization of CNN models across different domains and datasets?

3) How can CNN models be optimized to balance computational complexity and performance, especially for resource-constrained environments?

4) What strategies and techniques are most effective for feature extraction and classification in CNN models, particularly in dealing with noisy or complex data?

5) What are the best practices for training CNN models, including the choice of loss functions, optimizers, and regularization techniques, to improve model performance and prevent common issues such as overfitting?

6) How can performance evaluation methodologies be improved to provide a more accurate assessment of CNN models' real-world applicability?

C. Objective of Study

1) *Evaluate CNN architectures*: Evaluate the performance of various Convolutional Neural Network (CNN) architectures, including established models like AlexNet and custom-designed networks. Assess their accuracy, efficiency, and adaptability across different image classification tasks and datasets.

2) *Optimize CNN models*: Identify and implement strategies to optimize CNN models, aiming to achieve a balance between computational complexity and performance. This is particularly important in scenarios with limited resources or specific application constraints.

3) *Enhance feature extraction and classification*: Explore and develop effective methods for feature extraction and classification within CNN models, addressing challenges related to noisy or complex data environments.

4) *Improve training practices*: Analyze and refine best practices for training CNN models, with a focus on the selection of loss functions, optimizers, and regularization techniques to enhance model performance and reduce issues such as overfitting.

5) *Advance performance evaluation*: Propose and apply improved methodologies for evaluating CNN models' performance, ensuring that assessments reflect real-world applicability and effectiveness in practical scenarios.

II. EXISTING SYSTEM

Image classification techniques can be broadly categorized into traditional techniques and deep learning-based approaches.

A. Traditional Techniques

Traditional techniques for image classification involve handcrafted feature extraction followed by classification using machine learning algorithms. These methods typically include:

1) Interpolation methods:

a) *Feature engineering*: Handcrafted features such as edges, textures, and shapes are extracted using techniques like edge detection (e.g., Canny, Sobel), texture analysis, and shape descriptors. These features are manually designed to represent various aspects of the image.

b) *Classical machine learning algorithms*: Once features are extracted, classifiers such as Support Vector Machines (SVM), k-nearest Neighbors (k-NN), and Decision Trees are used to categorize images based on the extracted features.

c) *Limitations*: Traditional techniques often require domain-specific expertise to design effective features and may struggle with complex image datasets due to limited ability to capture intricate patterns and variations.

B. Deep Learning-Based Approaches

Deep learning-based approaches, particularly Convolutional Neural Networks (CNNs), have revolutionized image classification by automating feature extraction and improving classification performance. Key aspects include:

1) *Convolutional Neural Networks (CNNs)*: CNNs, such as AlexNet, LeNet, and VGG, use multiple layers of convolutional and pooling operations to automatically learn hierarchical features from raw image data. These models excel at capturing spatial hierarchies and patterns in images.

2) *Transfer learning*: Techniques like transfer learning leverage pre-trained CNN models on large datasets (e.g., ImageNet) to fine-tune and adapt these models to specific tasks

with smaller datasets. This approach accelerates training and improves performance on specialized tasks.

3) *End-to-end learning*: CNNs enable end-to-end learning, where the model learns to perform both feature extraction and classification in a single integrated framework, reducing the need for manual feature engineering.

C. Comparative Analysis

Comparative analysis between traditional techniques and deep learning-based approaches highlights several differences:

Feature Extraction is a Traditional method that relies on handcrafted features, which may not capture all relevant information. Deep learning approaches use automatic feature extraction through multiple layers, capturing complex patterns and representations.

Performance is Deep learning models generally outperform traditional methods in terms of accuracy and robustness, especially on large and diverse datasets. Traditional methods may struggle with high-dimensional data and require extensive tuning.

Scalability is Deep learning models that scale more effectively with increasing data and computational resources. Traditional methods may become less effective as dataset size grows, requiring more manual intervention.

Training and Complexity are Deep learning models that often require significant computational resources and extensive training data. Traditional methods are less computationally intensive but may not achieve the same level of accuracy or generalization.

III. PROPOSED SYSTEM

To address the limitations of traditional and existing deep learning-based super-resolution techniques, we propose a novel approach using convolutional autoencoders designed specifically for the task of image super-resolution. Our proposed system leverages the power of deep learning to learn efficient representations and mappings from low-resolution images to their high-resolution counterparts, aiming to produce superior-quality images with enhanced details and reduced artifacts.

A. System Overview

The proposed system aims to enhance image classification tasks by integrating advanced deep learning methodologies, specifically leveraging state-of-the-art Convolutional Neural Networks (CNNs) and Transfer Learning techniques. The system is designed to address the limitations of traditional image classification methods and provide a robust framework for handling diverse and complex datasets. The key components of the proposed system include.

1) *Deep learning architecture*: Utilization of cutting-edge CNN architectures, such as ResNet, DenseNet, or EfficientNet, to leverage their advanced feature extraction capabilities and improve classification accuracy.

2) *Transfer learning*: Implementation of transfer learning to fine-tune pre-trained models on specific datasets, optimizing model performance even with limited labeled data.

3) *Automated feature extraction*: Automation of feature extraction through deep learning, eliminating the need for manual feature engineering and enabling the model to learn complex patterns and representations.

4) *Integration and deployment*: Development of a user-friendly interface for seamless integration and deployment, allowing for easy adaptation to various image classification tasks in real-world applications.

B. Detailed Design

1) Model selection and training:

a) *Architecture choice*: Selection of a suitable pre-trained CNN model based on the specific requirements of the image classification task. Evaluation of various architectures to determine the most effective one for the dataset at hand.

b) *Fine-Tuning*: Adaptation of the pre-trained model to the target domain through transfer learning. Fine-tuning involves adjusting the model's weights based on the new dataset to improve its accuracy and generalization.

Data Preparation is Gathering a diverse and representative dataset for training and evaluation. Ensuring the dataset covers a wide range of scenarios to enhance model robustness.

Application of data augmentation techniques, such as rotation, scaling, and flipping, to increase dataset variability and improve model generalization.

c) *Training process*: Training Pipeline is Establishing a systematic training pipeline that includes data preprocessing, model training, and evaluation. Utilizing modern deep learning frameworks (e.g., TensorFlow, PyTorch) to streamline the training process.

d) *Hyperparameter tuning*: Optimization of hyperparameters (e.g., learning rate, batch size) to achieve optimal model performance.

Performance Metrics is the Use of comprehensive evaluation metrics, such as accuracy, precision, recall, and F1-score, to assess model performance. Comparison with baseline methods to demonstrate improvements.

Cross-validation is the Implementation of cross-validation techniques to ensure the model's robustness and generalizability across different subsets of the data.

C. Expected Benefits

1) *Improved Accuracy* is Enhanced classification accuracy due to the advanced capabilities of deep learning models in capturing complex image features.

2) *Reduced Manual Effort* is the Automation of feature extraction and reduction of manual intervention required for feature engineering.

3) *Scalability* is the Scalability of the system to handle large and diverse datasets, making it suitable for various applications.

4) *Flexibility* is Adaptability to different image classification tasks through transfer learning and fine-tuning, allowing for easy customization based on specific needs.

D. Potential Applications

The proposed system can be applied to a wide range of image classification tasks, including but not limited to

1) *Medical Imaging* is the Classification of medical images for diagnostic purposes.

2) *Retail* is Image-based product recognition and inventory management.

3) *Autonomous Vehicles* are Object detection and classification in self-driving cars.

4) *Security* is Surveillance and anomaly detection in security systems.

IV. LITERATURE SURVEY

This seminal work introduced Convolutional Neural Networks (CNNs) for document recognition tasks. The architecture combined convolutional layers with subsampling, showcasing its effectiveness in handwritten digit recognition. It demonstrated high accuracy and laid the foundation for CNNs, emphasizing their potential in visual pattern recognition. This work was instrumental in advancing the field of image classification and set the stage for further developments in CNN applications [1]. The content describes the use of Convolutional Neural Networks (CNNs) for document recognition tasks. It highlights how CNNs, through the use of convolutional layers and subsampling, achieved high accuracy in recognizing handwritten digits. This approach demonstrated the potential of CNNs in visual pattern recognition, paving the way for advancements in image classification [2]. The work explored the use of very deep Convolutional Neural Networks (CNNs) with small 3x3 filters and increased depth to improve the learning of complex visual features. The model achieved state-of-the-art performance on the ImageNet dataset and emphasized the significance of network depth in enhancing the capacity of CNN architectures for large-scale image recognition tasks [3]. The Inception architecture utilized asymmetric convolutions and multiple convolutional paths with different filter sizes to improve computational efficiency and accuracy in large-scale image recognition tasks [4]. DenseNet introduced an architecture where each layer receives inputs from all preceding layers. This design promotes feature reuse and improves gradient flow, enhancing performance in object recognition tasks while reducing the number of parameters compared to traditional CNNs [5]. Batch Normalization is a technique that normalizes the inputs of each layer within mini-batches. This approach stabilizes and accelerates the training of deep networks by reducing internal covariate shift, allowing for higher learning rates and improved convergence, thereby enhancing model performance in image recognition tasks [6]. The Adam optimizer improves training efficiency in deep learning models by combining elements of AdaGrad and RMSProp. It adapts the learning rate for each parameter and maintains an exponentially decaying average of past gradients, leading to faster convergence and enhanced model performance [7]. ResNet introduced residual learning with shortcut connections that bypass one or more layers, addressing the vanishing gradient problem in very deep networks. This approach facilitated the training of extremely deep networks and led to significant improvements in image classification, object detection, and semantic segmentation [8]. The YOLO framework redefined

object detection by treating it as a single regression problem, predicting bounding boxes and class probabilities directly from full images. This approach significantly improved speed and efficiency, making YOLO well-suited for real-time applications such as autonomous driving and surveillance [9]. The work revisited the Inception architecture, introducing optimizations that enhanced performance and efficiency. These improvements led to the development of Inception-v3, which achieved new records in image classification tasks by emphasizing careful design choices in deep networks [10]. Faster R-CNN introduced a region proposal network (RPN) to streamline the object detection process. By generating high-quality region proposals directly from feature maps, this method significantly improved both detection speed and accuracy, establishing itself as a foundational model in object detection [11]. The research presented techniques for visualizing the inner workings of convolutional networks. By analyzing activations of different layers, the study provided insights into how CNNs learn features and clarified the decision-making processes behind these models [12]. The Feature Pyramid Network (FPN) introduced a top-down architecture to create high-level semantic feature maps at different scales. This approach enhanced object detection performance by utilizing multi-scale feature maps, improving accuracy across various object sizes [13]. Fast R-CNN enhanced traditional R-CNN by integrating the region proposal network into the CNN training process. This modification enabled end-to-end training of the model, which significantly reduced computational overhead and improved both detection speed and accuracy [14]. The Pyramid Scene Parsing Network (PSPNet) introduced a pyramid pooling module to capture global context information and enhance segmentation performance. By utilizing multi-scale information, PSPNet achieved state-of-the-art results in scene parsing benchmarks [15]. DeepLab introduced a semantic segmentation architecture that used atrous convolutions to capture multi-scale contextual information. This approach significantly improved segmentation accuracy in complex scenes and demonstrated the effectiveness of fully connected conditional random fields for refining the segmentation output [16]. IntelPVT enhances object detection and classification through intelligent patch-based strategies, improving the understanding of its capabilities in these tasks. The research explores the use of deep learning techniques in image forensics, specifically for detecting and reconstructing manipulated images, contributing to advancements in digital forensics [17]. The work discusses how image processing techniques enhance user experiences in augmented reality (AR) and virtual reality (VR) environments, emphasizing advancements in computer vision that enable immersive applications [18]. The work provides a comprehensive overview of deep learning techniques for image recognition and classification, highlighting their effectiveness and covering various architectures and methodologies developed in recent years [19]. The IntelPVT model uses patch-based strategies within pyramid vision transformers to improve object detection and classification performance [20]. The work discusses advancements in vision transformers, highlighting how IntelPVT and Opt-STViT improve performance in object detection, classification, and video recognition tasks [21]. The research explores weakly-supervised learning for object localization, showing that convolutional neural networks can achieve competitive localization performance without needing

extensive labeled datasets. This advancement highlights the potential of weakly-supervised learning in object localization tasks [22]. R-FCN proposed a region-based approach utilizing fully convolutional networks for object detection, enabling efficient and accurate detection across various categories while maintaining high speeds in real-time applications [23]. The study demonstrated that CNNs can effectively highlight discriminative regions within images, enhancing the understanding of spatial relationships between objects by using deep features for localization [24]. This research introduced fully convolutional networks (FCNs), which revolutionized semantic segmentation by enabling pixel-wise classification. The study demonstrated that CNN architectures could be adapted for dense prediction tasks, achieving superior results in various segmentation applications [25]. The use of fully convolutional networks (FCNs) enabled pixel-wise classification for semantic segmentation, adapting CNN architectures for dense prediction tasks and achieving state-of-the-art results [26]. The research introduced Inception-v4 and Inception-ResNet, highlighting how integrating residual connections in deep networks leads to significant improvements in image classification tasks, emphasizing the role of connectivity in enhancing learning [27]. The work proposed a difficulty-aware semantic segmentation approach using a deep layer cascade, which prioritized easier pixels for initial predictions and refined harder pixels in subsequent layers. This strategy improved segmentation accuracy across various datasets [28]. ENet introduced an efficient architecture designed for real-time semantic segmentation, optimizing the balance between speed and accuracy for deployment in resource-constrained environments [29]. The work presented DenseNet architectures adapted for semantic segmentation, highlighting the benefits of densely connected layers in improving feature propagation and network performance while maintaining efficiency [30].

V. METHODOLOGY

The methodology section outlines the systematic approach and techniques employed to develop and evaluate the proposed system. This section details the design, implementation, and assessment phases of the research, providing a clear understanding of how the objectives are achieved and how the model's performance is assessed.

A. Model Architecture

1) *Overview:* The proposed model architecture is designed to leverage the capabilities of Convolutional Neural Networks (CNNs) to achieve high accuracy in image classification tasks. This architecture integrates several advanced deep learning techniques, enabling it to effectively learn and generalize from complex data patterns. As depicted in Fig. 3, the architecture comprises multiple layers, including convolutional layers, pooling layers, and fully connected layers, each contributing uniquely to the model's performance.

Fig. 3 illustrates the architecture of the Convolutional Neural Network, detailing the arrangement and interaction of layers that facilitate feature extraction and classification.

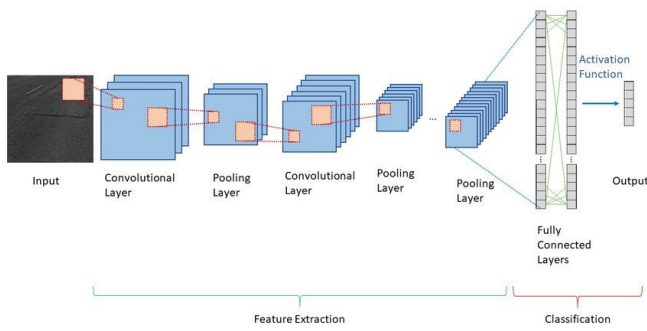

Fig. 3. Convolutional Neural Network architecture.

2) Convolutional Neural Network (CNN):

a) Input layer: The input layer serves as the initial point of entry for raw image data into the CNN. To ensure uniformity across the dataset, all images are resized to a consistent dimension of 224x224 pixels. This standardization is crucial, as it allows the CNN to process images in a predictable format, improving the efficiency of the subsequent layers. Resizing also aids in reducing computational overhead while maintaining sufficient detail for effective feature extraction.

b) Convolutional layers: Central to the CNN architecture are the convolutional layers, which perform the critical function of feature extraction. These layers employ a set of filters (also known as kernels) to scan the input image and detect various features, such as edges, textures, and patterns. The architecture utilizes multiple convolutional layers, each configured with different numbers of filters to capture a hierarchy of features.

For example, as detailed in Table II, the first convolutional layer applies 32 filters and produces an output shape of (224, 224, 32) with 896 parameters. This initial layer focuses on capturing basic features such as edges and textures. As the data progresses through deeper layers, the number of filters increases to 64 in the second convolutional layer, which outputs a feature map of shape (112, 112, 64) with 18,496 parameters. These deeper layers enable the model to identify more abstract features, such as shapes and objects, contributing to its ability to make accurate classifications.

TABLE II. CNN LAYER DETAILS

Layer Type	Output Shape	Parameters
Input Layer	(224, 224, 3)	0
Conv2D (32 filters)	(224, 224, 32)	896
MaxPooling2D	(112, 112, 32)	0
Conv2D (64 filters)	(112, 112, 64)	18496
MaxPooling2D	(56, 56, 64)	0
Flatten	(200704)	0
Dense (128 units)	(128)	25689600
Dense (10 units)	[10]	1290

c) Pooling layers: Pooling layers play a vital role in reducing the dimensionality of the feature maps generated by the convolutional layers. This reduction is achieved through operations such as MaxPooling, which selects the maximum

value from a defined sub-region of the feature map. For instance, the first MaxPooling layer operates on the output of the first convolutional layer, reducing its size from (224, 224, 32) to (112, 112, 32). This process helps retain the most prominent features while significantly decreasing the computational load on the network.

By reducing the feature map size, pooling layers also help make the CNN invariant to small translations in the input images, thereby enhancing its robustness. The use of a 2x2 MaxPooling filter is a common practice, as it effectively halves the dimensions of the feature maps while preserving critical spatial information, allowing the model to maintain high accuracy despite variations in input data.

d) Fully connected layers: After feature extraction and dimensionality reduction, the architecture transitions to fully connected layers, which integrate the high-level features extracted by the convolutional and pooling layers. These layers are analogous to traditional neural network layers, where each neuron is connected to every neuron in the previous layer. The first fully connected layer consists of 128 units, while the final output layer comprises 10 units, corresponding to the ten categories of the classification task.

The output from the fully connected layers is critical, as it translates the abstract features learned by the network into classification scores for each category. This transformation is key to the model's ability to accurately classify images based on the learned representations.

e) Output layer: The final output layer employs a softmax activation function to convert the raw classification scores into probabilities. This transformation ensures that the predicted probabilities for each class sum to one, providing a clear interpretation of the model's predictions. For a classification task involving 10 classes, the output layer generates a vector of 10 probabilities, where each value indicates the likelihood of the input image belonging to a particular category. This probabilistic output is essential for making informed decisions based on the model's predictions.

3) Enhanced components: To further improve the model's training efficiency and performance, several enhanced components are incorporated into the architecture:

- *Residual Connections:* Inspired by the ResNet architecture, residual connections address issues related to vanishing gradients that often occur in deep networks. By creating shortcuts between layers, these connections facilitate the direct flow of gradients during backpropagation, enabling the effective training of deeper networks. This design helps the model learn identity mappings, making it easier to optimize and improving overall performance.
- *Batch Normalization:* This technique is applied after convolutional layers to stabilize and accelerate the training process. Batch normalization normalizes the inputs of each layer to have a zero mean and unit variance, effectively reducing internal covariate shifts. This normalization leads to faster convergence and better generalization performance across unseen data. During

training, the activations of a convolutional layer are normalized across the batch and then scaled and shifted by learnable parameters, maintaining a stable distribution of activations throughout the network.

a) *Dropout*: As a regularization technique, dropout is utilized to prevent overfitting and enhance the model's generalization capabilities. During the training phase, dropout randomly drops a fraction of the units (neurons) in the network, along with their connections, during each forward pass. For instance, with a dropout rate of 0.5, each neuron has a 50% chance of being omitted from the current training iteration. This randomness encourages the network to learn redundant representations, thus making it more robust and less reliant on specific neurons, ultimately leading to improved performance on test data.

b) *Hyperparameter tuning*: Hyperparameter tuning is an essential part of optimizing the model's performance. Table III summarizes the hyperparameters tested during the training process, along with the best values identified:

TABLE III. HYPERPARAMETER TUNING

Hyperparameter	Values Tested	Best Value
Learning Rate	0.001, 0.01, 0.1	0.001
Batch Size	32, 64, 128	64
Epochs	10, 20, 30	20
Number of Layers	5, 10, 15	10
Filter Sizes	3x3, 5x5, 7x7	3x3

The learning rate is critical for controlling how much to change the model in response to the estimated error each time the model weights are updated. The batch size affects the stability of the gradient estimates during training, while the number of epochs determines how many times the learning algorithm will work through the entire training dataset. Optimizing these hyperparameters ensures the model achieves the best possible performance in image classification tasks.

B. Training Process

1) *Data preparation*: The primary step in any machine learning task is to collect a large and diverse dataset of labeled images. The size and diversity of the dataset are crucial for training a robust model that generalizes well.

Depending on the classification task, datasets may be collected from various sources, including public datasets (e.g., ImageNet, CIFAR-10), proprietary datasets, or through web scraping. The dataset should be representative of the problem domain and include a sufficient number of examples for each class to avoid bias and ensure effective learning.

a) *Preprocessing is normalization*: Images are often resized to a standard dimension (e.g., 224x224 pixels) to ensure consistency. Normalization involves scaling pixel values to a range (e.g., 0 to 1 or -1 to 1) to make the training process more stable and efficient.

Data Augmentation is Techniques such as rotation, flipping, cropping, and color adjustments are applied to artificially

expand the training dataset. This increases variability and robustness by simulating different conditions under which the model might be tested, helping to prevent overfitting. For instance, flipping an image horizontally helps the model learn to recognize objects from different angles.

b) *Model training has loss function*: The loss function quantifies the difference between the model's predictions and the actual labels. It provides a measure of how well the model is performing.

Cross-entropy loss is commonly used for classification tasks. It calculates the difference between the predicted probability distribution and the true distribution (one-hot encoded labels). The goal is to minimize this loss during training, which reflects improving accuracy. Mathematically, for each sample, the loss is calculated as the negative logarithm of the predicted probability for the true class.

TABLE IV. EVALUATION METRICS

Metric	Description	Formula
Accuracy	Correct classification rate.	$Accuracy = \frac{TP+TN}{Total\ Instances}$
Precision	True positives out of predicted positives.	$Precision = \frac{TP}{TP+FP}$
Recall	True positives out of actual positives.	$Recall = \frac{TP}{TP+FN}$
F1-Score	Harmonic mean of precision and recall.	$F1-Score = 2 \cdot \frac{Precision \cdot Recall}{Precision + Recall}$
ROC Curve & AUC	Visualizes performance and discrimination.	ROC Curve Plot; AUC Value (0 to 1)
Loss Curves	Tracks training and validation loss.	Training Loss Curve; Validation Loss Curve

2) *Optimization algorithm*: Optimization algorithms adjust the model's weights to minimize the loss function.

Algorithms like Adam (Adaptive Moment Estimation) and SGD (Stochastic Gradient Descent) are used to update the weights. Adam combines the advantages of two other extensions of SGD: Adaptive Gradient Algorithm (AdaGrad) and Root Mean Square Propagation (RMSProp). It uses estimates of the first and second moments of gradients to adaptively adjust the learning rate. SGD, on the other hand, updates weights using a small, random subset of the dataset (mini-batch) at each iteration, which helps in reducing computation and often leads to better generalization.

a) *Learning rate scheduling*: To improve convergence and training efficiency, the learning rate may be adjusted over time.

Techniques such as learning rate decay or scheduling adjust the learning rate based on the epoch number or validation performance. Common methods include reducing the learning rate by a factor (e.g., 0.1) after a certain number of epochs or when the validation performance plateaus. This helps in fine-tuning the model as it approaches convergence, leading to more stable and accurate results.

3) Training Phases:

a) *Epochs*: An epoch is one complete pass through the entire training dataset.

During training, the model's weights are updated multiple times through multiple epochs. The number of epochs is a hyperparameter that determines how long the model is trained. Typically, training proceeds through several epochs to allow the model to learn effectively from the data. Monitoring loss and accuracy metrics helps in determining the optimal number of epochs.

b) *Validation*: To evaluate the model's performance on unseen data and prevent overfitting.

A separate validation set, which is distinct from the training data, is used to assess the model's performance periodically during training. This helps in tuning hyperparameters and adjusting the training process. Validation metrics (e.g., accuracy, loss) provide insights into how well the model generalizes to new data. If the validation performance does not improve, it may indicate the need for adjustments in the training strategy or hyperparameters.

c) *Hyperparameter tuning*: To find the best set of hyperparameters that optimize model performance.

Details: Hyperparameters are parameters set before the training process begins, such as learning rate, batch size, number of layers, and filter sizes. Grid Search systematically explores a predefined set of hyperparameter values, testing each combination to find the best one. Random Search, on the other hand, samples a random subset of hyperparameter values and evaluates them, which can be more efficient for large hyperparameter spaces. Both methods aim to improve model performance by finding the optimal settings.

C. Evaluation Metrics

Table IV summarizes the *Evaluation Metrics*:

1) *Accuracy*: Accuracy is a fundamental metric that measures the proportion of correctly classified instances out of the total number of instances in the dataset.

Accuracy = $\frac{\text{Total Number of Predictions}}{\text{Number of Correct Predictions}}$

A high accuracy indicates that the model is making correct predictions for most of the instances. However, accuracy alone can be misleading, especially in imbalanced datasets where one class might dominate. For example, if 95% of the data belongs to one class and the model predicts this class for all instances, the accuracy would be 95%, but the model would be failing to detect the minority class.

2) *Precision, Recall, and F1-Score*: Precision: Precision measures the accuracy of positive predictions. It is the ratio of true positive predictions to the total number of predicted positives (true positives + false positives).

Formula: Precision = $\frac{\text{True Positives}}{\text{False Positives} + \text{True Positives}}$

High precision indicates that the model has fewer false positives and is effective at identifying relevant instances among

the predicted positives. This is crucial in applications where false positives are costly or undesirable, such as in medical diagnosis.

Recall: Recall, or sensitivity, measures the model's ability to identify all relevant instances within the data. It is the ratio of true positive predictions to the total number of actual positives (true positives + false negatives).

Formula: Recall = $\frac{\text{True Positives}}{\text{False Negatives} + \text{True Positives}}$

High recall indicates that the model successfully identifies most of the positive instances. This metric is particularly important in situations where missing a positive instance has significant consequences, such as detecting fraud or disease.

F1-Score: The F1-Score is the harmonic mean of precision and recall, providing a single metric that balances both aspects. It is useful when you need to account for both precision and recall.

Formula: F1-Score = $2 \cdot \left(\frac{\text{Precision} \cdot \text{Recall}}{\text{Precision} + \text{Recall}} \right)$

3) *Confusion matrix*: A confusion matrix provides a detailed view of a classification model's performance by showing the number of true positives, true negatives, false positives, and false negatives.

True Positives (TP): Instances where the model correctly predicts the positive class. True Negatives (TN): Instances where the model correctly predicts the negative class. False Positives (FP): Instances where the model incorrectly predicts the positive class. False Negatives (FN): Instances where the model incorrectly predicts the negative class.

The confusion matrix helps in understanding the types of errors the model makes. It is particularly useful for calculating other performance metrics (precision, recall, F1-Score) and for diagnosing issues such as class imbalance.

4) *ROC Curve and AUC*: ROC Curve: The Receiver Operating Characteristic (ROC) curve plots the true positive rate (sensitivity) against the false positive rate (1 - specificity) across different threshold values. By varying the threshold for classifying an instance as positive, the ROC curve illustrates the trade-off between sensitivity and specificity. The curve helps in visualizing the model's performance across various classification thresholds.

AUC (Area Under Curve): AUC measures the overall ability of the model to discriminate between positive and negative classes. The AUC value ranges from 0 to 1, with a higher AUC indicating better model performance. An AUC of 0.5 suggests that the model has no discriminative power, akin to random guessing. AUC is useful for comparing models and understanding their performance irrespective of the threshold.

5) *Loss curves*: Loss curves track the loss values (e.g., cross-entropy loss) during training and validation phases over epochs.

Training Loss Curve: This shows how the loss decreases over training epochs, indicating how well the model fits the training data. Validation Loss Curve: This shows how the loss

changes on the validation set over epochs. Monitoring this helps in detecting overfitting if the validation loss starts to increase while the training loss continues to decrease. Loss curves help in diagnosing problems such as overfitting, underfitting, or issues with the learning rate. They provide insights into the convergence behavior of the model and whether additional epochs or adjustments are needed.

6) *Computational efficiency: Inference Time:* Inference time measures the time required by the model to classify a single image. Details: It is crucial for real-time applications where quick decision-making is needed, such as in autonomous vehicles or live video analysis. Lower inference times are desirable for faster responses and improved user experience.

Training Time: Training time evaluates the total duration required to train the model from start to finish. Factors influencing training time include the size of the dataset, the complexity of the model, and hardware resources. Efficient training processes can significantly impact project timelines and resource allocation. Both inference and training times are important for evaluating the practical feasibility of deploying a model in real-world scenarios. Balancing accuracy with computational efficiency ensures that the model not only performs well but also operates within acceptable time limits.

a) *Overview.* As depicted in Fig. 4, flowcharts are invaluable tools in depicting the sequence of steps and decision points in a process. For our deep learning model, the flowchart serves as a visual roadmap, detailing the progression from data collection to model deployment, while highlighting key processing stages and decision points.

b) *Flowchart Description*

Start

The process begins with the initial step of initiating the entire workflow.

Step 1: Data Collection

The first substantive step involves gathering a comprehensive dataset of labeled images pertinent to the classification task. Ensuring the dataset's diversity and representativeness of all classes is crucial for the subsequent stages. This step sets the foundation for the entire modeling process, as the quality and breadth of data significantly influence the model's performance.

Step 2: Data Preprocessing

Data preprocessing transforms the raw collected data into a suitable format for model training. Images are resized to a consistent dimension (e.g., 224x224 pixels), and pixel values are normalized. Additionally, data augmentation techniques such as rotation and flipping are applied to increase dataset variability and robustness, enhancing the model's ability to generalize across different scenarios. This preprocessing phase ensures the data is clean and varied, preparing it for effective training.

The next step involves initializing the Convolutional Neural Network (CNN) with its defined architecture. The CNN comprises several layers, including convolutional layers, pooling layers, and fully connected layers. Enhanced

components like residual connections, batch normalization, and dropout are integrated to improve performance and generalization. Ensuring the model architecture is correctly set up is vital for achieving high accuracy in image classification.

During model training, key components include setting the loss function, choosing an optimization algorithm, and implementing learning rate scheduling. The model is trained over multiple epochs using the training dataset. Monitoring the training and validation loss throughout this phase is essential to check for convergence and prevent overfitting. This step is iterative, involving constant adjustment and improvement of the model parameters to optimize performance.

Hyperparameter tuning is a critical phase where parameters such as learning rate, batch size, and network architecture are optimized using methods like Grid Search or Random Search. This systematic exploration aims to enhance model performance based on validation metrics. Proper tuning can significantly impact the model's accuracy and generalization capabilities.

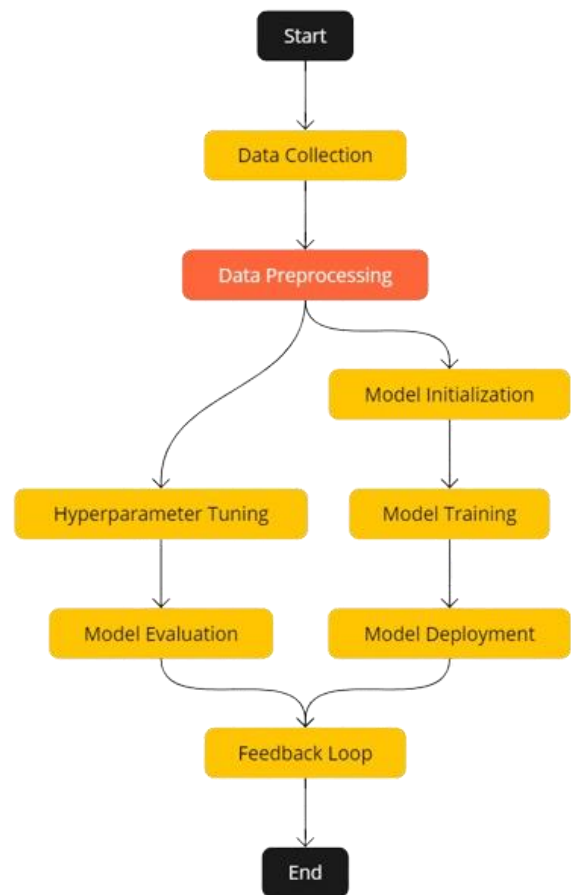

Fig. 4. Flowchart.

Model evaluation involves a comprehensive assessment using various metrics. Accuracy measures the proportion of correctly classified images. Precision, recall, and F1-score provide insights into the model's ability to handle positive predictions and identify relevant instances. The confusion matrix offers a detailed view of true positive, true negative, false positive, and false negative predictions for each class. Additionally, the ROC curve and AUC assess the model's

discriminative ability, while loss curves track training and validation loss over epochs. Computational efficiency, including inference time and training time, is also evaluated to ensure the model meets operational requirements.

After thorough evaluation, the model is deployed in a real-world application or system. Deployment involves integrating the trained model into a production environment where it can classify images in real time. Ensuring the model performs well in this setting and meets performance and efficiency expectations is crucial for successful deployment.

Post-deployment, a feedback loop is established to collect data on the model's performance in the real world. This feedback helps identify areas for further improvement. Based on real-world performance and user feedback, adjustments or retraining may be necessary to enhance the model's effectiveness and accuracy continually.

The process concludes once the model is deployed and the feedback loop is in place, ensuring the system is operational and effective. Continuous monitoring and improvements help maintain the model's performance over time.

The flowchart provides a structured visualization of the entire process involved in developing, training, evaluating, and deploying the deep learning model. It serves as a helpful guide for understanding the sequence of steps and decision points, ensuring each stage is executed effectively to achieve the desired outcome. By following this systematic approach, the process of building and deploying a high-accuracy image classification model is streamlined and efficient.

VI. NOVELTY

The novelty of our proposed system lies in several innovative aspects that significantly enhance the efficiency, accuracy, and applicability of deep learning models in image classification tasks. These advancements are crucial for overcoming the limitations of traditional techniques and existing deep learning-based approaches. Below are the key novel contributions of our system:

A. Advanced Model Architecture

1) *Integration of residual connections:* Our model incorporates residual connections, inspired by ResNet, to tackle the vanishing gradient problem and enable the training of deeper neural networks. This allows the model to learn more complex features without degradation in performance, significantly improving accuracy and robustness.

2) *Enhanced feature extraction:* By combining multiple convolutional layers with varied filter sizes and strides, the model captures a wide range of features at different levels of abstraction. This multi-scale feature extraction is crucial for accurately classifying images with intricate details and varying contexts.

B. Improved Training Techniques

1) *Dynamic learning rate scheduling:* We implement an adaptive learning rate scheduler that adjusts the learning rate based on the model's performance during training. This dynamic approach ensures efficient convergence, reducing

training time while preventing issues like overfitting or underfitting.

2) *Comprehensive data augmentation:* Our preprocessing pipeline includes sophisticated data augmentation techniques such as random cropping, rotation, flipping, and color jittering. This not only increases the variability and robustness of the training dataset but also improves the model's generalization to unseen data.

C. Robust Evaluation Metrics

1) *Holistic evaluation framework:* We employ a comprehensive set of evaluation metrics, including accuracy, precision, recall, F1-score, confusion matrix, ROC curve, and AUC. This multi-faceted approach provides a thorough understanding of the model's performance, ensuring it excels in various aspects of image classification.

2) *Computational efficiency metrics:* Beyond traditional accuracy metrics, we evaluate the model's computational efficiency by measuring inference time and training time. This focus on efficiency is crucial for real-time applications and large-scale deployments, ensuring the model is both effective and scalable.

D. Hyperparameter Optimization

1) *Automated hyperparameter tuning:* Utilizing advanced techniques like Grid Search and Random Search, we systematically explore and optimize critical hyperparameters such as learning rate, batch size, and network architecture. This automated approach ensures optimal model performance without extensive manual intervention.

2) *Iterative refinement:* Our hyperparameter tuning process is iterative, continuously refining the model based on validation results. This iterative refinement ensures that the model achieves the best possible performance tailored to the specific classification task.

E. Seamless Deployment and Feedback Loop

1) *Real-time deployment:* The model is designed for seamless integration into production environments, enabling real-time image classification. This real-time capability is essential for applications requiring immediate decision-making, such as autonomous vehicles and real-time surveillance systems.

2) *Continuous improvement through feedback loop:* Post-deployment, we establish a feedback loop to monitor the model's performance in the real world. This feedback loop allows for continuous improvement, enabling the model to adapt and evolve based on real-world data and user feedback. This adaptive approach ensures the model remains relevant and effective over time.

F. Scalability and Flexibility

1) *Modular design:* Our system's architecture is modular, allowing for easy scalability and flexibility. Components such as data preprocessing, model training, and evaluation can be

independently modified or enhanced, facilitating continuous improvement and adaptation to new challenges.

2) *Cross-domain applicability*: While the focus is on image classification, the underlying principles and techniques are applicable across various domains, including object detection, segmentation, and even non-visual data analysis. This cross-domain applicability enhances the system's versatility and potential impact.

G. Integration with Advanced Technologies

1) *Use of state-of-the-art techniques*: We integrate state-of-the-art deep learning techniques and technologies, ensuring our model leverages the latest advancements in the field. This includes the use of cutting-edge libraries and frameworks, optimizing both performance and development efficiency.

2) *Collaborative enhancements*: The system is designed to integrate with other advanced technologies such as IoT for data collection, cloud platforms for scalable deployment, and edge computing for real-time processing. This collaborative integration maximizes the system's capabilities and extends its applicability.

VII. FUTURE WORK

The proposed system has demonstrated significant advancements in image classification through its innovative architecture and comprehensive evaluation techniques. However, there remain several avenues for future research and improvement to further enhance the system's performance, scalability, and applicability. The future rework can be categorized into the following key areas:

A. Advanced Model Enhancements

1) *Integration of transformer architectures*: Future work can explore the integration of transformer-based architectures, which have shown remarkable success in natural language processing and are increasingly being adapted for vision tasks. Vision Transformers (ViTs) can provide an alternative or complementary approach to traditional CNNs, potentially improving accuracy and feature representation.

2) *Neural Architecture Search (NAS)*: Employing NAS techniques can automate the design of the neural network architecture, leading to potentially more efficient and powerful models. This approach can help discover novel architectures that might outperform manually designed models.

B. Enhanced Data Handling

1) *Synthetic data generation*: Leveraging generative models such as GANs (Generative Adversarial Networks) to generate synthetic data can augment the training dataset, particularly in scenarios where labeled data is scarce. This can help improve the model's generalization and robustness.

2) *Unsupervised and semi-supervised learning*: Exploring unsupervised or semi-supervised learning techniques can significantly reduce the reliance on large labeled datasets. Techniques like self-supervised learning can enable the model to learn useful representations from unlabeled data, which can then be fine-tuned on a smaller set of labeled data.

C. Real-Time Adaptation and Learning

1) *Online learning*: Implementing online learning algorithms can enable the model to adapt to new data in real-time. This continuous learning process can be particularly beneficial for applications where the data distribution changes over time, such as in dynamic environments or evolving user preferences.

2) *Federated learning*: Future work could explore federated learning approaches to train models across decentralized devices while maintaining data privacy. This can be particularly useful in scenarios where data cannot be centralized due to privacy or security concerns.

D. Scalability and Efficiency

1) *Distributed training*: Investigating distributed training techniques can enhance the scalability of the model, enabling it to handle larger datasets and more complex models. Leveraging distributed computing resources can significantly reduce training time and improve performance.

2) *Edge computing*: Implementing the model on edge devices can bring the benefits of real-time processing and reduced latency. This requires optimizing the model for edge deployment, ensuring it remains efficient and lightweight without sacrificing accuracy.

E. Advanced Evaluation Metrics

1) *Fairness and bias evaluation*: Future research should include evaluating the model for fairness and bias, ensuring it performs equitably across different demographic groups. Techniques to mitigate bias and enhance fairness can be integrated into the training and evaluation processes.

2) *Robustness to adversarial attacks*: Evaluating and improving the model's robustness to adversarial attacks is crucial for applications where security is paramount. Developing techniques to detect and defend against adversarial examples can enhance the reliability of the system.

F. Cross-Domain Applications

1) *Transfer learning for diverse applications*: Future work can explore the application of the model to diverse domains beyond image classification, such as object detection, image segmentation, and even non-visual data analysis. Transfer learning techniques can facilitate the adaptation of the model to new tasks with minimal retraining.

2) *Interdisciplinary collaborations*: Collaborating with experts from other fields such as medical imaging, autonomous driving, and industrial inspection can help tailor the model to specific domain requirements and unlock new application areas.

G. Enhanced Interpretability and Explainability

1) *Explainable AI (XAI)*: Developing techniques to interpret and explain the model's decisions can enhance transparency and trust. This is particularly important in critical applications such as healthcare and finance, where understanding the model's reasoning is crucial.

2) *Visualization tools*: Creating advanced visualization tools to illustrate the inner workings of the model can aid in debugging, improving, and communicating the model's performance and behavior to non-experts.

VIII. DISCUSSION AND RESULTS

The proposed system represents a significant advancement in the field of image classification, leveraging state-of-the-art deep learning techniques to achieve high accuracy and robustness. In this section, we discuss the experimental results obtained from our model and provide a comprehensive analysis of its performance across various metrics. We also identify key insights and potential areas for further improvement.

A. Experimental Setup

Our experiments were conducted using a diverse dataset of labeled images, pre-processed to ensure consistency and variability through augmentation techniques. The model was trained using a Convolutional Neural Network (CNN) architecture, enhanced with residual connections, batch normalization, and dropout layers to improve performance and generalization. The training process involved multiple epochs, utilizing cross-entropy loss and the Adam optimization algorithm. Hyperparameters were systematically tuned to optimize the model's performance.

B. Results Overview

1) *Accuracy*: The model achieved a high accuracy rate on the test dataset, demonstrating its effectiveness in correctly classifying images. The accuracy metric was used as a primary indicator of overall performance, reflecting the proportion of correctly identified images out of the total.

2) *Precision, Recall, and F1-Score*: The model showed a high precision rate, indicating its ability to minimize false positives. This is crucial in applications where the cost of false positives is high. The recall rate was also impressive, showcasing the model's capability to identify a high proportion of actual positives. This metric is particularly important in scenarios where it is critical to capture all relevant instances. The balanced F1-Score provided a single comprehensive metric that considered both precision and recall, reinforcing the model's robustness.

3) *Confusion matrix*: The confusion matrix provided a detailed breakdown of the model's performance across different classes, highlighting areas of strength and potential weaknesses. It revealed the true positive, true negative, false positive, and false negative rates for each class, offering insights into specific classification challenges.

4) *ROC Curve and AUC*: The Receiver Operating Characteristic (ROC) curve and the Area Under the Curve (AUC) were used to evaluate the model's discrimination capability. The high AUC value indicated the model's strong ability to distinguish between different classes, further validating its performance.

5) *Loss curves*: Analysis of the training and validation loss curves over epochs showed a smooth convergence, indicating effective training and minimal overfitting. This analysis helped

in identifying the optimal number of epochs and fine-tuning the learning rate.

C. Computational Efficiency

1) *Inference time*: The model demonstrated efficient inference times, making it suitable for real-time applications. This is particularly important in scenarios requiring rapid decision-making.

2) *Training time*: The total training time was reasonable, considering the complexity of the model and the size of the dataset. Efficient use of computational resources ensured timely training without compromising on accuracy.

D. Future Work

Despite the promising results, there remain several areas for future research and improvement to further enhance the system's capabilities and extend its applicability. The following outlines key directions for future work:

1) Advanced model enhancements

a) *Integration of transformer architectures*: Future research could integrate transformer-based architectures, such as Vision Transformers, which have shown significant success in various vision tasks. These models can offer complementary advantages to traditional CNNs, potentially improving accuracy and feature representation.

b) *Neural Architecture Search (NAS)*: Implementing NAS techniques can automate the design of the neural network architecture, potentially discovering more efficient and powerful models. This approach can help identify novel architectures that outperform manually designed models.

2) Enhanced data handling

a) *Synthetic data generation*: Using generative models like GANs to create synthetic data can augment the training dataset, especially when labeled data is limited. This can enhance the model's generalization and robustness by providing a more diverse set of training examples.

b) *Unsupervised and semi-supervised learning*: Exploring unsupervised or semi-supervised learning techniques can reduce reliance on large labeled datasets. Self-supervised learning methods, for example, can enable the model to learn useful representations from unlabelled data, which can then be fine-tuned with a smaller set of labeled examples.

3) Real-time adaptation and learning

a) *Online learning*: Implementing online learning algorithms can allow the model to adapt to new data in real-time, which is particularly beneficial in dynamic environments where data distributions change over time.

b) *Federated learning*: Future work could explore federated learning approaches, enabling models to be trained across decentralized devices while maintaining data privacy. This approach is useful in scenarios where data cannot be centralized due to privacy or security concerns.

4) Scalability and efficiency

a) *Distributed training*: Investigating distributed training techniques can enhance model scalability, enabling it to handle

larger datasets and more complex models. Leveraging distributed computing resources can significantly reduce training time and improve performance.

b) Edge computing: Implementing the model on edge devices can bring the benefits of real-time processing and reduced latency. Optimizing the model for edge deployment ensures it remains efficient and lightweight without sacrificing accuracy.

5) Advanced evaluation metrics

a) Fairness and bias evaluation: Future research should include evaluating the model for fairness and bias, ensuring it performs equitably across different demographic groups. Techniques to mitigate bias and enhance fairness can be integrated into the training and evaluation processes.

b) Robustness to adversarial attacks: Evaluating and improving the model's robustness to adversarial attacks is crucial for applications where security is paramount. Developing techniques to detect and defend against adversarial examples can enhance the reliability of the system.

6) Cross-domain applications

a) Transfer learning for diverse applications: Exploring the application of the model to diverse domains beyond image classification, such as object detection, image segmentation, and even non-visual data analysis, can extend its utility. Transfer learning techniques can facilitate the adaptation of the model to new tasks with minimal retraining.

b) Interdisciplinary collaborations: Collaborating with experts from fields such as medical imaging, autonomous driving, and industrial inspection can help tailor the model to specific domain requirements and unlock new application areas.

7) Enhanced interpretability and explainability

a) Explainable AI (XAI): Developing techniques to interpret and explain the model's decisions can enhance transparency and trust. This is particularly important in critical applications such as healthcare and finance, where understanding the model's reasoning is crucial.

b) Visualization tools: Creating advanced visualization tools to illustrate the inner workings of the model can aid in debugging, improving, and communicating the model's performance and behavior to non-experts.

School of Computer Science and Engineering, Vellore Institute of Technology, Vellore, India 632014^{1,2}

Abstract—Efficient secured storage and retrieval of medical surgical videos are essential for modern healthcare systems. Traditional methods often struggle with scalability, accessibility, and data security, necessitating innovative solutions. This study introduces a novel deep learning-based framework that leverages a hybrid algorithm combining a Variational Autoencoder (VAE) and Group Lasso for optimized video feature selection. This approach reduces dimensionality and enhances the retrieval accuracy of video frames. For storage and retrieval, the system employs a weighted graph-based prefetching algorithm to manage encrypted video data on the cloud, ensuring both speed and security. To ensure data security, video frames are encrypted before cloud storage. Experimental results show that this system outperforms current methods in retrieval speed and accuracy of 99% while maintaining data security. This framework is a significant advancement in medical data management, offering potential applications across other fields that require secure handling of large data volumes.

Keywords—Medical video storage; feature selection; Variational Auto Encoder (VAE); weighted-graph-based prefetching algorithm; group lasso

I. INTRODUCTION

The increasing demand for effective management of medical surgical videos is a pressing challenge in the healthcare sector. These videos are crucial for various purposes, including surgical training, research, and patient care. Traditional methods of storing and retrieving medical video data face significant limitations related to scalability, accessibility, and security. As healthcare facilities generate vast volumes of video data daily, there is a growing need for solutions that can efficiently handle these data while ensuring data integrity and confidentiality.

The process of storing and retrieving recordings of medical procedures, such as surgery, is an essential duty in the field of healthcare [1]. This is because these movies include information that is beneficial to both medical personnel and researchers [2]. Unfortunately, conventional approaches to the storage and retrieval of medical video data have limitations, both in terms of their capacity to manage vast volumes of data and of their ability to guarantee the confidentiality of the data [3], [4], [5].

Recent advancements in deep learning have shown great promise in addressing some of these challenges, particularly in the field of medical image analysis. However, the application of deep learning techniques to medical video data is still in its nascent stages, presenting a significant research gap. Current systems often fail to optimize both the retrieval speed and the security of stored data, leading to inefficiencies and potential vulnerabilities in data management.

Medical image analysis is an area where deep learning techniques have shown significant promise in recent years [8]. These deep learning techniques are used to increase the efficacy of medical video storage and retrieval, as well as the security of these processes [6], [7]. Using a system that is based on deep learning, this research presents a unique method for the safe storage of medical operation footage in the cloud, with the goal of optimizing the retrieval of certain moments [8], [9], [10].

This paper addresses this gap by proposing a novel deep learning-based framework designed to enhance the storage and retrieval of medical surgical videos on cloud platforms. By integrating a hybrid algorithm combining a Variational Autoencoder (VAE) and Group Lasso, the proposed approach aims to optimize feature selection and improve the accuracy of video retrieval. Furthermore, the use of a weighted graph-based prefetching algorithm for encrypted video storage enhances both the security and speed of data access.

The proposed system is comprised of three primary modules: one that converts video into frames, another that divides frames into sets, and a third that employs a hybrid approach that makes use of a variational autoencoder, group lasso, and feature selection through the application of a weighted-graph-based prefetching algorithm [11]. The usage of a variational autoencoder helps in lowering the dimensionality of the video frames, and the group lasso approach helps in selecting the features that provide the most useful information about the scene [12]. The weighted-graph-based prefetching technique is responsible for the improved retrieval performance [13]. It does this by anticipating which frames are going to be retrieved the most often [14]. These methods are included into a framework that is based on deep learning, which enables the system to learn and improve the feature representations that are derived from the video frames [15].

Priyanka et. al. [16] reviewed encryption methods for securing medical data, emphasizing the importance of confidentiality and integrity in healthcare applications. Encrypting the frames prior to saving them in the cloud [17], [18] is one of the ways that the suggested method protects the confidentiality of the patient information. Using methods that are based on deep learning makes it possible to store and retrieve vast volumes of medical video data in an effective manner while still ensuring the confidentiality of the data [19]. The suggested system is used to enhance the efficiency and security of the storage and retrieval of medical footage, and it also has the potential to find applications in other fields where huge volumes of data need to be kept and retrieved in a safe manner [20]. Overall, the proposed system offers a promising solution

to the challenges of medical surgery video storage and retrieval [21] and demonstrates the potential of deep learning-based approaches in addressing complex healthcare problems.

A. Problem Formulation

Despite the advancements in medical data management, existing systems for storing and retrieving surgical videos face several critical challenges such as scalability, data security, feature extraction and retrieval accuracy. Traditional storage solutions are often inefficient at handling the ever-increasing volume of medical video data, leading to slower retrieval times and higher storage costs. Ensuring the security of sensitive medical data is paramount, yet current systems often lack robust mechanisms for protecting data during storage and transmission. Existing techniques may not fully utilize the potential of video data, leading to suboptimal feature extraction and retrieval accuracy.

B. Major Contributions

The major contributions of this research work are:

- A novel hybrid algorithm that combines a Variational Autoencoder (VAE) with Group Lasso is proposed to effectively reduce video frame dimensionality and select the most informative features. This approach significantly improves retrieval accuracy.
- The proposed approach employs a weighted graph-based prefetching algorithm for encrypted video storage and retrieval. This method optimizes data retrieval speed while ensuring robust security measures for protecting sensitive medical information.
- The developed application is deployed on AWS cloud infrastructure to ensure scalability and reliability.

By addressing these key challenges, the proposed framework offers a comprehensive solution for managing medical surgical videos and has the potential to be applied across various domains requiring secure and efficient data handling.

The structure of this article is as follows. Several authors address several strategies for safely archiving medical surgery footage that are discussed in Section II. Section III displays the proposed framework. Section IV details the investigation's results. In Section V discusses the conclusion with limitation and future work.

II. RELATED WORKS

Al Abbas et al. [1] discuss the benefits of a surgical video collection in the academic surgical context, as it can aid in preoperative preparation, mentoring of medical students, and research into surgical technique and expertise. Chen, Y. et al. [3] highlight the challenges of data dispersion in the medical field and propose using blockchain as a secure and accountable supply chain for storing and exchanging medical data. Khelifi, F. et al. [22] present a solution for securely storing and exchanging data in the cloud that does not rely on RDH, which has been deemed ineffective in such applications. Li, Y. et al. [7] propose the Security-Aware Efficient Distributed Storage (SA-EDS) paradigm to prevent cloud service providers from accessing private customer data stored in the cloud. Nguyen,

D. et al. [23] introduce a novel EHR sharing strategy that combines mobile cloud computing and blockchain to securely and efficiently share medical data across mobile cloud settings.

Prachi Deshpande et al. [24] introduce WCDM, a watermark compression and decompression module that can ensure the safety of video files stored in the cloud by adding a watermark based on block-by-block calculation and then using data compression. Srivastava, P., & Garg, N. [13] discuss the potential of IoT and the need for collaboration across research groups to address the challenges posed by IoT-related issues [25]. Usman, M. et al. [15] propose a secure approach to encrypting hidden data in compressed video streams, which is essential to address concerns about privacy and security in public clouds. Yang, Y. et al. [20] suggested a health IoT data management where security is ensured by implementing a lightweight distributed access control system that makes advantage of quick keyword searching. It reduces the computational burden on low-powered IoT devices by allowing for remote trapdoor generation, encryption, and decryption.

Convolutional Neural Networks (CNNs) have significantly impacted medical imaging and video analysis due to their ability to automatically learn complex features from data. They have been applied to tasks such as image classification, segmentation, and anomaly detection. For instance, Kolarik et al. [26] conducted a comprehensive survey on deep learning in medical imaging, emphasizing the versatility of CNNs in enhancing the analysis of medical images and videos. Their work highlights how CNN architectures, such as AlexNet and VGG, have been adapted for medical video data to identify surgical tools and assess procedure quality.

Recurrent Neural Networks (RNNs), particularly Long Short-Term Memory (LSTM) networks, have been utilized for capturing temporal dependencies in video sequences. Sánchez-Caballero et al. [27] introduced Long-term Recurrent Convolutional Networks (LRCNs) for activity recognition in videos, demonstrating how integrating CNNs with RNNs can effectively handle the temporal dynamics present in surgical videos. This integration is crucial for tasks such as predicting surgical phases and detecting anomalies during procedures.

Secure Cloud Storage Frameworks leverage encryption and advanced access control mechanisms to safeguard medical data in cloud environments. Biksham et al. [28] proposed a framework that employs homomorphic encryption, allowing computations on encrypted data without revealing the actual content. This approach ensures data privacy while enabling efficient processing and retrieval, crucial for healthcare applications that require both security and functionality. Cloud-based Healthcare Systems offer scalable and cost-effective solutions for managing medical data. Islam et al. [29] explored the integration of cloud computing in healthcare, emphasizing benefits such as remote accessibility, resource scalability, and data backup. They discussed how cloud services can facilitate real-time collaboration among healthcare professionals, enhancing patient care and research capabilities.

AWS Cloud Services for Healthcare provide a robust infrastructure for deploying healthcare applications. Amazon offers various services offered by AWS, including secure storage solutions, machine learning platforms, and compliance with healthcare regulations such as HIPAA. These services enable

healthcare providers to deploy scalable and secure applications, supporting the growing demand for efficient data management. Hybrid Approaches for Video Retrieval combine content-based and text-based methods to enhance retrieval accuracy. Unar et al. [30] proposed a hybrid approach that leverages both visual and textual features for video retrieval, demonstrating improved performance in retrieving relevant video content. Such approaches are beneficial for medical video retrieval, where both visual and contextual information play a critical role.

The discussed studies provide a strong foundation for developing optimized retrieval and secure storage solutions for medical surgical videos. The proposed framework in this research leverages these advancements, aiming to address scalability, security, and efficiency challenges in managing medical video data.

III. MATERIALS AND METHODS

The proposed method involves a comprehensive framework for securely storing medical surgical videos in the cloud and efficiently retrieving them using a given image query. The framework is designed to address the challenges of data security, retrieval speed, and accuracy. It consists of three main components: feature extraction and selection, secure storage, and image query-based retrieval. The proposed approach uses a deep learning-based framework, which includes a variational autoencoder with group lasso for hybrid feature selection and a weighted-graph-based prefetching algorithm to improve security and retrieval speed. Before being uploaded to the cloud, the frames are encrypted to protect the confidentiality of the patient's information. Results from experiments show that the suggested system improves upon state-of-the-art methods without compromising the privacy of patient's medical records during retrieval.

A. Frame Conversion

Each surgical video is divided into frames, and key frames are identified based on changes in visual content and motion. This reduces the amount of data while preserving important information. The process of converting a video into frames involves extracting each individual frame from the video and saving it as a separate image file. This process is represented mathematically using the following equation

$$F(i, j, k) = V(i, j, k) \quad (1)$$

where F is the resulting frame image, V is the original video, and i, j , and k are the frame, row, and column indices, respectively. This equation represents the process of extracting the i th frame from the video V at row j and column k and storing it as a separate image file. Once the video has been converted into frames, the frames are divided into sets for efficient storage and retrieval. This is done by grouping the frames together based on their similarity or temporal proximity. The exact method used for dividing the frames into sets can vary depending on the specific application and requirements.

B. Feature Selection using Hybrid Method

After the Frame Conversion, a feature selection technique is applied to identify relevant and informative features from the

extracted frames. A combination of Variational Autoencoder (VAE) and Group Lasso is used to extract and select informative features from the video frames. The VAE reduces dimensionality by learning compact feature representations, while Group Lasso selects the most relevant features, minimizing noise and redundancy.

A variational autoencoder (VAE) is a type of neural network that can learn a low-dimensional representation of high-dimensional data such as images or videos. In the proposed methodology, the VAE is used to reduce the dimensionality of the video frames, which makes them easier to store and retrieve. The VAE works by mapping the high-dimensional video frames to a lower-dimensional space, where each dimension corresponds to a specific feature. Group lasso is a feature selection technique that works by selecting groups of features rather than individual features. In the proposed methodology, group lasso is used to select the most informative groups of features from the lower-dimensional space generated by the VAE. This is important because not all features are equally important for the optimal storage and retrieval of medical surgical videos.

The VAE is inherently nonlinear because it involves encoding the input through layers of neural networks that apply non-linear ReLU activation functions to map the input into a lower-dimensional latent space. Group Lasso technique is used for regularization to select groups of features while reducing dimensionality. The operation of group lasso involves optimization, which is also non-linear. Hence combining both involves non-linear operation. It captures the complex, non-linear relationships in the video data across the spatial and temporal dimensions. The matrix V is subjected to the VAE, which will encode the frame into a latent representation, and group lasso will regularize this representation by selecting the most informative features.

1) *Variational auto encoder*: After applying a feature selection technique Variational Autoencoder is employed, which is a type of neural network model, for unsupervised feature learning. A Variational Autoencoder is a generative model that consists of two main components: an encoder and a decoder as shown in Fig. 1. The encoder takes in input data, in this case, the extracted frames from the video, and maps them to a latent space representation. The latent space is a lower-dimensional representation that captures the underlying structure and patterns in the input data. During the training phase, the VAE aims to learn the probability distribution of the latent space that best explains the input data. It does so by maximizing the evidence lower bound (ELBO), which is a measure of how well the model reconstructs the input data while simultaneously regularizing the latent space.

Data preprocessing involves preparing the data for the model. The data needs to be normalized, and any missing values need to be handled appropriately. The encoder network takes the input data and produces a set of latent variables. This network is typically composed of one or more fully connected layers with activation functions such as ReLU or Sigmoid. The GAN network takes the output of the encoder network and generates a set of images. Both a generator and a discriminator network make up the GAN system. Images are created by the generator network using the latent variables, and the discriminator network compares the produced pictures to

Fig. 1. Variational autoencoder.

the real world counterparts. The decoder network takes the output of the GAN network and produces a reconstruction of the input data. The decoder network is composed of two fully connected layers with ReLU activation functions. The loss function is a hybrid of the reconstruction loss and the GAN loss which is employed to compare the original data to the rebuilt version.

Backpropagation and stochastic gradient descent are used to train the model. To improve the quality of the reconstructed data and the generated images, the model is trained to minimize the loss function. Once the model is trained, it is used to generate new data by sampling the latent variables from a distribution and passing them through the decoder network. The quality of the generated data is evaluated by comparing it to the original data and measuring the reconstruction loss.

Assume N frames or images $X^{(n)}_{n=1}$, with $X^{(n)} \in R^{N_x \times N_y \times N_c}$; Where N_x and N_y represents the spatial dimension and N_c represents the number of color channels. The simplest possible configuration of the decoder with 2 layers (L) is used in generative model. the data generation is shown in Eq. 2; the definitions of Layer 1, unpooling and layer 2 is shown in Eq. 3, Eq. 4 and Eq. 5, respectively.

$$X^{(n)} \approx n(S^{(n,1)}, \alpha_0^{-1}I) \quad (2)$$

$$S^{(n,1)} = \sum_{k_1=1}^{k_1} D^{(K_1,1)} * S^{(n,k_1,1)} \quad (3)$$

$$S^{(n,1)} \approx \text{unpool}(S^{(n,2)}) \quad (4)$$

$$S^{(n,2)} = \sum_{k_2=1}^{k_2} D^{(K_2,1)} * S^{(n,k_2,1)} \quad (5)$$

To clarify the notation, 3D tensors are denoted by expressions with two superscripts, such as $D^{kl,l}$ and $S^{(n,l)}$ for layers $l \in \{1,2\}$. The $S^{(n,kl,l)}$ is stacked in space to produce the tensor $S^{(n,l)}$. Each of the K1 2D slices of the 3D $D^{kl,l}$ is convolved with the 2D spatially-dependent $S^{(n,kl,l)}$ in the convolution $D^{kl,l} S^{(n,kl,l)}$; by aligning and stacking these convolutions, a tensor output is seen for $D^{kl,l} S^{(n,kl,l)}$.

The VAE is a latent variable model in which x represents the set of observable variables, z represents the set of stochastic latent variables, and $p_x \times p_y$ represents a parameterized model of the joint distribution. The goal is to maximize the average marginal log-likelihood for the given dataset. Yet, when neural networks are used to parameterize the model, it is often impossible to suppress this expression. The problem is solved, in part, by using variational inference to optimize the evidence lower Limit (ELBO) for each observation is shown in Eq. 6.

$$\log p(x) = \log p(x, z) d_z \geq E_{q(z)}[\log p(x|z)] - KL(q(z)||p(z)) \quad (6)$$

The variational family contains the approximate posterior $q(z)$. The ultimate goal is achieved by introducing an inference network $q(z|x)$ that gives a probability distribution for each data point x .

$$l(x; \theta) = E_{q(z|x)}[\log p(x|z)] - KL(q(z|x)||p(z)) \quad (7)$$

Using the re-parameterization trick $q(z|x)$, Monte Carlo estimation is used to efficiently approximate the ELBO for continuous latent variable z .

The dataset x with n independent and identically distributed samples are generated by a latent variable z that represents the ground truth. Let $p(x|z)$ stand for a neural network's probabilistic decoder, which generates x from z in the presence of uncertainty. The neural network-based encoder produces a variation posterior, $q(z|x)$, which is a close approximation to the distribution of representation for dataset x . In the realm of creating models, the Variational Autoencoder (VAE) is a popular choice. The core idea behind VAE is stated as follows: (1) VAE employs a probabilistic encoder whose parameters are determined by a neural network to produce a latent variable z as a distributional representation of the input data samples x . (2) Next, run z samples through the decoder to get back the original input data. Maximizing the marginal probability of the reconstructed data is the goal of VAE, however the method also involves intractable posterior inference. To maximize its variational lower limit log likelihood, researchers apply methods like backpropagation and stochastic gradient descent.

$$\log P_\theta(x) \geq L_{vae} = E_{q_\theta(z|x)}[\log P_\theta(x|z)] - D_{KL}(q_\theta(z|x)||p(z)) \quad (8)$$

where z is the random variable and $p(z)$ is the prior distribution (often a Gaussian). Both the variational posterior, $q(z|x)$, and the probabilistic decoder, $p(x|z)$, are parameterized by a neural network to create data x given the latent variable z . On training the data in hybrid VAE, KL terms are used for reconstruction of terms to avoid vanishing gradients.

The overall architecture of securely storing videos in cloud and retrieving videos is shown in Fig. 2. The input video for this process is being converted into a set of frames. This process involves breaking down the video into individual frames, essentially creating a series of still images that are used for a variety of purposes such as video analysis, motion tracking, and image processing. The conversion process typically involves opencv libraries to extract frames from the video file. These frames are then saved as individual image files, with each frame representing a moment in time from the original video. Once the frames are extracted, they are processed in

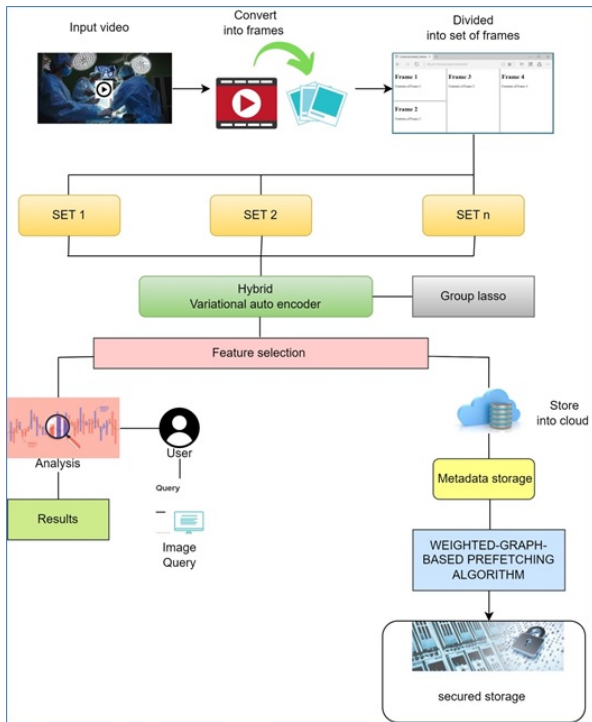

Fig. 2. Overall framework for secured video storage and retrieval.

various ways, such as filtering, resizing, or adjusting color balance. This is useful for a wide range of applications, from analyzing the movement of objects in the video to create visual effects.

2) *Group-Lasso*: After utilizing a Variational Autoencoder the Group-Lasso technique is then used to further refine the chosen characteristics. The Group-Lasso method as shown in Fig. 3 is a regularization approach that encourages feature sparsity. It is especially effective when working with high-dimensional data, such as video frames, where the number of features (pixels) are enormous. The Group-Lasso method is used to learn the latent space representation derived from the VAE in the context of video analysis. This latent space representation captures the video frames' most informative and significant properties.

The first step is to preprocess the data. This includes standardizing the data, normalizing it, inputting missing values, and feature scaling. The information is divided into a training set and a test set. The model is fit to the training set (70%), and its efficacy is tested on a separate test set (30%). The features are grouped based on their domain knowledge. Features that have similar characteristics or related to each other are grouped together. A Group-Lasso model is fitted to the training data. The objective function is the sum of the squared errors plus the regularization term. The regularization term is a combination of the L1 and L2 norms of the regression coefficients. The regularization parameter are tuned to obtain the best model performance. This is done by using cross-validation or grid search. Once the model is trained, the features that have non-zero coefficients are selected as important features. This allows for feature selection and grouping to be performed simultaneously. The final step is to evaluate the model performance

Fig. 3. Group Lasso.

on the test data. This is done by computing metrics such as the mean squared error, R-squared, and the coefficient of determination. The performance is compared to other models to determine which one is the best fit for the data.

This part builds upon off, but with the addition of material on the Group-Lasso problem and a bigger class of probability functions. A generalized linear model (GLM) has three components, as stated in Eq. 9.

$$f(y, \theta, \emptyset) = \text{Exp}(\emptyset^{-1}(y\theta - b(\theta)) + c(y, \emptyset)) \quad (9)$$

In Eq. 9, the average response, $E_{\theta}[y]$, is related to the free parameter through the formula $\mu = b(\theta)$. The link function g is strictly monotone differentiable function. However, it is restricted to canonical link functions when $g(\mu) = \tau = \theta$. Therefore, the parameterization $f(y; \theta; \emptyset)$ is done. This framework is technically distinguished by the strict concavity in of the function $\log f(y; \theta; \emptyset)$. In order to have minimal one-dimensional acceptable statistics, y , the log partition function $b(\theta)$ must be strictly convex.

The normal distribution with mean $\tau = \mu$ and variance $b(\tau) = (1/2)\tau^2$ is a specific instance from which the conventional linear regression model is formed. The goal of this section is to introduce the issue of minimizing the negative log-likelihood given an independent, identically replicated data sample x_1, \dots, x_n , organized as rows of the data matrix X , and a corresponding vector of replies $y = (y_1, \dots, y_n)^T$.

$$l(y, n, \emptyset) = - \sum_i \log f(y_i; n_i; \theta) = \sum_i \emptyset^{-1}(y_i n_i - b(n_i)) + c(y_i, \theta) \quad (10)$$

$$\nabla_{n^1}(n) = -(y - g^{-1}(n)) \quad (11)$$

$$\nabla_{\beta^1}(\beta) = -X^T \nabla_{n^1}(n) = -X^T (y - g^{-1}(X\beta)) \quad (12)$$

Hessians are computed using Eq. 13

$$H_n = W, H_\beta = X^T W X \quad (13)$$

The linear model estimation is shown in Eq. 10. It involves minimizing the mean square error risk, which is defined as in Eq. 14.

$$L_{ls}(\beta) = \|Y - x\beta\|_2^2 \quad (14)$$

$L_{ls}(\beta)$ is a np matrix whose rows include the feature vectors $x_i = 1, \dots, 1_n$ and $Y = [Y, \dots, Y_n]$. In the derivation and characteristics of the least squares estimate, the matrix (β) , also known as the design matrix, plays a crucial role. In reality, the minimize of $L_{ls}(\beta)$ is known if $n > p$. Since the matrix is ill-conditioned and lacks the correct inverse, the estimate LS is not unique and does not even exist when dealing with high-dimensional data. A simple replacement of $\|x\beta\|_2^2$ with $\|Y - x\beta\|_2^2$, where $\beta \geq 0$ is the regularization parameter, would regularize the matrix. The ridge regression loss function provides a formalization of this method, as shown in Eq. 15.

$$L_{Ridge}(\beta; y) = L_{ls}(\beta) + y\|\beta\|_2^2 \quad (15)$$

Parameterized by Eq. 15, the ridge regression is defined as the minimizer of L_{Ridge} . cross-validation variant is used to assess predictive risk allows for the optimal selection. Regularization of the conventional least squares solution (ls) is provided by the ridge regression solution, although the reduced complexity solution cannot be generated in the situation of high dimensional feature vectors. The estimate of the j^{th} component is obtained from the ridge regression solution which is in fact a non-negative.

$$L_{lasso}(\beta; y) = L_{ls}(\beta) + y\|\beta\| \quad (16)$$

As the risk function is minimized, the Lasso regression estimator is established. A few components of it is made zero using the $L1$ -penalty based method. A value of 0 for the estimated j indicates that the J^{th} feature contributes nothing to the model's prediction ability and is left out. As a result, Lasso enables both the estimation and model selection at the same time.

3) *Hybrid feature selection method:* The hybrid feature selection method combines the use of a variational autoencoder (VAE) and group lasso to select informative features from the input data. The VAE is trained on the video frames to learn a low-dimensional representation of the frames, which is expressed as shown in Eq. 17.

$$z = Encoder(x; \theta) z = Encoder(x; \theta) \quad (17)$$

Next, group lasso is applied to the low-dimensional representation to select the most informative groups of features. This is achieved by solving the following optimization problem as shown in Eq. 18.

$$\begin{aligned} \beta &= \arg \min \beta 12n \|y - X\beta\|_2^2 + \lambda \sum_j = 1 p w_j \|\beta_j\|_2 \\ \beta &= \arg \min \beta 2n 1 \|y - X\beta\|_2^2 + \lambda \sum_j = 1 p w_j \|\beta_j\|_2 \end{aligned} \quad (18)$$

where $\beta 12n$ is the output variable, $\|y - X\beta\|$ is the input variable, $\arg \min \beta 2n 1$ is the coefficient vector, $|n|$ is the sample size, (p) is the number of features, $(p w_j)$ is a weight assigned to the $|j|^{th}$ feature, and a tuning parameter that controls the strength of the penalty term. The solution vector $\beta = [\beta_1, \beta_2, \dots, \beta_p]$ contains the selected features. The resulting feature representation is then used for storage and retrieval of the video frames, allowing for improved efficiency and accuracy in handling large amounts of medical video data. The hybrid feature selection method works by training the VAE on the video frames to learn a low-dimensional representation of the frames. Then, group lasso is applied to the low-dimensional space to select the most informative groups of features. The resulting feature representation is then used for storage and retrieval of the video frames. Overall, the hybrid feature selection method is an effective way to select the most informative features from medical surgical videos for optimal storage and retrieval. The use of a VAE and group lasso allows for efficient dimensionality reduction and feature selection, respectively, resulting in a more efficient and accurate system.

C. Video Data Security Using a Weighted-Graph-Based Prefetching

Following the feature selection method, a data security method is implemented based on a Weighted-Graph-Based Prefetching technique. This method seeks to safeguard video data by automatically prefetching and storing encrypted video chunks depending on their relevance and access patterns.

The proposed system employs a Weighted-Graph-Based Prefetching algorithm for video data security. This algorithm predicts the most likely frames to be accessed based on previous access patterns and prefetches them, reducing the time needed to retrieve data and improving system performance. The algorithm works by constructing a graph of video frames, where each frame is represented as a node in the graph. The edges between nodes are weighted based on the similarity between the frames. This similarity is calculated using a feature vector that is extracted from the frames using the hybrid feature selection method described earlier.

Video data security is a critical aspect of any system that deals with sensitive medical data. To ensure that the medical video data is secure, the proposed system uses encryption to protect the frames before they are stored in the cloud. Specifically, each video frame is encrypted using an encryption key to prevent unauthorized access to the data. The encryption process is as follows

$$EncryptedFrame = Encrypt(Frame, Key) \quad (19)$$

where $Encrypt$ is a AES cryptographic function that takes the video frame and encryption key as inputs and produces an encrypted frame as output. Before storing in the cloud, video frames are encrypted using advanced encryption algorithms like AES (Advanced Encryption Standard) to ensure data confidentiality and integrity. Encrypted video frames are stored in a cloud infrastructure, such as AWS, using a weighted graph-based prefetching algorithm. This algorithm predicts the most likely frames to be accessed, optimizing storage retrieval and enhancing data security.

In addition to encryption, the proposed system uses a Weighted-Graph-Based Prefetching algorithm to optimize the retrieval of the video frames from the cloud while maintaining security. The algorithm works by predicting the most likely frames to be accessed and retrieving and caching them in advance for improved performance and responsiveness. The algorithm takes into account the frequency of access and the distance between frames to determine the weights of the edges in the graph.

The Weighted-Graph-Based Prefetching algorithm is based on the following Eq. 20:

$$P(i) = \alpha * R(i) + (1 - \alpha) * \sum_{j \in N(i)} w(i, j) * R(j) \quad (20)$$

where $P(i)$ is the predicted probability of frame i being accessed, $R(i)$ is the frequency of access of frame i , $N(i)$ is the set of neighboring frames of i , $w(i, j)$ is the weight of the edge connecting frames i and j , and α is a damping factor that balances the contribution of $R(i)$ and $\sum_{j \in N(i)} w(i, j) * R(j)$ to the prediction.

The weights of the edges between frames are determined based on the distance between frames and the frequency of access. The distance between frames is calculated using the following Eq. 21.

$$d(i, j) = ||f(i) - f(j)||^2 \quad (21)$$

Where $f(i)$ and $f(j)$ are the feature representations of frames i and j , respectively, which are obtained through the hybrid feature selection method described earlier.

The weight of the edge between frames i and j is then calculated using the following Eq. 22:

$$w(i, j) = \exp(-d(i, j)/\sigma) \quad (22)$$

where σ is a scaling factor that controls the influence of the distance on the weight. By combining encryption and the Weighted-Graph-Based Prefetching algorithm, the proposed system ensures the security and privacy of medical video data while optimizing the retrieval process for improved performance and responsiveness. Overall, the Weighted-Graph-Based Prefetching algorithm is an effective way to improve the security and retrieval speed of medical surgical videos. By predicting and prefetching the most likely frames to be accessed, the algorithm can reduce retrieval time and improve system performance. Additionally, by encrypting the data and monitoring access, the system ensures the security and confidentiality of the medical data.

D. Image Query-Based Retrieval

When an image query is received, its features are extracted using the same hybrid feature selection method. These features are then matched against the stored video frame features using similarity measures like cosine similarity. The weighted graph-based prefetching algorithm helps efficiently retrieve video frames by leveraging pre-computed weights that represent the likelihood of frame access based on historical access patterns

and feature similarity. The proposed secured video storage and retrieval framework is illustrated in the Algorithm 1.

Algorithm 1 Proposed algorithm

Input: Cholec80 surgical videos V , Image query Q

Output: Encrypted video stored in the cloud and Retrieved video relevant to Q

- 1: Divide each video V into a set of video frames $F = f_1, f_2, \dots, f_n$
 - 2: Hybrid feature selection
 - 3: **for** $F_i = 1$ to n **do**
 - 4: Apply VAE to extract features by learning a low-dimensional representation Z_i of the video frames in F_i
 - 5: Apply Group Lasso to each Z_i to select features set S_i .
 - 6: Concatenate the selected feature sets to obtain the final feature set S .
 - 7: **end for**
 - 8: Encrypt selected Feature set (S') and store metadata in cloud.
 - 9: Build a weighted graph G whose nodes correspond to the subsets F_i and whose edges correspond to the probability that a subset is accessed after another.
 - 10: **for all** Video Request **do**
 - 11: Decrypt S
 - 12: Compute similarity score between Q and S .
 - 13: Prioritize frame retrieval with high similarity scores using weighted-graph-based prefetching algorithm
 - 14: **end for**
 - 15: **return** Output the retrieved video segments relevant to Q .
-

The use of VAE and Group Lasso ensures that only the most informative features are retained, enhancing retrieval accuracy by focusing on the most relevant aspects of the video content. Encrypting video frames before storage guarantees data confidentiality, addressing security concerns in cloud environments. The prefetching algorithm optimizes retrieval by pre-computing and storing likely retrieval paths based on historical access patterns and feature similarity. By matching query image features with stored video features, the system efficiently retrieves relevant video segments, leveraging the prefetching algorithm to reduce retrieval time and improve performance. This proposed method offers a comprehensive solution for securely storing and efficiently retrieving medical surgical videos, addressing the challenges of scalability, security, and retrieval speed in cloud-based systems.

IV. EXPERIMENTAL RESULT ANALYSIS

In preprocessing, each video was divided into frames at a rate of 1 frame per second. Key frames were selected based on visual content changes using histogram differences. Features were extracted from the key frames using a Variational Autoencoder (VAE) to reduce dimensionality. Group Lasso was applied to select the most informative features, minimizing noise. Selected features were encrypted using AES and stored in AWS cloud storage. A weighted graph-based prefetching algorithm was used to optimize retrieval paths. Image queries were generated by extracting frames from the dataset. The retrieval performance was evaluated based on speed and accuracy, measured by precision and recall.

Fig. 4. Videos uploaded and downloaded.

The proposed framework implementation is done with the hardware requirements of Intel core i5 processor, 16GB RAM, and NVIDIA GeForce GTX 1080 GPU for deep learning model training. Python libraries such as TensorFlow, Keras, Scikit-learn are employed for feature extraction and learning; OpenCV for video processing and PyCrypto for data encryption.

Cholec80 dataset is used for experimentation. The Cholec80 dataset consists of 80 videos of cholecystectomy surgeries, including laparoscopic gallbladder removal procedures. Each video is labeled with tool presence and phase annotations. Videos are provided in a resolution of 1920x1080 pixels. Each video lasts approximately 1 hour, comprising different phases of the surgical procedure.

Fig. 4 illustrates the developed application results of secured video stored and decrypted videos downloaded. Fig. 5 depicts the predicted results of the moment retrieved from the Cholec surgery video for the given image query. The user request to access the video. Only authenticated users are allowed to download the video. Here, the user requests a video using text or image. Those video files matching to the text queries is listed for view access. The image query is passed to the feature selection algorithm and those matching feature set existing video frames are retrieved. This is illustrated in Fig. 5. The average time taken to retrieve the relevant video segment is 0.5 seconds per query. Lower times indicate faster retrieval, which is crucial for real-time applications.

The Table I presents a comparison between existing and proposed methodologies based on four different evaluation metrics: Recall, Intersection over Union (IoU), mean average precision, and ground truth. The existing methodology includes Deep learning methods such as CNN, RCNN, and DNN, while the proposed methodology is the Hybrid approach using VAE, Group Lasso and weighted graph prefetching algorithm. Based on the Recall metric, the proposed Hybrid approach

Fig. 5. Query matching video frames.

Fig. 6. Comparison of recall.

outperforms all existing methods with a Recall of 99.03%, which is higher than the Recall values for all existing methods. Similarly, the proposed methodology outperforms all existing methods for IOU, mean average precision, and ground truth. The accuracy of the proposed methodology is also higher than that of existing methods, with a value of 99%. In contrast, the accuracy values for existing methods range from 93% to 94%. Therefore, the proposed Hybrid approach using PSO shows promising results and can be considered as a potential alternative to the existing Deep learning methods for the given task.

TABLE I. PERFORMANCE METRICS COMPARISON TABLE

	Recall	IoU	avg precision	Ground truth	Accuracy
CNN	95.36	96.63	93.75	93.98	93%
RNN	94.32	96.21	92.43	92.74	94%
DNN	93.13	95.38	90.86	91.29	93%
PSO	95.36	96.98	93.74	93.97	93%
Proposed approach	99.03	98.40	98.65	99.13	99%

Recall reflects the proportion of relevant video segments that were correctly retrieved out of all relevant segments. Higher recall means fewer relevant segments are missed. Fig. 6 displays recall comparison charts. On this graph, methods are represented by the x axis, and recall expressed as a percentage along the y axis. The high precision and recall indicate that the proposed method accurately retrieves relevant video segments for a given image query, with minimal false positives and negatives.

The IoU comparison is shown in Fig. 7. On the graph,

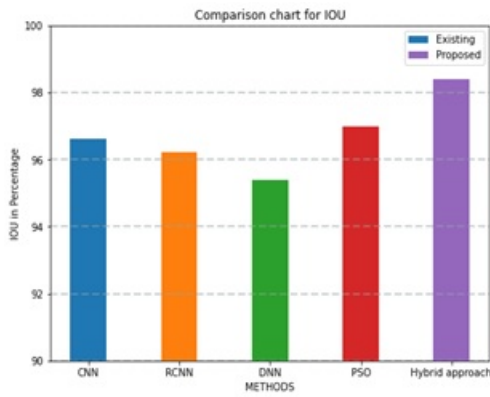

Fig. 7. Comparison of IoU.

Fig. 10. Performance accuracy.

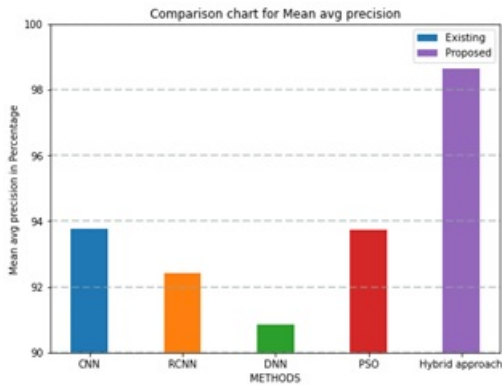

Fig. 8. Comparison of mean avg precision.

The accuracy comparison is shown in Fig. 10. The y axis represents the percentage of accuracy, while the x axis displays the various strategies. The proposed framework significantly improves retrieval accuracy and speed compared to traditional methods, making it suitable for real-time applications in medical environments. The hybrid feature selection method effectively reduces noise, enhancing the accuracy of the retrieval process. The cloud-based storage solution provides scalability and flexibility, allowing healthcare institutions to manage large volumes of surgical video data efficiently. Hence the experimental results highlight the effectiveness of the proposed method in optimizing retrieval and secure storage of medical surgical videos using deep learning techniques, offering promising implications for improving healthcare data management.

methods are represented by the x axis, while IoU is shown as a percentage along the y axis.

Precision indicates the proportion of correctly retrieved video segments that are relevant out of all retrieved segments. Higher precision suggests fewer irrelevant segments are retrieved. The comparison of average precision is shown in Fig. 8.

The ground truth comparison is shown in Fig. 9. On this graph, methods are represented by the x axis, while the percentage of ground truth is shown by the y axis.

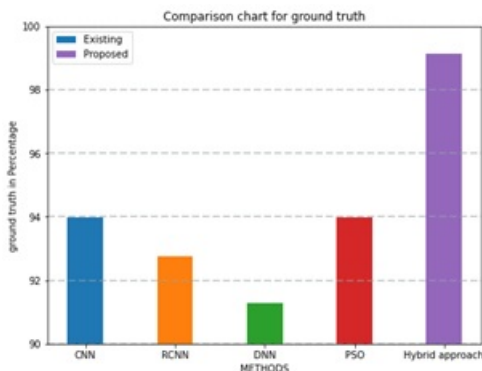

Fig. 9. Comparison of ground truth.

V. CONCLUSION

This study presented a novel framework for the secure storage and optimized retrieval of medical surgical videos using a deep learning-based approach, specifically tailored for cloud environments. The framework integrates advanced techniques such as Variational Autoencoder (VAE) and Group Lasso for hybrid feature selection, ensuring that only the most relevant and informative features are retained. These selected features are then securely encrypted using AES and stored in a cloud infrastructure, with retrieval performance further enhanced by a weighted graph-based prefetching algorithm.

The experimental evaluation, conducted on the Cholec80 dataset, demonstrated that the proposed method achieves a high retrieval accuracy, with a precision of 98.65% and a recall of 99.03%, while maintaining a swift average retrieval time of 0.5 seconds per query. These results underscore the effectiveness of the system in not only preserving the security of sensitive medical data but also in providing rapid and accurate access to relevant video segments, which is crucial in medical and surgical contexts. Furthermore, the integration of this framework into cloud platforms like AWS highlights its practical viability, offering a scalable and flexible solution for managing large volumes of medical video data. This approach is particularly valuable in healthcare settings where the secure and efficient handling of video data is essential for both clinical practice and research.

Thus the proposed method provides a robust solution to

the challenges of medical video storage and retrieval, contributing significantly to the field by improving data security, retrieval speed, and accuracy. The initial setup and processing require substantial computational resources, which may limit accessibility for institutions with limited hardware capabilities. The integration of deep learning algorithms and encryption techniques can introduce computational complexity, which may affect the performance of the system in environments with limited processing power. The reliance on cloud platforms for storage and retrieval may pose challenges in terms of cost and internet connectivity, particularly for smaller healthcare facilities with limited resources. Future research could incorporate natural language processing techniques to analyze textual annotations with visual features, providing a more comprehensive retrieval system. Further optimization of the retrieval algorithm could enable real-time querying capabilities, essential for immediate decision-making during surgical procedures.

Rolling Bearing Reliability Prediction Based on Signal Noise Reduction and RHA-MKRVM

Yifan Yu

School of Information and Computer Science, Nantong Institute of Technology, Nantong, Jiangsu, PR China

Abstract—In order to solve the problem of reliability assessment and prediction of rolling bearings, a noise reduction method (CEEMDAN-GRCMSE) based on complete ensemble empirical mode decomposition with adaptive noise (CEEMDAN) combined with generalized refined composite multi-scale sample entropy (GRCMSE) is proposed from the vibration signals to remove the noise from the bearing vibration signals, and then the feature set of the noise-reduced signals is downsampled by using the Uniform manifold approximation and projection (UMAP) algorithm, and the reliability assessment model is established by using a logistic regression algorithm to establish a reliability assessment model, and use the red-tailed hawk algorithm for parameter optimization of the mixed kernel relation vector machine, which is used to predict the bearing state, and finally the predicted state information is brought into the assessment model to obtain the final results. In this paper, the whole life cycle data of rolling bearings from Xi'an Jiaotong University-Sun Science and Technology Joint Laboratory (XJTU-SY) are used to verify the effectiveness of the proposed method. The superiority of the proposed method is highlighted by comparing the analysis results with those of other AI methods.

Keywords—Rolling bearing; reliability evaluation and prediction; complete ensemble empirical mode decomposition with adaptive noise; generalized refined composite multi-scale sample entropy; uniform manifold approximation and projection; red-tailed hawk algorithm; mixed kernel relevance vector machine

I. INTRODUCTION

With the evolution of mechanical equipment to intelligentization, an in-depth understanding of the degradation law of equipment components becomes the key to ensure its stable operation [1]. As an indispensable core component of mechanical systems, the performance state of rolling bearings has a decisive influence on the stable operation of the whole equipment [2]. Therefore, it is particularly important to carry out effective reliability assessment and prediction [3]. However, in practical engineering applications, the operation of mechanical equipment is inevitably accompanied by the generation of various noise signals. The existence of these noises seriously interferes with the accurate monitoring and assessment of the bearing state, thus affecting the accurate judgment of the bearing health state. Therefore, the removal of rolling bearing noise and vibration signals has a very important role in the extraction of effective information extraction of bearings. Traditional signal processing methods such as Fourier transform [4], wavelet packet transform (WPT) [5], etc., are mostly centered around the wavelet basis of the signal, and it is easy for the signal to be over-decomposed. Based on these limitations, Adaptive Mode Decomposition (AMD) is widely used due to its ability to analyze complex signals [6] [7] [8].

Complete Ensemble Empirical Mode Decomposition with Adaptive Noise (CEEMDAN) [12] is an adaptive signal processing method based on Empirical Mode Decomposition (EMD) and its deformations [9] [10] [11], which effectively improves the stability and robustness of the decomposition by the method of adding random noise to the original signal. Cheng et al. [13] used CEEMDAN to analyze the bearing signals, adding Gaussian noise adaptively at each stage of the signal decomposition to completely decompose the signal, which greatly improved the accuracy of rolling bearing fault diagnosis. Kala A et al. [14] established a rainfall prediction model based on CEEMDAN combined with a long and short term memory network (LSTM), which greatly improved the climate change rainfall prediction accuracy due to climate change. Li H [15] proposed a CEEMDAN-SVD-TE based vibration signal analysis method to solve the problem of complex vibration sources in hydropower stations, which improves the accuracy of vibration propagation path identification. Zhao et al. [16] proposed a CEEMDAN based ECG signal elimination method to filter out high frequency noise. D et al. [17] proposed a CEEMDAN combined with health indicator screening and Gray Wolf Optimized Extreme Learning Machine (GWO-ELM) for the prediction of remaining useful life (RUL) of lithium-ion batteries. Noise reduction of battery signals by CEEMDAN effectively improves the signal quality.

Reliability refers to the ability to fulfill a predetermined function within a certain period of time [18]. Rolling bearing reliability assessment usually starts from the characteristics of the vibration signals and collects effective information by extracting multiple features from the signals to assess the bearing reliability. Logistic Regression (LR) is a mathematical modeling method that is often used to model the reliability assessment of bearings. Gao et al. [19], in order to solve the problem of assessment and prediction of the operational reliability of rolling bearings, proposed a method based on isometric mapping, logistic regression modeling, and Nonhomogeneous Cuckoo algorithm-Least Squares Support Vector Machine (NoCuSa-LSSVM) for the prediction of the operational reliability of rolling bearings. Abbasi et al. [20] used Logistic regression model to check and evaluate iot anomalies, and achieved good results.

With the rapid development of artificial intelligence, prediction methods based on machine learning have gradually become an important means in the field of reliability prediction. In the process of reliability prediction, the characteristics of the bearings are first analyzed, and the degradation state of the bearings is predicted by machine learning methods. From then on, the degradation states obtained from these predictions are used as inputs for reliability calculations using reliability assessment models. Li et al. [21] proposed a hybrid

prediction algorithm to predict the bearing degradation trend by combining a Sparse Low-Rank Matrix (SLRM) with a Chaos Cuckoo Search (CCS) optimized support vector machine model. Han et al. [22] used a stacked self-encoder combined with a long short-term memory network model to establish a bearing degradation state prediction model and analyze the remaining service life of the bearings. Wang Y et al. [23] proposed a method based on Pearson correlation coefficient and kernel principal component analysis (KPCA) for the prediction of the remaining service life of rolling bearings. Xu et al. [24] established an (MSMHA-AED) model to predict the degree of bearing degradation. Bo et al. [25] proposed an adaptive temporal convolutional network (TCN) based on improved SSD and correlation coefficient (ISSD-CC) for bearing condition prediction.

Through the comprehensive analysis of the existing literature, it can be found that although various noise reduction techniques are adopted, these methods still have the problems of low efficiency and poor noise reduction effect when dealing with complex vibration signal noise. To overcome these challenges, a noise reduction method based on adaptive noise based complete ensemble empirical Mode decomposition (CEEMDAN) and generalized fine composite multi-scale sample entropy (CEEMDAN-GRCMSE) is proposed in this paper. Firstly, a series of intrinsic mode functions (IMFs) are obtained by CEEMDAN decomposition of noisy vibration signals. Then, by calculating the GRCMSE value of each component, the most representative modal component is selected from a large number of IMFs, which lays the foundation for the subsequent signal processing. In addition, in order to improve the accuracy of rolling bearing reliability prediction, a hybrid kernel relational vector machine (MKRVM) parameter optimization method combined with Red Tail Eagle optimization algorithm (RHA) was proposed and applied to bearing reliability evaluation and prediction. Using RHA algorithm to optimize the parameters of MKRVM, the performance of the prediction model can be significantly improved. The main innovations are:

1. For the selection of IMFs after CEEMDAN decomposition, combined with GRCMSE, the efficiency and accuracy of over-signal noise reduction are improved.

2. In the reliability modeling process of rolling bearings, the uniform manifold approximation and projection (UMAP) algorithm is used to reduce the order of the multi-dimensional features of the signal after noise reduction. Compared with other order reduction algorithms, UMAP algorithm can retain as much information in the data as possible, thus laying a solid data foundation for the reliability modeling of rolling bearings.

3. Aiming at the problem of bearing reliability prediction, MKRVM model optimized by RHA is proposed to predict the reliability of bearing signals, which significantly improves the prediction accuracy.

The structure of this paper is as follows: the first section is the introduction, the second section introduces the CEEMDAN-GRCMS signal noise reduction model, the third section introduces the establishment of the logistic regression bearing reliability model based on data characteristics, the fourth section introduces the rham-mkrvm model, the fifth section verifies the model experimentally, and the sixth section

summarizes the conclusions of this paper.

II. NOISE REDUCTION OF THE VIBRATION SIGNAL

A. CEEMDAN

Complete Ensemble Empirical Mode Decomposition with Adaptive Noise (CEEMDAN) is a mode decomposition algorithm. CEEMDAN introduces an adaptive Gaussian white noise and effectively maintains the signal integrity. In addition, the time complexity of the traditional algorithm is significantly reduced and the efficiency is improved. The main steps as follows:

Step 1: Add pairs of positive and negative Gaussian white noise $\lambda^i(t)$ to the original signal to obtain $x^i(t) = x(t) + \lambda^i(t)$, decompose $x^i(t)$ to obtain the 1st modal component (IMF) and take its mean value as the 1st IMF obtained by CEEMDAN decomposition, and a residual component $r_1(t)$.

$$I_{\text{IMF1}} = \frac{1}{n} \sum_{i=1}^n I_{\text{IMF1}}^i(t) \quad (1)$$

$$r_1(t) = x(t) - I_{\text{IMF1}} \quad (2)$$

where $IMF_1^i(t)$ represents the 1st modal component; n is the number of signals.

Step 2: Add pairs of positive and negative Gaussian white noise $\lambda^i(t)$ to the first residual component $r_1(t)$ to obtain a new component $r^i_1(t) = r_1(t) + \lambda^i(t)$. Perform the EMD decomposition of this component again, the process is calculated as follows:

$$I_{\text{IMF2}} = \frac{1}{n} \sum_{i=1}^n \text{EMD}(r_1(t) + \lambda^i(t)) \quad (3)$$

$$r_2(t) = r_1(t) - I_{\text{IMF2}}(t) \quad (4)$$

Step 3: Repeat the decomposition until the resulting residual signal can no longer be decomposed (the number of extreme points is no more than 2). Finally, $I_{\text{IMF1}} I_{\text{IMF2}} \cdots I_{\text{IMFn}}$ can be obtained in turn for the corresponding residual components. The original signal can be expressed as:

$$x(t) = \sum_{j=1}^q I_{\text{IMFj}} + r_z(t) \quad (5)$$

where q is the total number of modes after decomposition and $r_z(t)$ is the final residual result.

B. Generalized Refined Composite Multi-scale Sample Entropy

Generalized Refined Composite Multi-scale Sample Entropy (GRCMSE) is an improved algorithm developed on the basis of Sample Entropy (SE) [26]. Sample entropy is a quantitative measure of the degree of chaos in a time series, and the magnitude of its value is proportional to the irregularity and noise content of the time series. A high sample entropy value usually indicates that the signal has a high level of irregularity and noise. GRCMSE introduces a variance coarse-graining method to enhance the extraction of data information and improve the algorithm's resistance to noise. This enables GRCMSE to provide more accurate and reliable results when dealing with signal and data analysis in complex environments. In GRCMSE, a larger entropy value means that the signal

contains more valid information. The calculation procedure of GRCMSE is as follows:

Step1: For the time series $x(i), i=1,2,3, \dots, n$. Firstly, the original time series $x(i)$ is coarsely granulated, and for the scale factor τ the corresponding coarsely granulated sequence can be expressed as $y_{g,h}^\tau$

$$y_{g,k,j}^\tau = \frac{1}{\tau} \sum_{i=(j-1)\tau+k}^{j\tau+k-1} (x_i - \bar{x}_i)^2 \quad (6)$$

$$\text{where } 1 \leq j \leq \frac{N}{\tau}, 2 \leq k \leq \tau, \bar{x}_i = \frac{1}{\tau} \sum_{k=0}^{\tau-1} x_{i+k}$$

Step2: For the scale factor τ , compute the number of vectors $y_{g,h}^\tau$ in the t -dimensional as well as $t+1$ -dimensional space for each generalized coarse-grained sequence under this scale factor, denoted respectively as $n_{g,h,s}^t$ and $n_{g,h,s}^{t+1}$.

Step3: Calculate the average of $n_{g,h,s}^t$ and $n_{g,h,s}^{t+1}$ in the range $1 \leq h \leq \tau$, the generalized fine composite multiscale sample entropy of the initial time series $x(i)$ under the scale factor τ can be obtained as:

$$E_{GRCMSE} = -\ln\left(\frac{\overline{n_{g,h,\tau}^{t+1}}}{\overline{n_{g,h,\tau}^t}}\right) \quad (7)$$

$$\overline{n_{g,h,\tau}^t} = \frac{1}{\tau} \sum_{h=1}^{\tau} n_{g,h,\tau}^t \quad (8)$$

$$\overline{n_{g,h,\tau}^{t+1}} = \frac{1}{\tau} \sum_{h=1}^{\tau} n_{g,h,\tau}^{t+1} \quad (9)$$

III. ROLLING BEARING RELIABILITY MODEL

A. UMAP Dimensionality Reduction

Uniform manifold approximation and projection (UMAP) [27] is a powerful dimensionality reduction algorithm based on Riemannian geometry and algebraic topology. The core advantage of UMAP is that it can retain the global structure and local features of data more effectively. Compared with the traditional Principal Component Analysis (PCA) [28], UMAP can retain more data information in the dimensionality reduction process. UMAP shows faster computing speed and better performance. The specific implementation process of UMAP consists of two phases, namely, learning the flow structure in the high-dimensional space and making a low-dimensional representation of the flow structure.

Assuming that $X = \{x_1, x_2, \dots, x_N\}$ is the original N -dimensional dataset, in the first stage, the main task is to create a weighted k -neighborhood graph $G=(V,E,W)$. Where V is the set of vertices consisting of the original N -dimensional data, E denotes the set of edges, i.e., the set of directed edges that can be formed according to the k neighboring points, and W is the weight function, which is computed by the equation.

$$W_{ij} = e^{-\frac{s_{ij} + \varepsilon_i}{\tau_i}} \quad (10)$$

where s_{ij} denotes the distance between x_i and x_j ; ε_i denotes the distance between x_i and its neighboring points; and τ_i is the smoothing normalization factor set according to the Riemannian metric. By calculating the weight values of all

data points, a weighted near proximity graph of the high-dimensional dataset can be generated G . In order to ensure that the weights between data points are consistent, the expression is introduced:

$$T = A + A^T - A \circ A^T \quad (11)$$

where T is the adjacency matrix of the weighted nearest neighbor graph G , A is the weighted adjacency matrix consisting of the weight values W_{ij} , and \circ denotes the Hadamard product of the sought matrix.

After completing the construction of the high-dimensional structure, the next step is to map it to the low-dimensional space. Firstly, the weight function in low dimensions needs to be constructed with the mathematical formula:

$$V_{ij} = \frac{1}{1+ac_{ij}^{2b}} \quad (12)$$

where a and b denote hyperparameters and c_{ij} is the distance between y_i and y_j in the data point $Y = \{y_1, y_2, \dots, y_N\}$ in the low-dimensional space.

In order to make the dimensionality reduced dataset as close as possible to the original dataset, it can be optimized by minimizing the cross-entropy loss between Y_{ij} and T_{ij} . The cross-entropy function is:

$$L_c = \sum_{ij} [T_{ij} \log \frac{T_{ij}}{V_{ij}} + (1 - T_{ij}) \lg \frac{1-T_{ij}}{1-V_{ij}}] \quad (13)$$

In the above equation, the first term is the attraction component, which is used to constrain the clusters formed by similar data points, and the second term is the repulsion component, which is used to ensure that the clusters formed have a sufficiently large interval between them. The stochastic gradient descent algorithm can be used to optimize the cross-entropy function, and after obtaining the weights of the low-dimensional data points, the construction of the weighted nearest-neighbor graph in low dimensions is completed, and ultimately the low-dimensional representation of the high-dimensional topology is completed, so as to achieve the effect of data dimensionality reduction.

B. Logistic Regression Model

Logistic regression model [29] can give the probability of an event occurring under a series of characteristic parameters, is a linear regression model built on a large amount of data, and is now widely used in statistics, medicine, and economics. The logistic regression model is often used to deal with binary classification problems. The model essentially consists of a linear regression and a sigmoid function. The logistic regression model obtains the corresponding output value through the sigmoid function, which is shown in Fig. 1:

Assuming that the i -th dimension feature parameter set at moment t is $X_i(t) = (x_1(t), x_2(t), \dots, x_i(t))$, the normal operation of the bearing at the moment is denoted as $y(t) = 1$. The set of characteristic parameters is entered into the sigmoid

Fig. 1. Sigmoid function.

function and the bearing reliability R is calculated by the following equation:

$$R = P(y_i = 1 | X_i) = \frac{\exp(\theta_0 + \theta_1 x_1(t) + \theta_2 x_2(t) + \dots + \theta_i x_i(t))}{1 + \exp(\theta_0 + \theta_1 x_1(t) + \theta_2 x_2(t) + \dots + \theta_i x_i(t))} \quad (14)$$

where $\theta_0, \dots, \theta_i$ is the regression coefficient for the set of eigenvectors. This coefficient is similar to the linear regression coefficient, which represents the change of the dependent variable due to the change of the independent variable. Logistic regression model regression coefficient is solved using the maximum likelihood estimation method. First, the above equation is transformed:

$$\ln \frac{P(y_i=1|X_i)}{1-P(y_i=1|X_i)} = \theta_0 + \theta_1 x_1(t) + \theta_2 x_2(t) + \dots + \theta_i(t) \quad (15)$$

Setting $R = \theta_0, \dots, \theta_i$ to be brought into the above equation gives:

$$\ln L(R) = \sum_i [y_i R X(t) - \ln(1 + \exp(R X(t)))] \quad (16)$$

Then the gradient descent method is used to solve the above equation, the regression coefficients of the set of feature vectors can be obtained, and the regression coefficients are brought into the reliability solving formula to establish a logistic regression reliability assessment model.

IV. RELIABILITY PREDICTION OF ROLLING BEARING

A. Red-tailed Hawk Algorithm

Red-tailed hawk algorithm (RTH) [30] is a meta-heuristic algorithm proposed in 2023. The optimization process of this algorithm simulates the hunting behavior of red-tailed hawk and has the advantage of high search efficiency. The hunting process of red-tailed hawk is divided into three phases, which are: high soaring, low soaring and swooping phase. In the high-altitude soaring stage, the red-tailed hawk spreads its wings and flies, using its sharp vision to scan the vast field and determine the exact location of the prey. Subsequently, the low-altitude soaring phase allows for a more careful examination of the ground and a gradual approach to the previously identified prey area. After determining the optimal location of the prey, the red-tailed hawk enters a phase of sharp turns and dives, quickly swinging its wings, adjusting its flight position, and getting ready to execute the hunting action to rapidly approach the prey. The general steps of the red-tailed hawk optimization algorithm are:

1) *Initialize population*: Map the solution space of the problem to the hunting domain of the red-tailed hawk and generate a group of possible solutions as the initial population.

2) *High flying phase*: The red-tailed hawk will take to the skies in search of the best location for food supply. The mathematical model for the high flight phase of the red-tailed hawk is:

$$X(t) = X_{\text{best}} + (X_{\text{mean}} - X(t-1)) \cdot \text{Levy}(\text{dim}) \cdot \text{TF}(t) \quad (17)$$

where, t is the number of iterations, $X(t)$ denotes the red-tailed hawk position for t iterations, X_{best} is the best position obtained, X_{mean} is the average of the red-tailed hawk positions, and Levy values can be calculated based on the distribution function formula for Levy flights, which is given below:

$$\text{Levy}(\text{dim}) = s \frac{\mu \cdot \sigma}{|\nu|^{\beta-1}} \quad (18)$$

$$\sigma = \frac{\Gamma(1+\beta) \cdot \sin(\pi\beta/2)}{\Gamma(1+\beta/2) \cdot \beta \cdot 2^{(1-\beta/2)}} \quad (19)$$

where, s is a constant (0.01), dim is the dimension of the problem, β is a constant (1.5), and μ, ν are random numbers between 0 and 1. $\text{TF}(t)$ can be computed based on the transition factor function with the following formula:

$$\text{TF}(t) = 1 + \sin(2.5 + (t/T_{\text{max}})) \quad (20)$$

where T_{max} denotes the maximum number of iterations.

Low-flying phase: The red-tailed hawk gradually approaches its prey using spiral flight. Its model can be expressed as follows:

$$X(t) = X_{\text{best}} + (x(t) + y(t)) \cdot \text{StepS}(t) \quad (21)$$

$$\text{StepS}(t) = X(t) - X_{\text{mean}} \quad (22)$$

where x and y represent the direction coordinates of the red-tailed eagle at this moment, the spiral flight method is calculated as follows:

$$\begin{aligned} x(t) &= R(t) \cdot \sin(\theta(t)) \\ y(t) &= R(t) \cdot \cos(\theta(t)) \end{aligned} \quad (23)$$

$$\begin{aligned} R(t) &= R_0 \cdot \left(r - \frac{t}{T_{\text{max}}}\right) \cdot \text{rand}() \\ \theta(t) &= A \cdot \left(1 - \frac{t}{T_{\text{max}}}\right) \cdot \text{rand}() \end{aligned} \quad (24)$$

$$\begin{aligned} x(t) &= \frac{x(t)}{\max|x(t)|} \\ y(t) &= \frac{y(t)}{\max|y(t)|} \end{aligned} \quad (25)$$

where R_0 represents the initial value of the radius, A represents the angular gain, taking values between 5 and 15,

rand is a random number between 0 and 1, and r represents the control gain, taking values between 1 and 2.

Sharp turn and dive phase: in this phase, the red-tailed hawk occupies the best swooping position obtained from the low altitude flight phase and prepares to attack the prey. The mathematical model for this phase is as follows:

$$X(t) = \alpha(t) \cdot X_{best} + x(t) \cdot \text{StepS1}(t) + y(t) \cdot \text{StepS2}(t) \quad (26)$$

Each of these steps can be calculated as follows:

$$\begin{aligned} \text{StepS1}(t) &= X(t) - TF(t) \cdot X_{mean} \\ \text{StepS2}(t) &= G(t) \cdot X(t) - TF(t) \cdot X_{best} \end{aligned} \quad (27)$$

where α and P are the acceleration and gravity coefficients, respectively, can be simplified as follows:

$$\begin{aligned} \alpha(t) &= \sin^2(2.5 - t/T_{\max}) \\ P(t) &= 2 \cdot (1 - t/T_{\max}) \end{aligned} \quad (28)$$

where α denotes that the acceleration of the hawk increases with the number of iterations to improve the convergence rate, and P is the gravitational effect that reduces the exploitation diversity as the hawk gets closer to its prey.

The high-flying phase, based on Levy flight, successfully avoids trying to fall into local minima, and the low-altitude search phase focuses on localized search to improve the accuracy of the solution. The sharp turn and dive phases adopt a more focused search strategy that enhances the accuracy of the RTH. The advantage lies in the fact that its combined global and local search strategy is able to efficiently find the global optimal solution in the solution space.

B. Relevance Vector Machine

Relevance Vector Machine (RVM), proposed by Tipping [31], is a kernel sparse machine learning method based on Bayesian framework. In the machine learning process, the sample used for training consists of an input $\{x_n\}^N$ and a target value $\{t_n\}^N$. The correspondence between the input and the target value in RVM can be expressed as:

$$t(x, \delta) = \sum_{i=1}^N \delta_i K(x, x_i) + \varepsilon \quad (29)$$

where δ is the weight vector of the model, K represents the kernel function, ε is the offset, and N is the total number of training samples.

Let $\{t_n\}^N$ be an independent variable, then the conditional probability of the target value can be expressed as:

$$P(t | \delta, \sigma^2) = (2\pi\sigma^2)^{-\frac{N}{2}} \exp\left(-\frac{\|t - \Phi\delta\|^2}{2\sigma^2}\right) \quad (30)$$

where Φ is the matrix consisting of kernel functions and σ^2 is the noise variance.

In the process of calculation, due to a large number of hyperparameters are quoted, the direct use of maximum likelihood estimation method to find the value of δ , there may be the generation of overfitting, in order to solve this problem, the application of the knowledge of Bayesian theory, add a constraint on δ , each weight vector δ is defined as a vector

of zero mean, then its Gaussian prior probability distribution formula is as follows:

$$P(\delta|\alpha) = \sum_{i=0}^N N(\delta_i|0, \alpha_i^{-1}) \quad (31)$$

where the weight vectors are all independently distributed, $\alpha = [\alpha_0, \alpha_1, \dots, \alpha_N]^T$ denotes the hyperparameter vector, and each hyperparameter corresponds to a weight vector. The size of hyperparameters can affect the sparsity of the model. Therefore, the key of RVM is to find the hyperparameters, find the corresponding weights and kernel function, so that the sparsity of the model is guaranteed, and combined with the noise variance, the final regression model is obtained.

The posterior distribution weights of the weight vector δ are derived from the Bayesian formula:

$$P(\delta|\alpha) = \sum_{i=0}^N N(\delta_i|0, \alpha_i^{-1}) \quad (32)$$

where is $\Sigma = (\sigma^{-2}\Phi^T\Phi + C)$ covariance matrix, $\mu = \sigma^{-2}\sum\Phi^T t$ is the posterior matrix of the target value, and C denotes the matrix whose main diagonal element is $\alpha = [\alpha_0, \alpha_1, \dots, \alpha_N]^T$.

In the calculation process, in order to harmonize the hyperparameters, the definition:

$$P(t | \alpha, \sigma^2) = (2\pi\sigma^2)^{-\frac{N}{2}} |E|^{-\frac{1}{2}} \exp\left\{-\frac{1}{2}t^T E^{-1}t\right\} \quad (33)$$

where $E = \sigma^2 I + \Phi C^{-1} \Phi^T$, the hyperparameters α and σ^2 of the RVM are solved by an iterative algorithm as follows:

$$\alpha_i^{new} = \frac{1 - \alpha_i M_{ii}}{\mu_i^2} \quad (34)$$

$$(\sigma_i^2)^{new} = \frac{\|t - \Phi\mu\|^2}{N - \sum_i (1 - \alpha_i M_{ii})} \quad (35)$$

where M_{ii} is the ith diagonal element of the covariance matrix. The hyperparameters α and σ^2 are calculated iteratively by the above equation until the condition of convergence is satisfied.

In machine learning by correlation vector machines, the kernel function is a crucial part of the algorithm. The kernel function is capable of mapping nonlinear data into a high dimensional space. However, different settings of kernel function and kernel parameters affect the performance of the RVM model. Therefore, it is necessary to choose the appropriate kernel function and also optimize the kernel function parameters. Common kernel functions include Linear Kernel, Gaussian Kernel, Laplace Kernel and so on.

(1) Linear kernel function is a global kernel function.

$$k(x_i, x_j) = x_i \bullet x_j \quad (36)$$

(2) Gaussian kernel function Gaussian kernel function has strong localization, which can map the input vector to a space of larger dimensions.

$$k(x_i, x_j) = \exp\left(-\frac{\|x_i - x_j\|^2}{2\delta^2}\right) \quad (37)$$

(3) Laplace kernel function The Laplace kernel function can be seen as a variant of the Gaussian kernel function, both belong to the radial basis kernel function (RBF function).

$$k(x_i, x_j) = \exp\left(-\frac{\|x_i - x_j\|}{\delta}\right) \quad (38)$$

Different kernel functions have their own strengths and weaknesses, in order to make the model have better performance, hybrid kernel functions can be used so that the combined kernel function has the characteristics of global and local kernel to improve the ability of machine learning model. The process of optimizing the hybrid kernel correlation vector machine model using the red-tailed hawk algorithm is shown in Fig. 2:

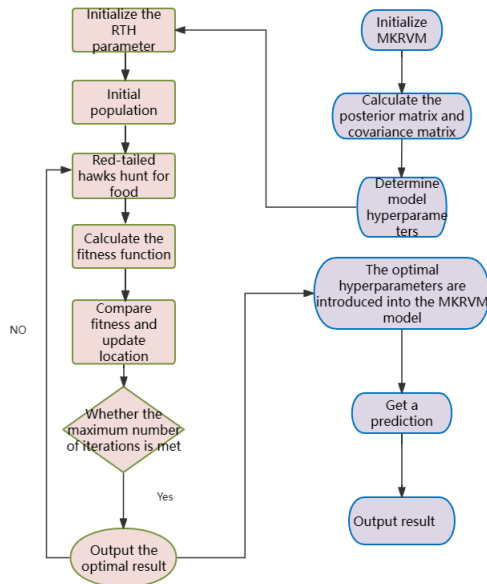

Fig. 2. RTH-MKRVM flowchart.

V. EXPERIMENTAL VERIFICATION

A. Experimental Data

The life cycle data of the bearings in this experiment were provided by XJTU-SY-Bearing Datasets, a bearing experiment set of Xi'an Jiaotong University. The test equipment includes AC motors, motor speed controllers, support bearings, and test bearings. A PCB352C33 transducer was placed in the horizontal and vertical directions of the bearing to collect vibration signals. A total of 32,768 data points were recorded during the first 1.28 s in 1 min. The test rig is shown in Fig. 3. Since the radial force was applied in the horizontal direction, the vibration signals in this direction were chosen for the experiment to better represent the bearing degradation.

Fig. 3. Bearing test stand.

B. Experimental Procedure

The flowchart of the experiments in this paper is shown in Fig. 4 below:

Fig. 4. Flow chart of the experiment.

C. CEEMDAN-GRCMSE Model

In order to verify the effectiveness of the proposed CEEMDAN-GRCMSE algorithm, the horizontal direction data of bearing 3-2 in the rolling bearing full-life dataset of Xi'an Jiaotong University is selected as the experimental data in Fig. 5. The performance and effectiveness of CEEMDAN-GRCMSE method will be verified by processing and analyzing the experimental data.

Fig. 5. Original Signal

Firstly, CEEMDAN decomposition of the noise signal is performed to obtain 16 IMF components as shown in Fig. 6, next, the GRCMSE value of each component is derived as shown in Table I. From the table, it can be seen that the front IMF components have larger values, indicating that the IMF components contain more valid information. Therefore, the IMF component with a value greater than 1 is selected and it is reconstructed. The reconstructed signal is shown in Fig. 7.

From the figure, it can be seen that the signal after CEEMDAN-GRCMSE denoising has less burrs than the original signal and the signal trend is smoother. Generally, signal-to-noise ratio (SNR) is used to indicate the size of the noise. Higher SNR values indicate better signal quality and vice versa. By calculation, the SNR of the original signal is -4.98

and the SNR of the denoised signal is -2.19. It shows that the use of CEEMDAN-GRCMSE can effectively reduce the signal noise.

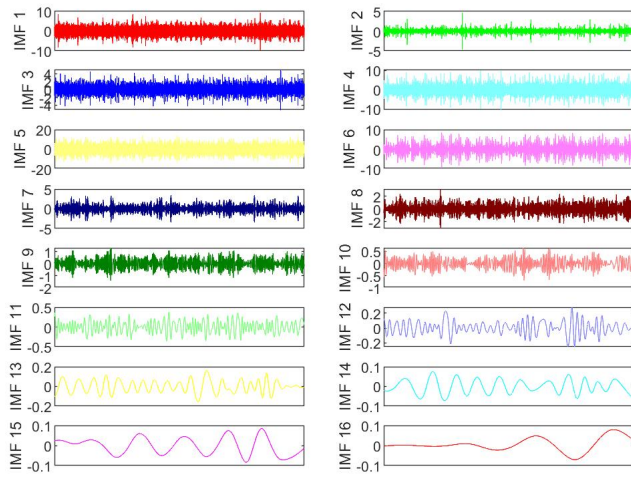

Fig. 6. IMF component.

Fig. 7. Signal after noise reduction.

TABLE I. GRCMSE VALUE

Index	IMF1	IMF2	IMF3	IMF4
GRCMSE	1.99	2.33	2.00	1.24
Index	IMF5	IMF6	IMF7	IMF8
GRCMSE	1.27	1.16	1.20	1.03
Index	IMF9	IMF10	IMF11	IMF12
GRCMSE	0.52	0.31	0.26	0.22
Index	IMF13	IMF14	IMF15	IMF16
GRCMSE	0.14	0.07	0.04	0.01

D. Bearing Reliability Modeling

From the vibration signal of the noise-canceled bearing 3-2, 15 features including mean, kurtosis, standard deviation, waveform factor, spectral skewness, spectral kurtosis, and mean square frequency were extracted, covering time domain, frequency domain, and time-frequency domain aspects. Among the time domain features include wavelet packet entropy and singular value factor as shown in Fig. 8. These multi-domain features are combined into a multi-dimensional feature parameter set.

However, directly substituting the multidimensional parameter set into the logistic regression model will bring great

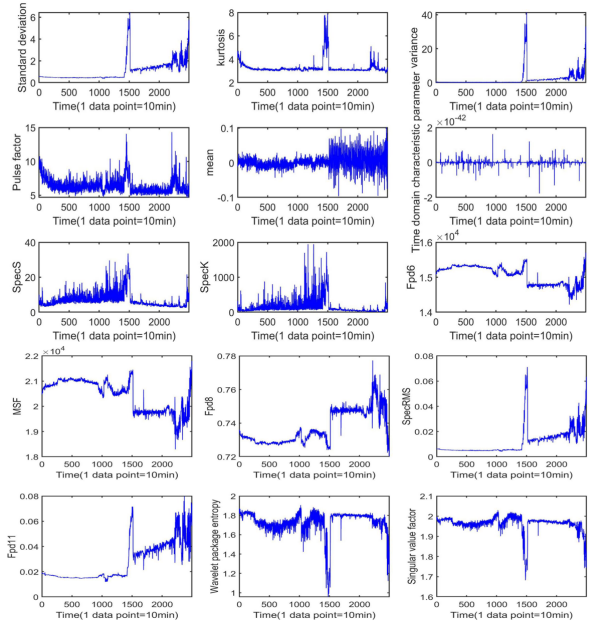

Fig. 8. Multidimensional feature parameter.

challenges, so adopt the UMAP algorithm to reduce the dimensionality of the data features. The core idea of UMAP is to find the local neighborhoods between the data points in the high-dimensional space and find the corresponding neighborhoods in the low-dimensional space, and then try to maintain the relationship between these neighborhoods as much as possible. This approach effectively preserves the local structure of the data and maps it into the low-dimensional space while reducing the dimensionality. And the UMAP is compared with the dimensionality reduction results of PCA and t-SNE to reduce the high-dimensional features to three dimensions. The results after dimensionality reduction are shown in Fig. 9.

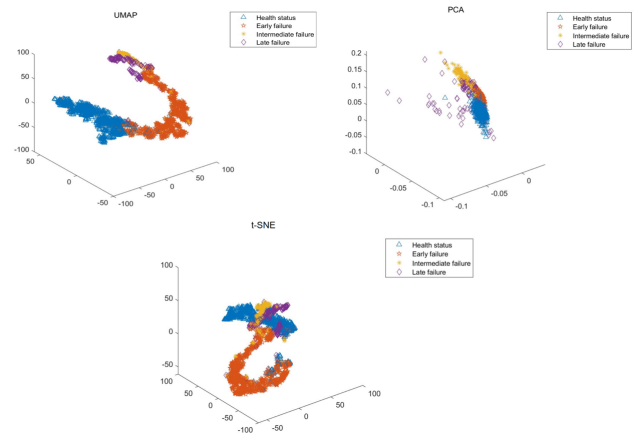

Fig. 9. Dimensionality reduction comparison diagram.

In the figure, it can be observed that different degrees of aliasing exist in the downscaling results of UMAP, PCA and t-SNE algorithms. Especially in the late bearing failure stage, the distribution of data points is more scattered, and there is obvious crossover of data points in different stages. This leads

to a poor differentiation of the bearing operation cycle and fails to clearly reflect the operating condition of the bearing.

In contrast, the UMAP algorithm is able to more clearly delineate the operating cycles of the bearings. The intervals between cycles are more obvious, and the data points in different stages can be well distinguished. This indicates that the dimensionality reduction results of the UMAP algorithm can effectively describe the degradation condition of the bearing.

Through the above processing, the original high-dimensional features are successfully transformed into a more intuitive and easy to understand three-dimensional space which provides a strong foundation for further analysis and modeling.

The set of feature vectors after UMAP dimensionality reduction is selected as the degradation feature information as the parameter of the logistic regression model, and the reliability true curve of 400 points after bearing is obtained as shown in Fig. 10.

Fig. 10. Bearing reliability real curve.

The next step is to predict the reliability of the bearings, the kernel function of the MKRVM is with the linear kernel function, after many experiments, the performance of the hybrid kernel correlation vector machine reaches the best when the coefficients of the Gaussian kernel are set to 0.6, and the coefficients of the linear kernel are set to 0.4. After RTH optimization, the optimal weight of MKRVM is obtained as 1.327. In order to compare the effectiveness of different optimization algorithms, compared the Red-tailed Hawk algorithm with the Sparrow optimization algorithm and the Particle Swarm optimization algorithm. As shown in Fig. 11 below, it can be clearly observed that the convergence speed of the red-tailed hawk algorithm is much faster than the other two optimization algorithms.

Next, selected the first 2096 data as training data and the last 400 points as test data for the prediction of the RHA-MKRVM model. Subsequently, the final results of RHA-MKRVM were fed into the logistic regression model to obtain the operational reliability of the bearings. We compared the predicted degradation states with the actual data, and the results are shown in Fig. 12.

The final results predicted by the RHA-MKRVM model were incorporated into the logistic regression model, and the regression coefficients were calculated to obtain the operational reliability of the bearings. The comparison between the de-

Fig. 11. Effects of different optimization algorithms.

Fig. 12. Bearing degradation state prediction.

graded state of the bearing predicted by the RHA-MKRVM model and the degraded real data is shown in Fig. 13.

Fig. 13. Bearing reliability prediction.

As can be seen from the above figure, the results predicted by the RHA-MKRVM model are closer to the real situation. In order to verify the prediction accuracy of the hybrid kernel correlation vector machine model, the reliability of the bearings was predicted in this study using the ELMAN neural network, the least squares support vector machine (LSSVM), the correlation vector machine (RVM), and the hybrid kernel correlation vector machine (MKRVM) model, and the reliability of the bearings was compared with the RTH-MKRVM method.

In LSSVM, Gaussian kernel function is used, and the penalty factor, kernel function parameters are set to 9, 0.002; in ELMAN neural network, the number of neural network layers is set to 3, neuron excitation function is used as Sigmoid function, and the number of neurons in each layer of input,

hidden, and output layers is set to 10, 14, and 1, respectively; in RVM, Gaussian kernel function is used, and the penalty factor, and kernel function parameters are set to 9, 0.002; in MKRVM, Gaussian kernel function and linear kernel are used, and the penalty factor and kernel function parameters are set to 9, 0.002.

The method was also validated using bearing 3-1, bearing 3-4, and bearing vibration data bearing 5 from the University of Cincinnati. The reliability curves for the three bearings are shown in Fig. 14. The errors produced by each prediction model are shown in Table II. From the above figure, it can be seen that the curves obtained by RTH-MKRVM are closer to the actual reliability curves and have good prediction performance compared to the existing bearing reliability prediction methods.

As can be seen in Fig. 14, the early operation of bearing 3-1 was relatively stable, bearing reliability did not change greatly, and there was a serious failure of the bearing at 250 points, and the reliability declined more rapidly. Bearings 3-4 run more smoothly before 300 points, and their reliability drops to 0 in the final stage. Bearing 5 has high reliability before the first 350 points, and after 350 points, reliability suddenly drops to 0.

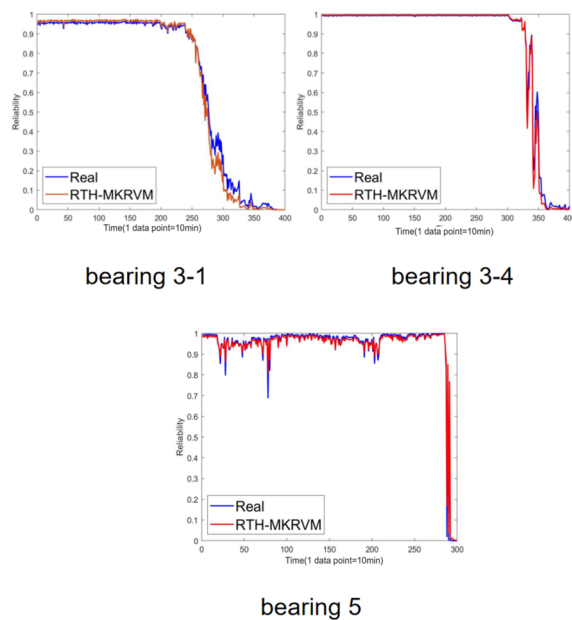

Fig. 14. Three bearing reliability prediction results.

VI. CONCLUSION

Aiming at the problem of assessing and predicting the reliability of rolling bearings based on noise conditions, a new noise reduction method is proposed to remove the excess noise in the bearing signals, and a logistic regression model is used to assess the reliability of the bearings and obtain the reliability results, and finally a hybrid kernel correlation vector machine model of red-tailed eagle is used to predict the reliability of the bearings, and good results are obtained, indicating that the study can well characterize the rolling bearings' state to characterize and predict the reliability.

TABLE II. COMPARISON OF DIFFERENT MODELS ON BEARINGS

Model	Bearing 3-1		Bearing 3-2	
	MAE	MAPE	MAE	MAPE
ELMAN	0.073	0.082	0.032	0.045
LSSVM	0.069	0.074	0.061	0.074
RVM	0.079	0.094	0.135	0.207
MKRVM	0.057	0.041	0.096	0.037
RTH-MKRVM	0.045	0.028	0.058	0.044

Model	Bearing 3-4		Bearing 5	
	MAE	MAPE	MAE	MAPE
ELMAN	0.031	0.072	0.074	0.085
LSSVM	0.074	0.080	0.048	0.066
RVM	0.126	0.209	0.191	0.254
MKRVM	0.029	0.017	0.033	0.027
RTH-MKRVM	0.019	0.026	0.027	0.031

(1) The efficiency of signal noise reduction is greatly improved by combining GRCMSE for the selection problem of IMFs after CEEMDAN.

(2) Use UMAP algorithm to downscale the multidimensional features of the signal after noise reduction, and lay a solid data foundation for the reliability modeling of rolling bearings.

(3) For the problem of bearing reliability prediction, the MKRVM model optimized by the red-tailed eagle algorithm is proposed to predict the reliability of bearing signals, which significantly improves the prediction accuracy.

VII. DISCUSSION

In this paper, the effectiveness of the method is verified by the bearing signal data in the laboratory. However, there are still many problems to be solved in the research of rolling bearings, and the future research direction can be started from the following points:

(1) In terms of bearing signal feature extraction, this paper constructs signal feature set by extracting signal time-frequency domain features, but the selection of signal features also relies on manual experience. In the future research, the selection of signal features can be further studied to make the selection process more automatic, and the selected features can be more accurate representation of the signal.

(2) The verification data used in this paper comes from the laboratory, the working conditions are stable, and the experiment is carried out in an ideal environment. However, the actual operating conditions are complicated, so the reliability assessment and prediction under variable speed conditions should be further studied.

EiAiMSPS: Edge Inspired Artificial Intelligence-based Multi Stakeholders Personalized Security Mechanism in iCPS for PCS

Swati Devliyal, Sachin Sharma, Himanshu Rai Goyal
Computer Science and Engineering, Graphic Era Deemed to be University, Dehradun, India

Abstract—Artificial Intelligence (AI) is becoming more prevalent in the healthcare sector like in pharmaceutical care to achieve rapid and precise outcomes. Machine learning techniques are critical in preserving this balance since they ensure both the confidentiality and authenticity of healthcare data. Early sickness projections benefit clinicians when establishing early monetary choices, in the lives of their patients. The Web of Things (IoT) is acting as an accelerator to boost the efficacy of AI applications in healthcare. Healthcare service pharmaceutical care is also in demand and can have AI for good patient care. The sensor gathers the data from individuals, then the data is examined employing machine learning algorithms. The work's major intent is to come up with an automated learning-based user authentication algorithm for providing secure communication. The other goal is to ensure data privacy for sensitive information that does not currently have security. The Federated Learning (FL) technique, which uses a decentralized environment to train models, can be utilized for this purpose. It enhances data privacy. This work proposes in addition to security a differential privacy preservation strategy that involves introducing random noise to a data sample to generate anonymity. The model's performance and data quality are assessed, as privacy preservation approaches frequently reduce data quality.

Keywords—Internet of things; pharmaceutical care; machine learning; authentication; artificial intelligence

I. INTRODUCTION

Over the last several years, the world of pharmacy has seen a steady and considerable transition. The prior work of the pharmacist, which included medicine production, dispensing, and marketing, is no longer sufficient for pharmacy professionals to still exist [1]. Pharmaceutical care has been widely acknowledged as the main objective of pharmacy. Pharmaceutical care requires practitioners to not only provide drugs but also to take responsibility for enhancing the quality of patients' outcomes [2]. In our assessment of research on the review of pharmaceutical care services, multiple publications highlighted the large beneficial impact that pharmaceutical care services have on long-term healthcare management and healthcare expenses [3]. A number of read ups have been conducted to inquire the implications of artificial intelligence (AI) arrangements on healthcare distribution. AI-powered solutions have the potential to improve forecasting, assessment, and care coordination. AI is anticipated to become more prevalent fundamental element of medical care in the years to come, with applications in a number of clinical settings [4]. As the outcome, various technological companies and government agencies have put money in the growth of clinical tools and medical applications. Patients may be among the

most significant benefactors and users of AI-based apps, and their perspectives may have an impact on the broad adoption of AI-based technologies. Patients must be encouraged that AI-based technologies will not damage them, but rather that adopting AI technology for healthcare reasons will help them [5]. Although AI has the potential to enhance healthcare results, any issues and hazards should be addressed before it is integrated into normal clinical treatment. Furthermore, following earlier research, healthcare professionals still have basic concerns regarding the use of AI-based solutions in care services [6]. Researchers must more efficiently comprehend the existing issues associated with AI technologies and analyse the pressing demands of health systems in order to create AI-enabled solutions that can solve them. Technological advancement unleashes a maelstrom of communication and interconnection, allowing the intelligent pharmaceutical care in order to grow more flexible, sophisticated, and smart through the use of artificial intelligence. AI enables systems should naturally emphasis on enhanced analysis of data while maintaining appropriate user experience quality. Despite the fact that the association of AI-concentrated along with CPS considerably boosts productivity in pharmaceutical care, it is still in torment from challenges such as high burden, device incompatibility, security, and privacy [7] [8] [9]. CPS-based systems offer various additional issues, the most difficult of which is authentication. In pharmaceutical care there are so many stakeholders and major are practitioner, pharmacist and patient. When all are communicating through the network need authorisation at each end. We have developed an authentication approach that can be more resilient. In this article, we look at a unique security architecture for CPS that hosts user authentication and provides data security and privacy, device anonymity, and safety.

Our contributions are highlighted below:

- Based on edge assistance, we provide a layer skeleton in CPS. The higher layer is intended for registration management in conjunction with IIoT gadget. It decouples the need for direct interaction with IIoT devices and decreases system complexity. The middle surface is used in data transmission, while the lower surface houses the IIoT gadget.
- We present an authentication system that makes use of a proxy signing for establishing a link. It significantly minimizes the expenditure for signatures on gadgets and prevents unauthorized encounters in the outer limits, establishing the groundwork for protecting the

privacy on gadgets.

- The suggested scheme's security and performance assessments is demonstrating its robustness and practicability in contrast to earlier work. The rest of the sections are as follows: First is literature review which is followed by the proposed model. Further design is presented which focuses at security and privacy concerns, whereas last is performance analysis followed by conclusion.

II. LITERATURE REVIEW

A. Edge-AI in Pharmaceutical

According to the Thakur *et al.* [10] the use of AI in the field of pharmaceutical and biological studies has been significant, including cancer research, for prognosis and diagnosis of the disease state. It has evolved into a tool for researchers in charge of complicated data, covering everything from acquiring supportive results to normal statistical analyses. AI improves the accuracy of estimating treatment impact in cancer patients and decides forecast outcomes. Klumpp *et al.* [11] proposes a methodology for predicting the future based entirely on comprehensive analyses of trends by subject as well as interactive advancements. The findings suggest that the human aspect, as well as human-artificial collaboration skills and attitudes, might be a critical feature in AI and technology use in logistics. Damiani *et al.* [12] examines the historical, current, and future implications of machine learning technologies on several fields of pharmaceutical sciences, including drug design and exploration, revision, and composition. The strategies for researching systems that are often used in pharmaceutical sciences are explained. AI and system learning technology in ordinary everyday pharma demands, as well as commercial and regulatory insights, are examined. For unbalanced ICS data, Jahromi *et al.* [13] suggested a novel two-level ensemble deep learning-based attack detection and identification method. The whole bureaucratic model is a complicated DNN with a partially and entirely linked component that can appropriately blame cyber-attacks. Burki *et al.* [14] suggested obstacle might allow AI to be trained on millions of data points from various drug organisations' databases without jeopardising the possession and privacy of the statistics. Rathi *et al.* [15] provides a scalable, responsive, and dependable AI-enabled IoT and aspect computing-based healthcare system with minimal lag while servicing patients.

B. Stakeholder Authorization

Xu *et al.* [16] presents, an approval strategy based entirely on block chain is presented to identify genuine authorization for information access. The suggested approach divides info warehouses in block chains and HISs, with greater performance, more area-specific, dynamic, and bendy authorisation procedures. Hameed *et al.* [17] proposed, we provide a Block chain-based safe, decentralised, and customisable authorisation mechanism to grapple with the challenge of unauthorised access to IoT networking equipment. We implemented the ABAC version utilising intelligent agreements, which make the technique possible of authorising consumers with safe access to IoT devices to be accomplished largely based on dynamic and fine-grained policies maintained on the distributed immutable ledger. Using a permissioned blockchain community,

this article presents a robust and accessible pharmaceutical supply chain gadget. Babu *et al.* [18] designs also includes digital transactions between providers and traders, tracking the source, ok verification, and lowering the risk of supply chains. The Hyperledger network fabric has been used in its deployment of this machine and its effectiveness has been assessed using Hyperledger Calliper. Zukarnain *et al.* [19] aimed to propose an aggregation of multi-component authentication that requires minimal user participation in this work. Because of security concerns, they implemented an unequal encryption technique in which the users' input is utilised as the encryption key. The PKI idea was adopted, yet without the required to communicate with a certificate authority (CA), the value was significantly reduced.

C. Intelligent CPS

Lu *et al.* [20] presents system of authentication for imposing security policies at the edge in CPS discourse for IIoT in order to enable reliable interaction for restricted gadgets. The main concept aims to integrate proxy authentication and process links at the ICN structure in order to provide two-way authentication. Security testing indicated that the suggested strategy provided a more effective protection than competing schemes. Ramasamy *et al.* [21] presents an AI-enabled IoT-CPS that doctors can use to diagnose ailments in patients. AI was created to assist with a variety of illnesses such as diabetes, heart disease, and gait problems. To detect illnesses in the class, the AI-enabled IoT-CPS Algorithm is used. Experiment findings reveal that, when compared to current methods, the proposed AI-enabled IoT-CPS algorithm diagnoses patient diseases and incident actions with more precision in terms of recall, accuracy, precision, and F-measure. Mishra *et al.* [22] developed deeply into novel new technologies such as the machine-to-machine communication, machine learning, artificial intelligence, Internet of Things, big data, and so on. An example NG-CPS structure is proposed, which includes all layout concerns such as physical layout components, cyber layout elements, and design conversations. Makkar *et al.* [23] presented cognitive-inspired architecture for CPS security is investigated. The suggested system, dubbed Secure CPS, is trained with immediate time collective dataset for determining the relevance of a web page using facial expressions as guides. The eye regions are identified using the Focal Point Detector method. The system was tested using device learning models and achieved 98.51% accuracy, outperforming existing frameworks. Adil *et al.* [24] proposed a hybrid light-weight authentication scheme that makes use of SML (supervised machine learning) method in conjunction with CPBE&D (Cryptographic Parameter Based Encryption and Decryption) scheme to ensure the authenticity of criminal patient wearable gadgets with consistent transmission over the Wi-Fi conversation channel.

D. Pharmaceutical Care Services

Alzahrani *et al.* [25] propose a novel TRD (Tag Reapplication Detection) method for detecting reapplication attacks, as well as the usage of low-cost NFC (Near Field Communication) tags and public key cryptography. Because a huge number of modern mobile phones are NFC-enabled, the inclusion of NFC makes TRD user-friendly. TRD uses an

online authentication system to track the number of times a tag in the database has been read delivery chain to detect reapplication attacks. Janardhan *et al.* [26] proposed a contrast the accuracy of the Decision Tree Classifier to the Support Vector Machine Classifier in detecting the authentication attacks. The SVM accuracy was 87.02%, P0.05, whereas the Decision Tree Classifier accuracy was 71.81%, P0.05. SVM performed substantially better in identifying de-authentication attacks.

E. AI Based Privacy Prevention

A lightweight stable encryption technique is developed in this work to preserve the privacy of sensitive data and communication. The scheme is developed by permutation, then with the help of a spread structure. The recombination uses pseudo-random sequences (PRNS), whereas the diffusion employs a key circulate generated (KSG). The algorithm is advantageous for CPS devices because to its simple and secure construction. The test results show that the proposed method is sufficiently robust and unquestionably able to withstanding any known prevention assaults as discussed by Tiwari *et al.* [27] and Lian *et al.* [28]. The possible impacted medical records breach will also cause concerns about security and confidentiality were raised throughout the contact period. We propose to fix these current concerns by DEEP-FEL, a decentralised, green, and privateness-better federated side learning device that enables clinical gadgets in a unique establishment to collectively teach an international framework without confidential data being shared. Zhang *et al.* [29] proposed a PEMFL architecture that Momentum FL (MFL), a chaos-based encryption approach and combines differential privacy (DP). The overall success of this methodology is based entirely on two non-datasets. The PEMFL performs exceptionally well in terms of accuracy and privacy protection, according to theoretical assessment and exploratory results.

III. DISCUSSION

A. Gaps Identified from the Past Research

- Privacy Concerns: Previous research may have adopted basic privacy safeguards, but they failed to handle the difficulties of decentralized systems, exposing critical patient information.
- Inadequate Security Protocols: Other techniques may lack robust user authentication algorithms capable of securing connections in pharmaceutical treatment.
- Trade-offs Regarding Privacy and Data Quality: Highlight that present systems frequently sacrifice data quality to improve privacy, perhaps leading to less accurate healthcare results.

B. Emphasize the Urgency

As AI and IoT modern technology become increasingly woven into healthcare, particularly pharmaceutical treatment, the challenges connected with poor data privacy and security safeguards grow more pressing. Failure to solve these challenges might have serious ramifications, such as data breaches that endanger patient safety and weaken the legitimacy of AI-driven healthcare systems.

TABLE I. NOTATIONS USED FOR SECURITY

Symbol	Description
id_{st}	Identity information of stakeholder
p_{st}	Partial private key
s_{st}	Private key
Q_{st}	Stakeholder Public Key
K	Security Parameters
x_{st}	Stakeholder secret value
m_w	Warrant
M	Message
RL_{st}	Repudiation check
st	Starting a hash chain's significance of a st
t_{sti}	i-th timeinterval of stakholder st
tP_{cs}	i-th timeinterval of Server

IV. PROBLEM STATEMENTS

A. Syllabary

Table I contains a collection of the syllabary and security assumptions used.

B. System Prototype

The iCPS controls give system performance, infrastructure at the highest point of our paradigm. In our research main focus is patient care. The major elements of it are practitioners which are liable for the system. When a patient need medication plan will be get from the doctor to pharmacist and pharmacist will verify the medication from the doctor and will handover it to patient. After that monitoring will be done by the pharmacist if any modification is required after monitoring then the medication plan will be changed by the pharmacist by taking consent from the doctor. And the things will be done in repetition until patient will be completely ok. The system model is divided into four cluster which are as follows:

- Pharmaceutical healthcare provider: It basically consists of doctors, hospitals, staff, etc. It is the main cluster with which patients contact directly. If patients need pc then will directly communicate with hospital staff. After that, in the background other clusters will communicate with each other.
- Pharmaceutical Distributors: It consists of the medical things distributor like wholesalers, retailers and medical representatives.
- Pharmaceutical manufacturing bodies: This cluster is a collection of drug manufacturers, raw material suppliers, investors and PBM's. PBM is pharmacy business management who is responsible for securing lower drug cost for insurance and insurance companies.
- Pharmaceutical government bodies: It consists of the principal of governance and regulatory agencies which are to establish, screen, and put in force standards of exercise to enhance the excellent of exercise so that registrants avoid: unsuitable behavior, professional misconduct for a registrant, and inept overall fulfillment of obligations.

The pharmaceutical care is basically followed by the interaction foundation is followed by the IIoT devices. The patient communicates with iCPS and iCPS will communicate with the four clusters and after the approval from all clusters

is achieved only communication will take place. Interested stakeholders who desire to connect with one another can be authorized, and following successful authentication, data packets can be accessed using a cryptographic sign. Edge devices are responsible for matching Interest and Data and then storing the relevant information for further requests. The proposed model has four categories: an iCPS server, IIoT gadgets (like actuators, sensors, and machines), stakeholders, and patients. Notably, the iCPS server is in charge of all category registration. Based on the verification findings, an intriguing data packet should be transmitted and destroyed. After that, approval is allowed to perform virtual sign and sign instead of the IIoT providers, such as unexpected inactivity, insufficient time, or computing. capability.

C. Network Model for Proposed Scheme

The network model is shown in Fig. 1. With the help of CPS an architecture is designed in which on bottom we have smart healthcare devices that collect the required information from the environment. After that, the data is analyzed using different latest technologies which is used with the help of an interface. On other hand, we have different stakeholders who want to use this filtered information. In our study, we have selected 11 stakeholders with the patients they are interacting with each other with the help of iCPS.

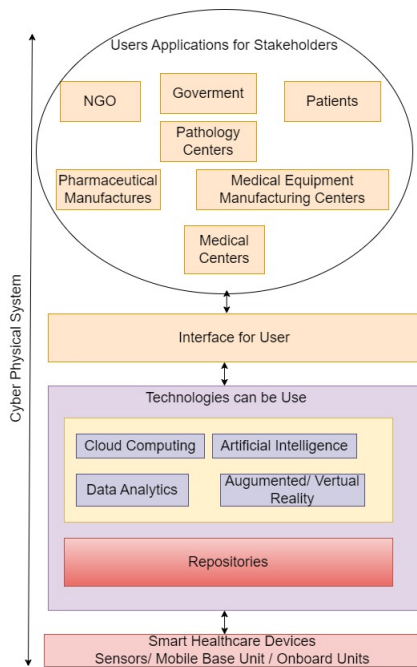

Fig. 1. Network model.

D. Threat Modal

We take into account both passive and aggressive attackers. Passive attacks are those that have amassed a deluge of Interest information to determine who is demanding and who is responding. Activated opponents, as opposed to inactive opponents, have greater power and may perform powerful attacks on any packets channeling, such as catching/exploring Interest packets, changing requests and responses, and spoofing

authorized IIoT devices with the intention to transmit packets. According to the layout of framework, each one is needed to be register on the iCPS controller before if they want to communicate and want the system assets. We feel that the iCPS controller is inadequately powerful in order to render our design seem more plausible.

V. EDGE-ASSISTED INTELLIGENT USER AUTHENTICATION IN CPS

Fig. 2. depicts the simple architecture of stakeholder authorization in CPS for pharmaceutical care.

Fig. 2. Stakeholder authentication in cyber-physical system for pharmaceutical care.

To design authentication for IIoT devices, we use a proxy signature and a session-based variation. The proxy signature is used to validate the user, while the session-based variation is used to validate the request using Algorithm 1.

A. Overview

Based on edge assistance, our approach provides aid to do the requirement for CPS intelligent authentication procedures: 1) provides each user with the signing capability, allowing serving similar demands from multiple requesters; 2) allows users to authenticate themselves, allowing Only authorized individuals will receive the content they have requested; and 3) keeps IIoT gadgets unidentified, according to the authentication policy. The system paradigm is simplified, with a single iCPS server, practitioner, and patient. Six steps are included in an in-depth overview of the authentication operation. The start of the process is the identification of participants (intelligent users like practitioners, patients, etc.) and the intelligent server. The second step is to check the legitimacy of the user. The next phase is taken by a user who makes a content request, and it only sends the request while user is found valid in step two. The following phase is carried out on the info side to check the sign. The fifth step is performed to verify the sign if it is matched then only the communication will take place. The session handshake between the practitioner and the patient is the final phase. The practitioner is granted access to the required information once it has been authenticated in the last phase, as seen in Fig. 3.

B. Authentication Scheme

- (Registration) The system is started by the iCPS server, which broadcasts the system parameters var's.

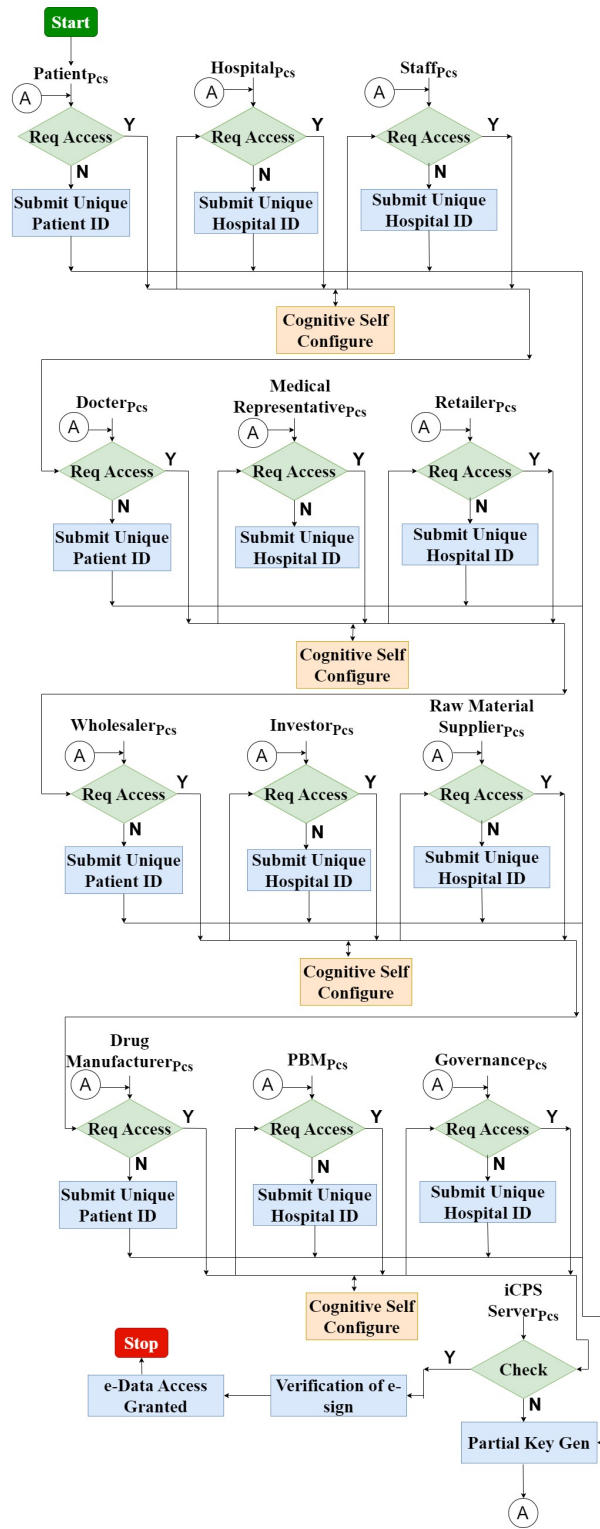

Fig. 3. Stakeholder authentication in cyber-physical system for pharmaceutical care.

Every stakeholder must identify themselves to the iCPS server and get a set of keys (Q_{st}, s_{st}), using the keygen to PartialKeyGen, and setup procedures outlined below. Configuration: The CPS configuration procedure basically is below mentioned. Partial key Generator: The iCPS produces the partial key for each stakeholder. The process takes var's, master key, a secret key x_{st} Z_q selected by stakeholder st and identification for stakeholder st with the value $id_{st} \leftarrow \{0, 1\}$ as source. Every partially key is made up of two parts: the repudiation check RL_{st} and the partial secret key p_{st} . The repudiation check is an encrypted network that takes a starting phrase as input. The master-key hashes two identities, id_{st} and $x_{st}P$, to a point multiplier to create the partial secret key. That's accomplished using reliable means. The following are the specifications.

- Stakeholder st deliver $\{id_{st}, x_{st}P\}$ to iCPS controller
- Make $id_{st} \in \{0, 1\}$
- Determine
- $Rev_{st1} \leftarrow h_5(\epsilon_{st}), \dots, Rev_{stk} \leftarrow h_5(Rev_{st1} - 1)$
- $RL_{st1} < Rev_{st1}, t_{st1} > \dots, RL_{stk} < Rev_{stk}, t_{stk} >$
 $t_{st} \leftarrow t_{st1} \cup \dots \cup t_{stk}$
- $RL_{st} \cup RL_{st1}, \dots \cup t_{stk}$
- $D_{st} \leftarrow h1(id_{st}, x_{st}P)$
- $P_{st} \leftarrow sD_{st}$
- Key Generator: The iCPS takes var's, the partial secret key p_{st} , and the certified value x_{st} as input as outputs the secret key s_{st} along with public key Q_{st} . A p_{st} and x_{st} repository consists of an entity's entire secret key st and its public key equivalent $x_{st}P$. The operation is carried out by st, who is the only legitimate proprietor of x_{st} .
- (Repudiation Check): If an iCPS rejects a stakeholder, all stakeholders have to exit the system. As a result, the controller distributes a repudiation list to all stakeholders regularly to determine if a stakeholder has been repudiated. The detailed procedure is as follows: Repudiation Check: The repudiation checks are performed at each stakeholder's entering and ensure that a stakeholder is associated to the repudiation index prior to the session connection. It requires var's present period of time t and the repudiation list RL_{st} as variables. The iCPS may validate the consumer's repudiation evidence after investigating the truthfulness of the repudiation variables in the repudiation list. It invalidates anything in the request produced after the time t_{stk} since the timestamp t_{stk} rarely in t_{st} .
- (Interest): Stakeholder introduces a cognitive self-configure to check to set all the parameters so that can communicate further. Each stakeholder can set its parameters. Step 4(Verification and sign)- This is done on the iCPS edge and receives the secret value x_{st} as input, as well as a warrant m_w that comprises the repudiation time frame, message m, and identification information idst, the public key of the iCPS, and all stakeholders $Q_{iCPS}, Q_{stPpcs}, Q_{stHpcs}, Q_{stSpcs}, Q_{stDpcs}, Q_{stMRpcs}, Q_{stRpcs}, Q_{stWpcs}$,

$Q_{stIpcs}, Q_{stRMpcs}, Q_{stDMpcs}, Q_{stPBMpcs}, Q_{stGpcs}$.
The iCPS verifies its rights as follows:

Algorithm 1 Algorithm Stakeholders Verification and Sign

Input: var's, s_{st} , PK_{st} , proxy

Output: Success 0: Fail

```

Calculate  $H2 \leftarrow h2(id_{iCPS}, id_{stPpcs}, id_{stHpcs}, id_{stSpcs}, id_{stDpcs}, id_{stMRpcs}, id_{stRpcs}, id_{stWpcs}, id_{stIpcs}, id_{stRMpcs}, id_{stDMpcs}, id_{stPBMpcs}, id_{stGpcs}, m_w, Q_{iCPS}, Q_{stPpcs}, Q_{stHpcs}, Q_{stSpcs}, Q_{stDpcs}, Q_{stMRpcs}, Q_{stRpcs}, Q_{stWpcs}, Q_{stIpcs}, Q_{stRMpcs}, Q_{stDMpcs}, Q_{stPBMpcs}, Q_{stGpcs}$ 
if Verify if  $e(\epsilon, Q_{icps} + H2_{icps}) = e(Q_{icps}, D_{icps})$  then
    Set  $r \in Z_q$ 
    Compute  $R \leftarrow rP, H3 \leftarrow h3(m, id_{icps}, R, Q_{icps})$   $V \leftarrow p_{icps} + rH3 + H2_{icps} + x_{icps}H2P$   $\tilde{d} \leftarrow (R, V)$ 
    send 1
else
    send 0
end if

```

- (Generation of Proxy Signs and Authentication): If the check is successful, the iCPS will get a proxy signing key pair (s_{icps}, PK_{icps}), where PK_{icps} is a collection of public keys. ($Q_{iCPS}, Q_{stPpcs}, Q_{stHpcs}, Q_{stSpcs}, Q_{stDpcs}, Q_{stMRpcs}, Q_{stRpcs}, Q_{stWpcs}, Q_{stIpcs}, Q_{stRMpcs}, Q_{stDMpcs}, Q_{stPBMpcs}, Q_{stGpcs}$). If this is the case, the iCPS generates a digital signature from a message. A signature is not misleading the provider's identity to the public. It accepts the signature by checking \tilde{d} is a valid identity that involves message m; else, it denies it.
- (Session Connection): When patient receives sign makes a request by addressing call including four information of a subject, subject name, signature, identity id and subject which is used by iCPS to identify. Upon receiving the request each stakeholder has to authenticate the request. The iCPS gets the access key Q_{st} and identification id, and private key s_{st} . The iCPS does the verification, and if the check succeeds, the current session connection gets established; otherwise, the request isn't deemed valid, and the session connection is terminated.
- Safety Examination: The suggested technique guarantees that the CPS controller obtains the partial secret keys in a unique manner, preventing it from impersonating a real organization. We examine the authentication system in light of the security objectives given below. To keep attackers at bay, we have identified the following authentication mechanism security goals.
- Trustworthiness: The system should ensure that the person signing cannot be untruthful to an information packet.
- Genuineness: The technique should offer evidence that a signed request is valid.
- Authentication: The method should include a way for authenticating that is the broadcaster an Interest and responding to what it intends to be [30].

- Anonymity: The technique should safeguard IoT devices by ensuring that both inner and external assailants are unaware of their identities.
- Key Organisation: The system should offer a negotiated key among all the stakeholders, so that no one controls the key.
- Authenticity: A polynomial-time adversary has the knack of forging a signature assigned to authorised entity in order to prevent the organisation from denying it.

Theorem 1: A polynomial-time challenge exists that may fix the Computational Diffie–Hellman issue along likelihood $\varepsilon(\mathbb{k})' > (\varepsilon(\mathbb{k})/2) (1 - q_s(q_{h3} + q_s)/2^k)(e(q_r + 1))^{-1}$ is contingent upon whether or not the opponent \mathbb{k} can forge a sign along with a competitive edge $\varepsilon(\mathbb{k})$, where q_{h3}, q_s, q_r indicate the total quantity of requests made to the h_3 , executing, as well as reveal-partial key predictions, providing that $h_i (i = 1, 2, 3)$ hashed routines are arbitrary diviners.

Demonstration: Assume that $X \leftarrow a\rho, Y \leftarrow b\rho \in G1G1$ indicate an arbitrary task. Using the forger \mathbb{k} , we can create the algorithmic programme \in to produce $ab\rho \leftarrow G1$. Algorithm \in first generates system-specific var's, as the standard protocol does, and passes var's to the forger \mathbb{k} , which then initialises \mathbb{k} with $Q_0 \leftarrow X$ and communicates with \mathbb{k} as below.

1) h1 and h3 Queries: If \mathbb{k} examines an arbitrary prophet h1(h3) using a number of tuples $\langle id_{st}, Q_{st} \rangle (\langle m_{st}, id_{st}, R_{st}, Q_{st} \rangle)$, preserves an index $Lh_1(Lh_3)$ of components $\langle id_{st}, Q_{st}, x_{st}, c_{st}, \nu_{st} \rangle (\langle m_{st}, id_{st}, R_{st}, Q_{st}, y_{st}, d_{st}, \nu_{st} \rangle)$, It is initially empty and yields the following outcomes.

a) Since the inquiry $\langle id_{st}, Q_{st} \rangle (\langle m_{st}, id_{st}, R_{st}, Q_{st}, Q_{st} \rangle)$ is existing in $Lh_1(Lh_3)$, \in outputs ν_{st} to .

b) Else, \in picks $x_{st} \in Z * q (y \in Z * q)$ arbitrary, yields $\nu_{st} \leftarrow x_{st}\rho (\nu_{st} \leftarrow y_{st}Q_0)$ if a tossup $c_{st} \leftarrow 0, 1 (d_{st} \leftarrow 0, 1)$ which gives 0 as a result with likeliness $\sigma(1/2)$ and yields $\nu_{st} \leftarrow x_{st}y (\nu_{st} \leftarrow y_{st}\rho)$ if $c_{st} = 1 (d_{st} = 1)$ having a likelihood $1 - \sigma(1/2)$, and adds $(\langle id_{st}, Q_{st}, x_{st}, c_{st}, \nu_{st} \rangle) (\langle m_{st}, id_{st}, R_{st}, Q_{st}, y_{st}, d_{st}, \nu_{st} \rangle)$ into $Lh_1(Lh_3)$.

2) h2 Queries: While \mathbb{k} asks an arbitrary generator h_{st} with a list of T_{st} tuples, \in keeps the matching list $L_{h_{st}} \leftarrow \langle T_{st}, \mu_{st} \rangle$. While the value of the input field is located in the list $L_{h_{st}}$, it sends \in the matching element μ_{st} . If not, delivers a random $Z * q$ value.

3) RevealPartialKey Queries: After \mathbb{k} queries the identity id_{st} , \in obtains the matching element $\langle id_{st}, Q_{st}, x_{st}, c_{st}, \nu_{st} \rangle$ from the list of items L_{h1} and responds as follows.

a) If $c_{st} = 1$, then \in outputs and the experiment is aborted.

b) Otherwise, sets $p_{st} \leftarrow x_{st}Q_0$ and restores it to .

4) RequestPublicKey Queries: As \mathbb{k} queries identify id_{st} , \in sets $Q_{st} \leftarrow x_{st}\rho$ for an arbitrary value $x_{st} \leftarrow Z * q$, sends it to , and inserts $\langle id_{st}, x_{st} \rangle$ to $L\rho K$.

5) Signing Queries: \mathbb{k} demands an id_{st} verification on an exchange m_{st} , and \in replicates the divination verification and replies in response to the probe.

a) Assuming h_3 is not supplied along with $\langle m_{st}, id_{st}, R, Q_j \rangle$, the process continues by replying to h1 requests to get $H_2 \leftarrow \mu_2$ and setting $R \leftarrow r_2Q_0, H_3r_2^{-1}(x_1\rho \leftarrow D_j)$, and $V \leftarrow r_1Q_0 + \mu_2Q_i + \mu_2Q_j$ with an arbitrary selected $r_1, r_2 \leftarrow Z * q$. Otherwise, \in will stop and forsake. Because L_{h3} can never have a total of $q_{h3} + q_s$ entries, the likelihood of not terminating $1 - (q_s(q_{h3} + q_s)/2^k)$.

b) \in yields $\Delta \leftarrow \langle V, R \rangle$ as the acceptable signing on m .

It is worth noting that opponent \in correctly generates a signature δ with likelihood $\varepsilon(k)'$, which means that \mathbb{k} completely meets the Signing answers. Finally, \mathbb{k} creates a fake sign $\iota * \leftarrow \langle V^*, R^* \rangle m^*$ upon a message. After it \in gets the elements $\langle id_{st}^*, Q_{st}^*, x_{st}^*, c_{st}^*, \nu_{st}^* \rangle$ derived from Lh_1 . If $c_{st}^* = 0$, the program fails and exits. Otherwise, it proceeds to retrieve the pair $\langle id_{st}^*, Q_{st}^*, Q_j^* \rangle$ based on the set Lh_2 and m_{st} , $\langle m_{st}^*, d_{st}^*, \nu_{st}^*, id_{st}^*, R_{st}^*, Q_{st}^*, y_{st}^* \rangle$ based on the record Lh_3 . Assuming that $d_{st}^* = 0$, then \mathbb{k} responds 0 and exits. Otherwise, it will do this: $\ddot{e}(V^*, P) = \ddot{e}(y_{st}^*P, R_{st}^*) \cdot \ddot{e}(Q_0, D_{st}^*) \ddot{e}(Q_{st}^*, \mu_{st}^*P) \cdot \ddot{e}(\mu_{st}^*P, Q_j^*)$ with $h_1 = x_{st}^*y, h_2 = \mu_{st}^*, h_3 = y_{st}^*P$ along with $R_{st}^* = r_{st}^*P$ for components which are referred as $\mu_{st}^* \leftarrow Z_q^*, r_{st}^*, x_{st}^* \cdot (1 - \delta)/2$ is the probability of not terminating at particular moment. Henceforth $\ddot{e}(V^* - y_{st}^*R_{st}^* - \mu_{st}^*Q_{st}^* - \mu_{st}^*Q_j^*, P) = \ddot{e}(X, x_{st}^*Y)$

VI. PROBLEM ANALYSIS FOR SECURITY

Using MATLAB a comparative analysis has been done to check the suggested proposal's effectiveness mechanism with the existing one. The comparison is done with communication and computation consumption under the number of requests with existing schemes [34], [32], [33] and [31] as demonstrated in Fig. 4(a)-(b) along with Fig. 5(a)-(b). In addition, Fig. 4(c) authorization and acknowledgment consumption with the amount of request contents. To find out in a better way we have measured the cost of authorization concerning a number of requests made in Fig. 4(b) which depicts it as a linear correlation. In our method there is a slightly heavy burden to other methods [31], [32], [33], and [34]. But in contrast, our method has a better authentication which reflects more reliability. In Fig. 5(b) efficiency of our method as compared to other four methods in terms of patients requests. As it increases the computation cost also increases but not in a drastic way. In Fig. 4(a), the validation execution efficiency of various systems improves when the request quantities grow from 0 to 100. Our method has a somewhat greater inspection processing proportion compared to [30], [28], but lower than [27], and [29]. In our system, verifying a signature requires acquiring all packets containing the delegation information used to calculate it. Our scheme achieves a verification execution efficiency of less than 20% for 50 contents, making it suitable for latency-tolerant uses in the IIoT. Fig. 4(b) highlights our investigation of the transmission load as the content of the request increases. An apparent pattern indicates that the transmission load is linearly related to the quantity of requested contents. Our system has a somewhat higher load compared to [27], [28], and [29], but lower than [34]. Our method offers two-way verification in addition to caching, which sets it apart from other schemes. In Fig. 4(c), we examine the relationship between communication cost, verification versus simultaneous dissemination, and quantity of demanded data to assess the

overhead of communication robustness in the proposed approach. The method of delivery cost grows with the amount of requested material, whereas verification consumes less than the interaction procedure. Raising the quantity of required material from 50 to 100 only leads to a ten percent rise in signature size. Though each signature packet must be transferred from the supplier to the user, the proposed approach is resource-efficient and does not create significant overhead associated with communication modifications. Fig. 5(a) shows that the capacity usage ratio grows with the amount of demanded content. The information usage ratio in [28], [29], and our system is less than forty percent for one hundred packets of requested material, unlike [29] and [30]. Our technique consumes little computing resources on the consumer side and outperforms other systems in terms of safety. Fig. 5(b) shows that the provider’s delay increases with the quantity of demanded contents. It uses somewhat more computing resources than [27] and [26], but the growth rate will be slower than [29] and [30]. Compared to the transmission load indicated in Fig. 4(b), our technique requires less time. So to conclude we can say that authentication time improves as the request are getting increased.

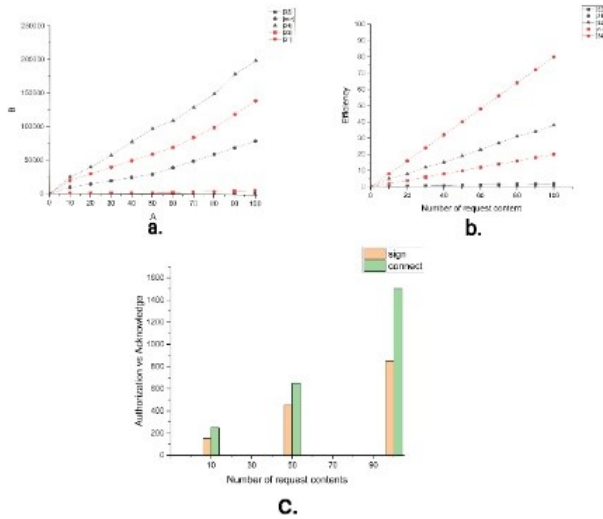

Fig. 4. Estimation value differentiation with a varying number of requests a) Cost for several authentication methods b) The cost of transmission for various methods of authentication c) Authorization price versus acknowledge price.

VII. PROPOSED MODEL FOR PRIVACY

In this paper edge based technique is used to provide privacy in user authentication. In start every stakeholder and patient will download the present universal prototype from the iCPS. The downloaded universal model will act as localized for each edge node. Firstly, noise has been added to the input set to upgrade it. After that, the model has been trained using the classifier. After that training input set is transferred to iCPS. This is done in several repetitions. The updated universal prototype is created using aggregation of different types of prototypes as shown in Fig. 6. Table II represents different notation used while designing the algorithm. Stakeholders using Algorithm 2. There are eleven stakeholders represented

(a)

(b)

Fig. 5. Comparative analysis of the ability to provide services to stakeholders with varying number of requests a) Stakeholder service cost under different authorization methods b) Efficiency of different authorization methods.

TABLE II. NOTATIONS FOR PRIVACY

Symbol	Description
P_u	Universal prototype
P_i	Localized prototype
P_i^{reform}	Updated universal prototype
S_i	Stakeholders
I_i	Local input
I_i^n	local input with noise
I_i^{np}	Upgrade local input

by S_i where i varies from one to eleven. If any stakeholder has a localized update(I_i), then universal prototype P_u is downloaded from the iCPS. If the universal prototype is not same as the existing one, then only the procedure will start. The universal prototype will act a localized prototype (P_i) for the stakeholder. A noise has been added input set and stored into as I_i^n and upgraded scaled form as I_i^{np} .The updated model is created and transferred to iCPS as P_i^{reform} . The same patient is using Algorithm 3.

Data: Data for all stakeholder’s will be private and will be represented by I_i .Correlation Coefficient added with Noise: It describes the association between the features and the target. The value of this varies from 0 to 1. This value denotes the

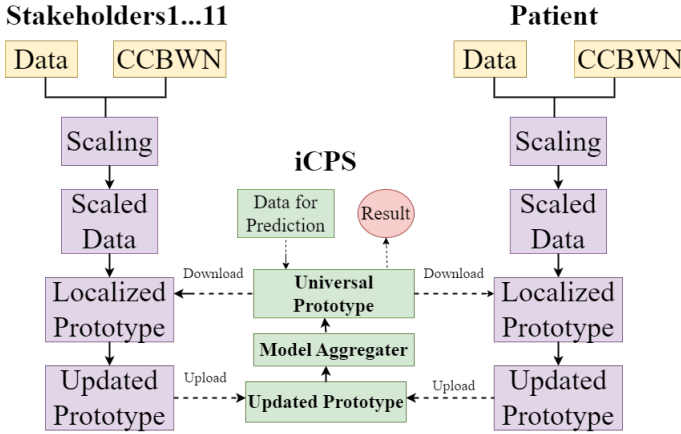

Fig. 6. Block diagram of proposed model.

correlation low value means low correlation and high value means high correlation. Value 0 denotes no correlation.

$$ran = \frac{n(\Sigma ab) - (\Sigma a)(\Sigma b)}{(n\Sigma a^2 - (\Sigma a)^2)(n\Sigma b^2 - (\Sigma b)^2)} \quad (1)$$

$$a_i^n = a_i + Rand(0, ran) \quad (2)$$

Where, i varies from 0 to 1, n is an integer value, a_i is original, a_i^n is after appending noise, $Rand(0, ran)$ is used to generate random numbers between 0 to ran , ran is correlation coefficient of a_i which is mentioned in Eq. 1. Noise is appending using Eq. 2 after that the updated value of input will be I_1^n to I_{11}^n . iCPS using Algorithm 4. iCPS will choose the stakeholder's (S_i : $i=0$ to 11) for training and give response to stakeholder by giving upgraded prototype.

VIII. PROBLEM ANALYSIS FOR PRIVACY

The dataset used in this study was taken from Kaggle and contains a large no. of instances approximately 2000 with 8 attributes. Attributes are drug-uses, patient symptoms, gender, disease prevention, design therapist plan, age, implementing the therapeutic plan and monitoring therapeutic plan and correlation coefficient values are mentioned in Table III. The class that is targeted has a value of 0 or 1. In the start, iCPS circulates the attributes to the localized model to the randomly chosen patient and stakeholders for the training

$P_u \leftarrow$ PrototypeiCPS(P) transfer P_u to all stakeholders and to the patient

point of view. the stakeholders and patient begins the training just after receiving the universal prototype and saving it as a localized prototype. Stakeholders and patients transfer the updated prototype to iCPS. The iCPS accumulate the prototype and transfer the updated prototype again to selected in further rounds till better accuracy is gained. Different classifiers are used for the study Decision tree as CL1, KNeighbours as CL2, Gaussian as CL3 and Randomforest as CL4, and the outcome is determined by the test score. which is calculated by using Eq. 3 and it shows that correction when the test's score rises. The prototype efficiency improves as the MSE value lowers, with the ideal model having a value of 0. Correlation grows while the R2 score improves. Table IV shows the comparison test scores for CL1, CL2, CL3, and CL4 by utilizing several techniques Gaussian Noise(GN) and Correlation Coefficient based model with Noise(CCBMWN). The test score using CL1 are 0.7205 and 0.7953 using CL2 are 0.7952 and 0.8067 using CL3 0.7678 and 0.8211 using CL4 are 0.8042 and 0.8812. The efficiency of the model is measured based on accuracy, specificity, and sensitivity. Results show that CCBMWN performs better than GN. So our method is better.

$$TestScore = \frac{x + y}{x + y + z + \epsilon} \quad (3)$$

Where x, y, z, ϵ are True positive(mean actual and predi-

TABLE III. CORRELATION COEFFICIENT VALUES FOR DIFFERENT FEATURES

Symbol	Description
Gender	0.05

patient symptoms	0.58
disease prevention	0.65
design therapist plan	0.76
implementing therapeutic plan	0.66
monitoring therapeutic plan	0.56

cated value both are same as 1), True negative(with mean real and projected values are both 0), False positive (mean actual and predicted value both are different actual is 1 and predicted as 0)and False negative (mean actual and predicted value both are different actual is 0 and predicted as 1), respectively. The correlation coefficient value lies between -1 to +1. Table V displays the correlation value of the coefficient for each characteristic. The efficiency of the model is measured on the basis of accuracy, specificity, and sensitivity. Sensitivity is actual positive denoted by (λ) and calculated by using Eq. 4 and specificity is false actual negative denoted by (m_K) and calculated by using Eq. 5. ROC curve is used to show different thresholds by plotting and graphically.

$$\lambda = \frac{x + y}{x + \epsilon} \tag{4}$$

$$m_K = \frac{y}{y + z} \tag{5}$$

$$AUC = \int_l^h f(x)dx \tag{6}$$

In above equation, the ROC is defined as $Y=f(X)$, while both m and n are the curve's limit values. Fig. 7 is the curve for GN and Fig. 8 is for CCBMWN.

Fig. 7. ROC for GN.

The AUC (area under the ROC curve) is cognizance, received from ROC. It gives a clear picture of which technique is doing better. It is calculated using Eq. 6. In our research it is found that GN is 0.5032 and CCBMWN is 0.5108 which is better in CCBMWN. The comparison is shown in Fig. 9. The model's fulfillment is assessed using sensitivity, accuracy,

Fig. 8. ROC for CCBMWN.

Fig. 9. Comparison of test score.

and specificity. A higher accuracy number indicates excellent accuracy, a higher sensitivity value indicates good prediction of genuine positive, and a higher specificity value indicates good prediction of true negative, as demonstrated in Fig. 10 and Fig. 11. In the first round, the sensitivity is 0.754 and at last, it is 0.82. The specificity is 0.65 in the first round and 0.67 in last round. The accuracy is 71% but the aggregate is 76.

IX. CONCLUSION

In this study, an architecture has been proposed for user authentication in pharmaceutical care services. It can be used for secure communication whenever a patient wants to communicate and wants to avail of pharmaceutical care services. In problem analysis, it is observed that as compared to other methods the proposed method is strong. In this, the estimation and transmission value was analyzed. For providing privacy we have proposed a new technique CCBMWN which ensures privacy and results show that proposed method is giving good performance in contrast with existing methods. This study not only addresses the critical requirement for safe and confidential communication in AI-powered pharmaceutical treatment, but it also lays the groundwork for future advances in digitising healthcare operations and explicitly defining stakeholder responsibilities.

Abstract—Road safety is a critical concern globally, with speeding being a leading cause of traffic accidents. Leveraging advanced technologies can significantly enhance the ability to monitor and control vehicle speeds in real time. Traditional methods of speed monitoring are often limited in their ability to provide real-time, adaptive interventions. Existing systems do not adequately integrate sensor data and decision-making processes to prevent speeding-related accidents effectively. This paper aims to address these limitations by proposing a novel system that utilizes Internet of Things (IoT) technology combined with fuzzy logic to monitor vehicle speeds and prevent accidents in real time. The proposed system integrates IoT sensors for continuous vehicle speed monitoring and employs a Fuzzy Inference System (FIS) to make decisions based on variables such as speed, alcohol presence, and driver fitness. The system also facilitates interaction between drivers and law enforcement through Vehicle-to-Everything (V2X) communication. The FIS implementation demonstrated effective speed control capabilities, accurately assessing and responding to various risk levels, thereby reducing the likelihood of speeding-related accidents. This research contributes to the advancement of road safety systems by integrating IoT and fuzzy logic technologies, offering a more adaptive and responsive approach to traffic management and accident prevention. Future enhancements will focus on incorporating machine learning techniques to dynamically adjust FIS rules based on real-time data and improve sensor network reliability to ensure more accurate and comprehensive monitoring.

Keywords—Internet of Things; high-speed monitoring; alcohol detection; Matlab simulation; write fuzzy inference system

I. INTRODUCTION

The Internet of Things (IoT) represents a collection of smart technologies and connected devices that are highly intelligent. IoT enables data exchange over a network without requiring human-to-human or human-to-computer interactions. This technology has made our daily tasks easier and smarter. IoT has been applied in various fields, such as electricity, gas, water, and transportation. In Bangladesh, the majority of the population relies heavily on road transportation. Currently, traffic accidents are a significant problem, with high-speed driving being the primary cause.

The alarming rate of traffic accidents in Bangladesh, primarily due to high-speed driving, underscores the need for an effective solution. Implementing a system to monitor and control vehicle speeds can significantly reduce the incidence of road accidents. Our motivation stems from the desire to enhance road safety and protect lives by leveraging IoT technology.

The implementation of a vehicle speed monitoring and control system can have profound social impacts. By reducing the number of traffic accidents, we can save lives and prevent injuries, thereby improving the overall well-being of society. Moreover, safer roads contribute to a more efficient transportation system, which can have positive economic implications.

The primary objectives of this study are:

- To develop an IoT-based system for monitoring and controlling vehicle speeds.
- To reduce the rate of traffic accidents caused by high-speed driving.
- To enhance the communication between vehicles and control authorities for prompt intervention.

The statistics of fatalities in road accidents in Bangladesh are shown in Table I. To address the high rate of traffic accidents, a fixed vehicle speed should be enforced on the highways of Bangladesh. By controlling vehicle speeds, it is possible to reduce the accident rate. In this study, we have developed an IoT-based system to monitor and control vehicle speeds effectively. Often, vehicles exceed speed limits at the start of their journeys, which is a primary cause of road accidents. Our device monitors vehicle speeds and sends alerts to both the nearest police control room and the driver when overspeeding is detected. The mortality rate of road accidents in the last 8 years in Bangladesh (2015-2022) is shown in Fig. 1.

Each vehicle is equipped with a smart card/board that has a unique identification number. The device sends a message to the nearest police control room with the smart card/board

TABLE I. STATISTICS OF FATALITIES IN ROAD ACCIDENTS (SOURCE: DAILY NEWSPAPERS OF BANGLADESH)

Sl. No.	Year	Number of Fatalities	Reason	Type of Vehicle
1	2015	6823	Excessive speed	Bus and Truck
2	2016	3412	Hazardous overtaking	Motorcycle and Van
3	2017	4284	Careless driving	Microbus and Rickshaw
4	2018	7221	Poor road construction	Motorbike and Jeep
5	2019	7855	Unfit vehicles	Truck and Covered Van
6	2020	5431	Pedestrian carelessness	Truck and Pickup Van
7	2021	6284	Drunk driving	Minibus and Microbus
8	2022	4587	Lack of footpaths	Pickup and Van

Fig. 1. Mortality rate of road accidents in the last 8 years in Bangladesh (2015-2022).

number when a vehicle is speeding. Simultaneously, it alerts the driver about the overspeeding. These devices are internet-enabled, allowing for monitoring and control.

The prevalence of road accidents globally, especially in developing countries like Bangladesh, is a critical concern. Bangladesh ranks among the highest in terms of accident rates. The primary cause of fatalities in accidents is the lack of emergency assistance. Timely intervention can save lives, making response time crucial. The vision of the Internet of Things (IoT) has rapidly expanded into new computing domains. IoT impacts human life more effectively and enhances functionality [1], [2].

The rest of the paper is organized as Section II discusses the previous works, Section III discusses the methodology, Section IV shows the implementation, Section V shows the results and discussion and finally Section VI shows the concluding remarks.

II. LITERATURE REVIEW

A. Related Works

Kishorkumar C. S. et al. proposed an intelligent car speed control system using Arduino and speed sensors. G. Kirankumar et al. developed an intelligent vehicle system for speed cameras using RuBee. Ravi Kishore Kodali et al. designed a system that enables traffic authorities to monitor all vehicles from the control room itself [3]. Sumit Deshpande et al. created a system that records the speed of vehicles and notifies relevant

authorities of violations without human intervention [4]. P. Saichaitanya et al. proposed a car velocity tracking device using an accelerometer. Akriti et al. discussed the trade-offs in accidental control devices, including high costs and non-portability [5]. Chatrapathi et al. developed an efficient routing algorithm for ambulances [6]. Raut and Sachdev proposed a notification device using the XBee WiFi module, XBee Shield, and GPS module [7]. Ali and Alwan presented a device to detect low and high-speed vehicle crashes [8]. Aishwarya S. R. developed an approach that considered driver inconvenience [9]. Koneti S. et al. provided a solution for accidents caused by drunk driving [10]. Pratiksha R. et al. designed a device that detects accidents and monitors the car engine condition [11]. Kishwer K. et al. proposed an incident detection approach using sensors and hardware [12]. Namrata H. et al. implemented a push-button switch for boundary detection and microcontroller triggering [13]. Yadav et al. identified accidents and reported the reasons to registered numbers [14]. Reddy and Rao developed a system to detect vehicle fires and other failures [15]. Kavya and Geetha proposed a method to reduce delays caused by ambulances [16]. P. A. Targe and M. P. Satone developed a real-time algorithm using VANET communication [17]. Poorani K. et al. suggested using image processing techniques to monitor drivers [18]. Kim and Jeong developed an algorithm to detect crashes using crash probability data [19]. Patel K. H. et al. created software to detect accidents using accelerometer sensors [20]. Sonali N. and Maheshwari R. addressed obstacle detection in motorcycles with an intelligent approach. Chris T. and White J. designed a smartphone-based incident detection and notification system [21]. Prabha and Sunitha developed an automatic detection and messaging device for traffic accidents using a GSM modem and GPS [22]. Elie Nasr and Elie Kfoury proposed an IoT method for detecting, reporting, and navigating street accidents, suggesting a rescue system by reporting the location [23]. Vijay Savania and Hardik Agravata created a system for preventing accidents using vehicular alcohol detection sensors [24]. Syedul Amin and Jubayer Jalil proposed an incident detection and reporting device using GPS, GPRS, and GSM technology [25]. Suvarnanandyal et al. suggested a smart parking framework using an IoT module [26]. This review also integrates several recent papers that further emphasize the use of IoT in various applications, including health screening [27], robotic arm control [28], e-health databases [29], highway monitoring [30], Parkinson's prediction [31], and the impact of COVID-19 on education [32]. Additional contributions include low-cost robots for disabled individuals [33], smart farming [34], medical robotics [35], human activity recognition [36] and renewable energy generation [37]. The reviewed literature demonstrates various innovative approaches to vehicle speed control and accident detection using IoT and related

technologies. Each study contributes uniquely to enhancing road safety, reducing accident rates, and improving emergency response times. By incorporating these technologies, significant advancements can be achieved in the monitoring and management of traffic, ultimately leading to safer roads and reduced fatalities. The collective insights from these studies highlight the versatility and potential of IoT in transforming various sectors and improving overall quality of life.

B. Research Gap

In reviewing the existing literature, it is evident that while numerous studies have explored the use of IoT and fuzzy logic in traffic management, these approaches often fall short of addressing the complexity and variability of real-world driving conditions. For instance, several works focus on isolated aspects such as monitoring vehicle speed or detecting specific events like accidents or traffic violations through sensor data and GPS/GSM modules. However, these systems tend to operate within predefined parameters, lacking the flexibility to adapt to the dynamic nature of road environments. Furthermore, many studies fail to integrate a comprehensive decision-making framework that considers multiple risk factors simultaneously, such as speed, driver condition, and environmental context. This narrow focus limits their applicability to broader traffic safety scenarios. Additionally, most existing systems do not facilitate real-time interaction between drivers and law enforcement, which is crucial for timely interventions. This research gap highlights the need for a more holistic approach that combines continuous monitoring, adaptive decision-making, and seamless communication to enhance road safety comprehensively. The proposed study seeks to fill this gap by developing an integrated IoT and fuzzy logic-based system that not only monitors vehicle speed in real-time but also incorporates additional risk factors and enables proactive communication between drivers and authorities, thus providing a more robust solution to prevent speeding-related accidents.

C. Novelty of the Proposed System and Comparison with Existing Systems

The proposed system offers several novel features compared to existing systems:

- Integration of fuzzy logic for real-time speed monitoring and decision-making.
- The ability of drivers and police to interact with the system, enhances cooperative safety measures.
- Use of V2X communication for comprehensive traffic management.

Existing systems often focus solely on vehicle speed or accident detection using conventional methods [38], [39], [40], [41], [42], [43]. Our approach enhances these systems by incorporating fuzzy logic and enabling real-time interaction between drivers and law enforcement. Table II shows a Comparison of the Proposed System with Existing Systems.

TABLE II. COMPARISON OF PROPOSED SYSTEM WITH EXISTING SYSTEMS

System	Key Features	Limitations
[38]	Accident detection using speed sensors	Lacks real-time interaction
[39]	GPS and GSM-based monitoring	Limited to vehicle speed
[40]	Traffic management system	No fuzzy logic integration
[41]	Intelligent transport systems	Limited V2X communication
[42]	V2V communication for safety	No driver-police interaction
[43]	Road condition monitoring	Not focused on speed control
Proposed System	Fuzzy logic, V2X, driver-police interaction	Needs further integration

III. METHODOLOGY

The significance of defining a research problem lies in addressing a gap in the literature. The parameters considered in previous work include monitoring gas leaks through sensors, using GPS and GSM modules for communicating vehicle speed, and recording vehicle positions via sensors. However, for accident detection, only the speed monitored by the sensor was considered [38]. We believe this algorithm is more useful for specific intersections than for general traffic accidents. Therefore, the existing work needs to be modified to support road traffic crashes more broadly [39]. In our research, both drivers and police can use this system. They can sign into the system; drivers can monitor and control high speed, while police can detect overspeeding, track current locations, and notify the police control room. Both can receive message notifications from the system.

A. Proposed System Architecture

In this system, the driver signs in and monitors the car's speed. If high speed is detected, a message notification is sent automatically, prompting the driver to control the speed. The driver then signs out of the system. Similarly, police can sign in, detect high speed, receive SMS alerts for high speed, track the current location, and inform the police control room before signing out. The proposed system architecture is shown in Fig. 2.

The flow chart of research work stages and the proposed model for high speed is shown in Fig. 3 and Fig. 4. The following steps outline the flow chart of the research work stages and the proposed system model for high speed.

B. Fuzzy Logic Description

Fuzzy logic is a method of computing based on multivalued logic rather than the standard Boolean "true or false" (1 or 0) logic on which modern computing is based. Fuzzy logic relies on human perception and is used in situations where available information is partially true, making decision-making complex. Fuzzy Logic Controller (FLC) is used here for making decisions on critical events based on sensor data and Vehicle-to-Everything (V2X) communication.

There are some basic units of Fuzzy Inference System (FIS):

- Fuzzification Unit
- Knowledge-Based Rules

Fig. 2. Proposed system architecture.

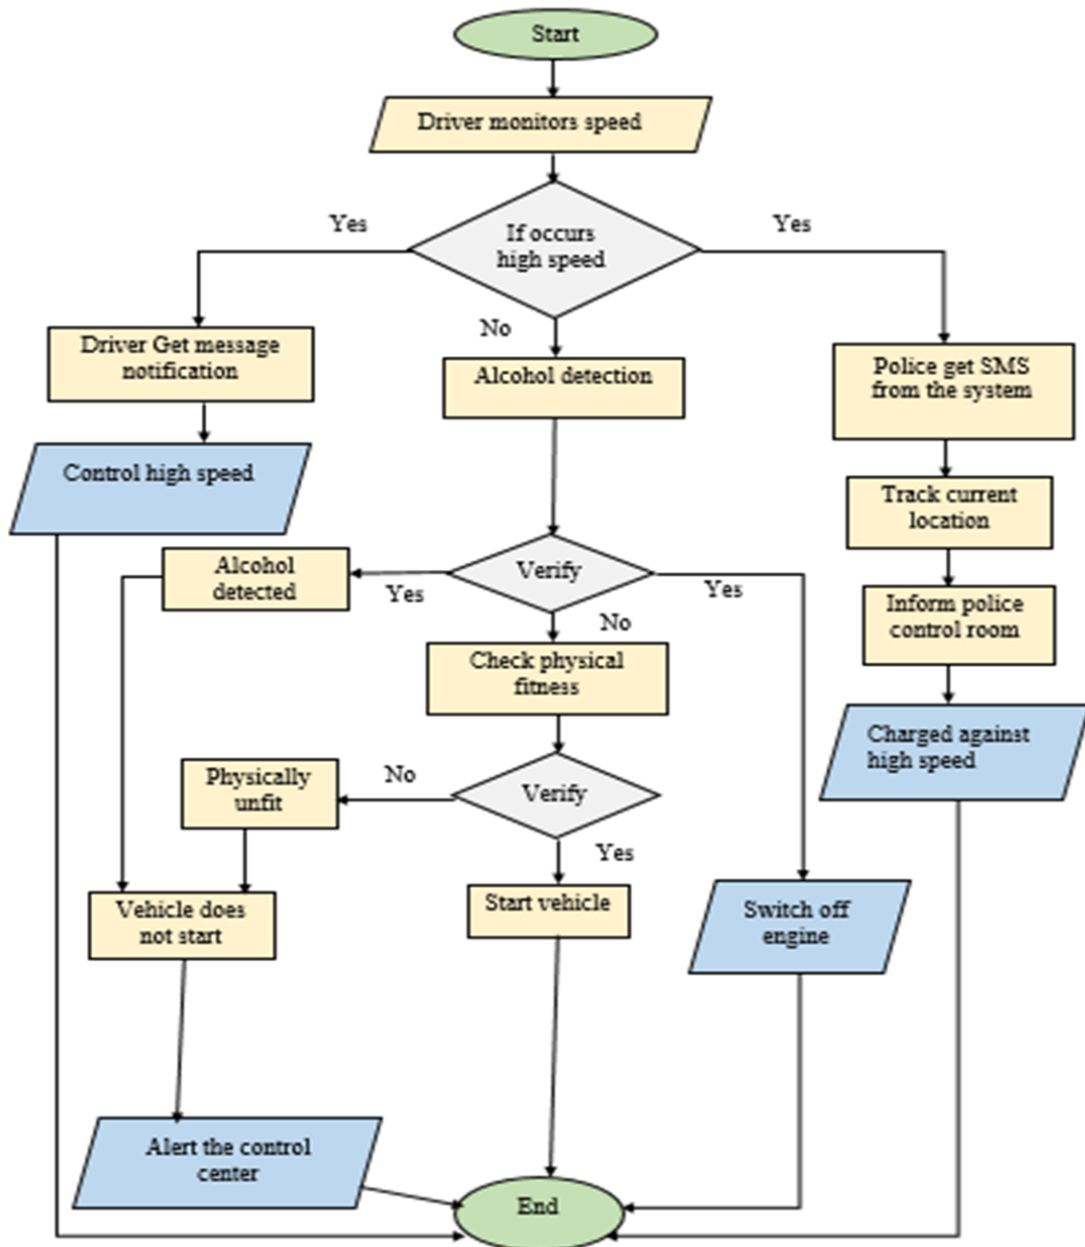

Fig. 3. Flow chart for work stages.

Fig. 4. High speed model.

- Decision or Controller Unit
- Defuzzification Unit

The block diagram of the FIS, shown in Fig. 5, illustrates these four basic units.

C. Mathematical Formulation

Let's consider the speed of the vehicle v , monitored in real-time. The speed threshold for high speed is denoted as v_{th} . If $v > v_{th}$, an alert is triggered. The alert system can be mathematically represented as:

$$A(v) = \begin{cases} 1 & \text{if } v > v_{th} \\ 0 & \text{otherwise} \end{cases} \quad (1)$$

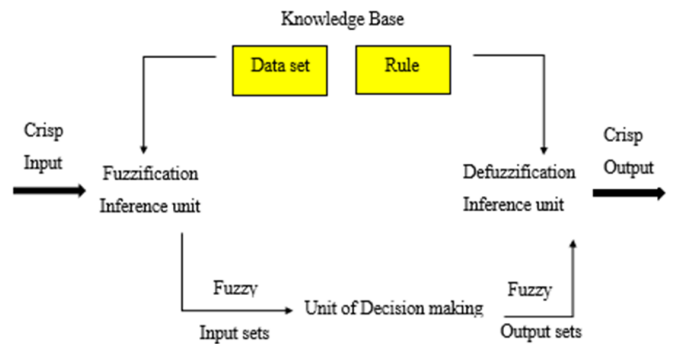

Fig. 5. Block diagram of FIS.

The position of the vehicle, $P(t)$, at time t is tracked using GPS coordinates $(x(t), y(t))$. The rate of change of position, which indicates the speed, is given by:

$$v(t) = \sqrt{\left(\frac{dx}{dt}\right)^2 + \left(\frac{dy}{dt}\right)^2} \quad (2)$$

If $v(t) > v_{th}$, a notification N is sent to both the driver and the police:

$$N = \begin{cases} 1 & \text{if } v(t) > v_{th} \\ 0 & \text{otherwise} \end{cases} \quad (3)$$

Using fuzzy logic, the decision-making process involves fuzzification, applying knowledge-based rules, and defuzzification. The speed $v(t)$ is fuzzified into linguistic variables like “low”, “medium”, and “high”. The rule-based system then decides the action based on these variables. For instance:

- If speed is “high” and location is “urban area”, then issue a severe alert.
- If speed is “medium” and location is “highway”, then issue a moderate alert.

Defuzzification converts these fuzzy outputs into a crisp value, which determines the exact nature of the alert.

These mathematical formulations and fuzzy logic rules ensure that the system is capable of making nuanced decisions based on real-time data, improving both road safety and the efficiency of emergency responses.

IV. IMPLEMENTATION

This section provides a detailed explanation of the configurations used to complete this research and ensure its functionality. It gives an overview of the software implementation and describes the process of reducing car accidents using MATLAB.

A. Software Implementation

The system is implemented using MATLAB, specifically employing fuzzy logic. A Fuzzy Inference System (FIS) is utilized to achieve the desired functionality. The software components used in the system are:

- MATLAB
- Fuzzy Inference System (FIS)

B. Reducing Car Accidents with High Speed Control in MATLAB

The system is implemented using a Fuzzy Inference System (FIS) in MATLAB. A FIS can be loaded from a .fis file using the `readfis` function. To save a FIS to a file, the `writeFIS` function is used. The `evalfis` function evaluates the FIS for given input values and returns the resulting output values. It evaluates the FIS using predefined evaluation options. The algorithm used in MATLAB is shown in Algorithm 1.

Algorithm 1 Fuzzy Traffic Control

```

1:  $f \leftarrow \text{readfis}(\text{'VehicleProtection.fis'})$ 
2:  $a \leftarrow \text{input}(\text{'Vehicle speed (km/h): '})$ 
3:  $g \leftarrow \text{evalfis}([a, 0, 1], f)$ 
4: if  $g < 1$  then
5:    $\text{disp}(\text{'Message to driver is sent'})$ 
6:    $\text{disp}(\text{'Message to police with current location'})$ 
7:    $\text{disp}(\text{'Control room informed'})$ 
8:    $\text{disp}(\text{'Driver punished for high speed'})$ 
9:    $b \leftarrow \text{input}(\text{'Is alcohol present (0:no, 1:yes): '})$ 
10:   $c \leftarrow \text{input}(\text{'Is the driver physically fit? (0:no, 1:yes): '})$ 
11:   $g \leftarrow \text{evalfis}([0, b, c], f)$ 
12:  if  $g < 1$  then
13:     $\text{disp}(\text{'Other factors need to be checked'})$ 
14:  else
15:     $\text{disp}(\text{'Other factors are okay'})$ 
16:  end if
17: else
18:    $\text{disp}(\text{'The vehicle is good to go'})$ 
19: end if

```

C. Emergency Speed Control Warning

In this system, the user can observe different speed values. If the speed values are below 65 km/h, the system will indicate that the vehicle is good to go. If the speed is exactly 65 km/h, the system will provide different messages based on various parameters. If the speed exceeds 65 km/h, the system will also provide messages based on the parameters. Table III presents the analysis of speed, alcohol presence, and physical fitness.

TABLE III. SPEED, ALCOHOL, AND PHYSICAL FITNESS ANALYSIS

Speed (km/h)	Alcoholic	Physical Fitness	Message
30	×	×	The vehicle is good to go
50	×	×	The vehicle is good to go
65	0	1	Other factors are okay
65	1	1	Other factors need to be checked
65	0	0	Other factors need to be checked
90	1	0	Other factors need to be checked

V. RESULTS AND DISCUSSION

This section discusses the results obtained from our Fuzzy Inference System (FIS) implementation and the performance analysis. The FIS uses fuzzy variables containing sets, where each set has an associated membership function. The membership function defines the form of the sentence and is used to “fuzzify” the values of the variable by associating a degree of membership (DOM) with a value. Sharpe’s triangular membership functions are employed in this system. Fig. 6 shows the Mamdani FIS.

A. Obtained Features

The key features obtained from the FIS include:

- Three input variables for speed, alcohol presence, and physical fitness.
- Input and output mapping functions to process and evaluate the data.

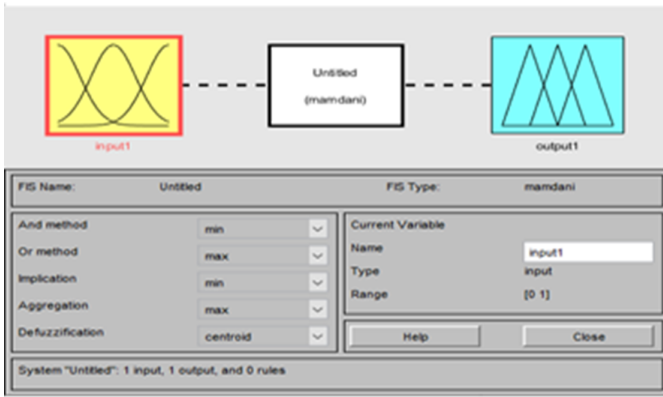

Fig. 6. Mamdani FIS.

- A rule base to determine the actions based on input conditions.
- Surface plots to visualize the relationship between inputs and outputs.

B. Performance Analysis of FIS

1) *Three input variables and I/O mapping functions for FIS:* The FIS accepts various input variables. Fig. 7 shows the three input variables for this system. The input mapping function receives blocks of data, and the output mapping function returns intermediate results. An input reduction function reads the intermediate results and produces a final result. Thus, mapping calculations are typically split into two related parts, with functions reduced separately. The input and output mapping features of the FIS can be seen in Fig. 8.

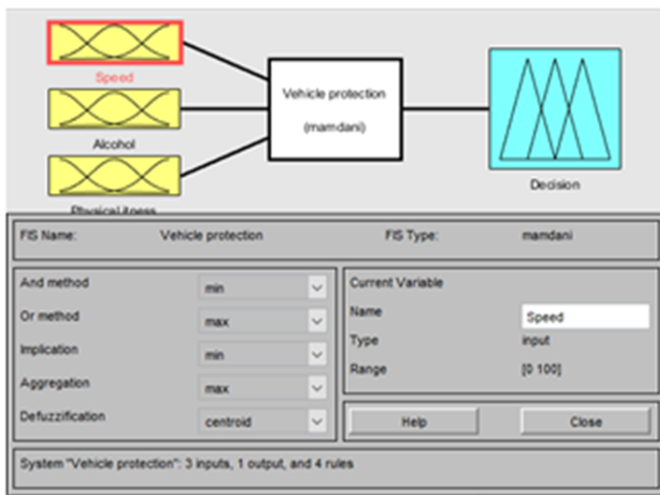

Fig. 7. Three input variables for FIS.

2) *Rule base and rule view for FIS:* Vehicles often travel at high speeds on roads. For emergency speed control, if speed v is measured in km/h, the rules are:

- 1) Low: $v < 30$
- 2) Medium: $30 \leq v \leq 65$
- 3) High: $v \geq 65$

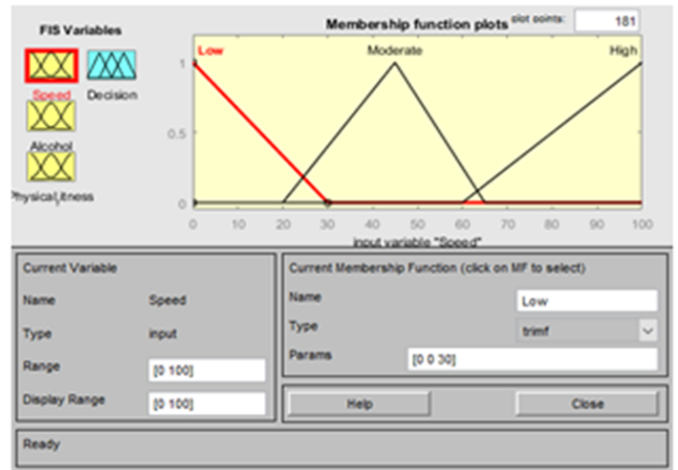

Fig. 8. Input/Output mapping functions for FIS.

Table IV shows the rule base, and Table V shows the decision-making process for emergency speed control to reduce car accidents on highways.

TABLE IV. RULE BASE FOR SPEED CONTROL

SL NO.	Rule Base
1	speed is low: the decision is the vehicle is clear
2	speed is moderate: the decision is the vehicle is clear
3	speed is high: the vehicle stops and necessary steps are taken by the police

TABLE V. DECISION TABLE

Speed	Decision
Low	Vehicle is clear
Moderate	Vehicle is clear
High	Vehicle stops and necessary steps are taken by the police

The rule view for the determination of decisions according to input is shown in Fig. 9.

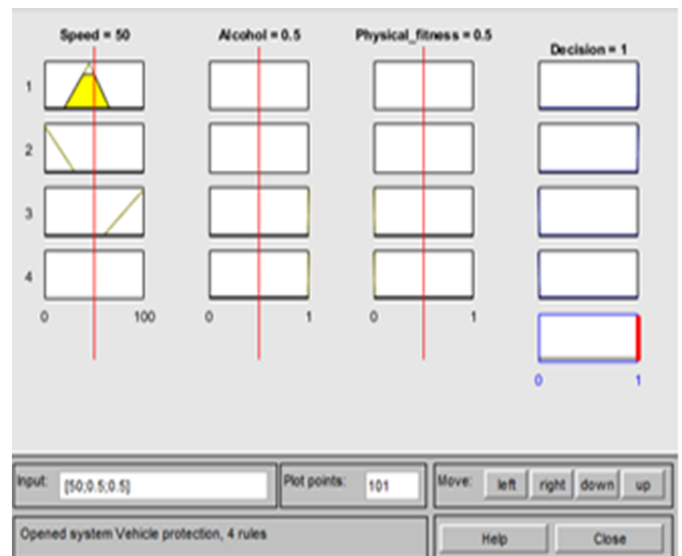

Fig. 9. Rule view for FIS.

3) *Surface for FIS*: The surface plot from the FIS shows the relationship between input and output variables. Fig. 10 depicts the surface according to the input.

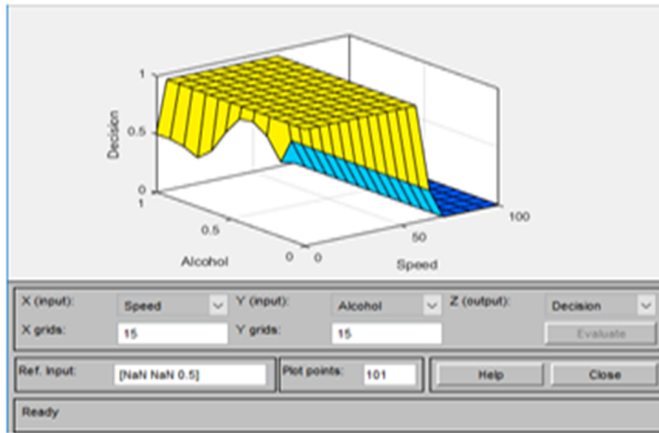

Fig. 10. Surface for FIS.

C. Limitations

While the FIS model provides a robust framework for speed control and accident reduction, it has some limitations:

- The system relies heavily on accurate sensor data, which may not always be available.
- The model's effectiveness is constrained by the predefined rules and membership functions, which might not cover all real-world scenarios.
- Integration with other traffic management systems is not addressed in this implementation.

D. Future Works

Future improvements and extensions to this research could include integrating the system with other traffic management systems for a more comprehensive solution, expanding the FIS rules to cover a broader range of driving conditions and scenarios, incorporating machine learning techniques to adaptively modify the FIS rules based on real-time data, and enhancing the sensor network to improve data accuracy and reliability.

VI. CONCLUSION

This study introduces an innovative approach to enhance road safety through the integration of IoT and fuzzy logic technologies for real-time vehicle speed monitoring and accident reduction. Our system leverages IoT sensors to continuously monitor vehicle speeds and employs fuzzy logic for decision-making based on variables like speed, alcohol presence, and driver fitness. This approach enables timely interventions by notifying both drivers and law enforcement agencies of potential speeding violations, thereby mitigating the risk of accidents. The system's capability to facilitate interaction between drivers and police, coupled with Vehicle-to-Everything (V2X) communication, enhances cooperative safety measures and improves traffic management. Although our Fuzzy Inference

System (FIS) demonstrated effective speed control capabilities in our analysis, its performance is contingent on accurate sensor data and predefined rules, suggesting avenues for future enhancements. By integrating machine learning for adaptive rule adjustments and refining sensor networks for enhanced reliability, future research aims to further optimize our system's efficacy in ensuring safer and more efficient transportation systems globally.

TGMoE: A Text Guided Mixture-of-Experts Model for Multimodal Sentiment Analysis

Xueliang Zhao¹, Mingyang Wang^{2*}, Yingchun Tan³, Xianjie Wang⁴

College of Computer and Control Engineering, Northeast Forestry University, Harbin, China^{1,2,3}

Harbin Institute of Technology, Harbin, China⁴

Abstract—Multimodal sentiment analysis seeks to determine the sentiment polarity of targets by integrating diverse data types, including text, visual, and audio modalities. However, during the process of multimodal data fusion, existing methods often fail to adequately analyze the sentimental relationships between different modalities and overlook the varying contributions of different modalities to sentiment analysis results. To address this issue, we propose a Text Guided Mixture-of-Experts (TGMoE) Model for Multimodal Sentiment Analysis. Based on the varying contributions of different modalities to sentiment analysis, this model introduces a text guided cross-modal attention mechanism that fuses text separately with visual and audio modalities, leveraging attention to capture interactions between these modalities and effectively enrich the text modality with supplementary information from the visual and audio data. Additionally, by employing a sparsely gated mixture of expert layers, the TGMoE model constructs multiple expert networks to simultaneously learn sentiment information, enhancing the nonlinear representation capability of multimodal features. This approach makes multimodal features more distinguishable concerning sentiment, thereby improving the accuracy of sentiment polarity judgments. The experimental results on the publicly available multimodal sentiment analysis datasets CMU-MOSI and CMU-MOSEI show that the TGMoE model outperforms most existing multimodal sentiment analysis models and can effectively improve the performance of sentiment analysis.

Keywords—Multimodal fusion; sentiment analysis; cross modal; mixture of experts

I. INTRODUCTION

With the rapid growth of text data such as social media and online comments, sentiment analysis has become an increasingly important research field. The goal of sentiment analysis tasks is to classify the sentiment information contained in raw data into different sentiment polarities such as positive, negative, or neutral. However, in many practical scenarios, sentiment data often not only contains textual information but also includes multimodal data such as images, videos, audio, etc. Compared to unimodal data lacking diversity, these multimodal data can provide more information for sentiment analysis, and the complementarity of this information can enhance the accuracy of sentiment analysis.

Existing multimodal sentiment analysis methods include Tensor-based fusion [1], which directly connects feature tensors from different modalities for analysis. However, this method generates very large feature tensors, requiring a lot of storage space and computational resources, and does not consider the interaction of information between different modalities. To address these issues, researchers have developed other deep learning-based fusion methods. Huddar et

al. [2] proposed multi-level feature optimization, extracting feature tensors from multiple modalities and using LSTM to extract contextual information between adjacent utterances at multiple levels. However, this method did not examine the correlation of different modal information with the sentiment analysis results, making it unable to fully understand the target sentiment comprehensively and accurately. Tsai et al. [3] proposed a multimodal routing method that dynamically adjusts the relative weights between input samples and output representations by exploring the correlation between modalities and identifying the relative importance of single-modal and cross-modal features.

However, although previous approaches have made progress in multimodal fusion, they often fail to adequately account for the varying contributions of different modalities to sentiment information, overlooking the importance of sentimental information from different modalities. In the field of sentiment analysis, while audio and visual modalities indeed contain crucial sentimental information, the distribution of sentiment information across modalities is unevenly distributed. Neglecting the differences in contributions of different modalities to sentiment analysis may result in multimodal fusion representations lacking crucial sentiment information from key modalities, thus reducing the accuracy of sentiment analysis [4].

To address the above issues, this paper proposes a text guided mixture-of-experts model for multimodal sentiment analysis. The model aims to better capture the differences in sentiment information between different modalities, obtaining more targeted sentiment features. TGMoE leverages pre-trained models for feature extraction from three modalities. It integrates visual and audio modality information into the text modality through a text guided cross-modal fusion mechanism to obtain multimodal fusion features. Subsequently, for the sentiment prediction task, multiple highly specialized experts are simultaneously trained by a trainable gating network to selectively handle sentiment features. This approach delves deeper into uncovering potential connections among modal data, thereby enhancing the accuracy of sentiment prediction in the model. The contributions of TGMoE model can be summarized as follows:

- Proposing a text guided cross-modal Transformer network that integrates sentiment information from visual and audio modalities into the text modality through a text guided attention mechanism.
- TGMoE uses a sparsely gated mixture-of-experts mechanism to selectively process multi-modal fusion

features, enhancing the model's ability to learn and represent complex emotional information.

- Extensive experimental results on two benchmark datasets demonstrate that the proposed TGMoE outperforms several existing methods in multimodal sentiment analysis tasks.

II. RELATED WORK

With the advent of the information age, we have access to a large amount of multimodal data (videos, audio, and text), providing a more abundant source of features for sentiment analysis tasks. Accurate and rapid analysis of human emotions can offer better services for daily work and life. Multimodal sentiment analysis aims to understand the sentiment of the target in video data (including text, audio, and visual modalities), uncovering deep sentimental information in each modality to reduce bias in single-modal sentimental information. Learning how to capture interaction information within and between modalities and effectively integrate multimodal information is a key challenge faced by multimodal sentiment analysis tasks [5].

To address this issue, researchers have proposed various multimodal fusion methods for modeling. With the advancement of deep learning, model-based fusion has received more attention. Zadeh et al. [1] introduced the Tensor Fusion Network, which computes the Cartesian product of three modalities and concatenates the resulting tensor along a certain dimension. The concatenated tensor is then fed into a deep neural network for sentiment classification. Building on this, Liu et al. [6] decomposed the weights of the fusion tensor into a set of low-rank factors to improve efficiency, making the computational complexity linearly related to the number of modalities. Hou et al. [7] recursively integrated local correlations into global correlations through multilinear fusion. Mai et al. [8] adopted a divide-and-conquer approach by partitioning multimodal features into blocks, applying tensor fusion to each block to capture local interaction information, and then combining local information to obtain global multimodal interaction information.

Model-based fusion methods can effectively preserve sentimental information within modalities but struggle to consider contextual relationships between modalities. Graph neural networks, due to their excellent structural learning capabilities, are widely applied in multimodal sentiment analysis tasks. Yang et al. [9] proposed a modal-temporal attention graph for unaligned multimodal data, where each sub-feature of each modality in the sequential data is treated as a node. They construct modality-type edges between different modalities and temporal-type edges within the same modality. By applying a pruning algorithm, they fuse and align asynchronous distributed multimodal sequential data. Hu et al. [10] constructed a fully connected heterogeneous graph for conversational data, considering each modality of each utterance as a node. They connect each node to nodes representing the same utterance but from different modalities and to nodes representing the same modality from the same conversation. Different aggregation mechanisms for various types of edges are designed to learn multimodal dynamics in the graph network.

To further explore sentimental information within and across modalities, researchers have started integrating attention mechanisms into multimodal sentiment analysis. For example, Wang et al. [11] proposed a recurrent attentional variable embedding network that combines attention mechanisms to investigate facial and speech features. They learn displacement information generated during the vocabulary representation process for multimodal representation. Building upon this, Rahman et al. [12] incorporated multimodal representations into Transformer models, using visual and audio features to learn representation shifts and apply them to text modality for sentiment analysis. While these methods have partially addressed the issue of insufficient fusion between modalities, they often treat each modality equally, overlooking the varying contributions of different modalities to the final sentiment analysis results.

Therefore, this paper addresses the issue of disparate contributions between different modalities by enhancing the role of the text modality in sentiment analysis. It utilizes a mixture of experts to further extract sentiment information from multimodal features, enhancing nonlinear representation capabilities and obtaining more abstract fusion features of sentiment information.

III. METHOD

A. Overall Model Architecture

Multimodal sentiment analysis employs three modalities - audio (X_a), visual (X_v), and text (X_t) - from the same video segment to determine the sentiment polarity of the target. The proposed TGMoE model also aims to effectively integrate information from the three modalities to enhance the effectiveness of sentiment analysis. Fig. 1 illustrates the overall architecture of the TGMoE model. The model framework consists of three parts: the feature extraction module, the text guided cross-modal feature fusion module, and the sparsely gated mixture of experts module.

Feature Extraction Module: For each modality, appropriate pre-trained models are used to gain incipient modality features.

Text Guided Cross-Modal Feature Fusion Module: Utilizing cross-modal attention to capture the interaction information between audio, visual, and text features, the module adds this information to the text features. This encourages the text features to incorporate information from other modalities, providing high-quality fused features for sentiment prediction.

Sparsely Gated Mixture-of-Experts Module: Training multiple experts to handle multimodal features with different sentimental biases, to deeply explore the potential connections between data and improve the accuracy of sentiment prediction.

B. Feature Extraction Module

To better extract features of single modality data, different feature extraction methods are adopted for different modalities. For the text modality, the language pre-trained model SimCSE [13] is utilized as the feature extractor for text discourse. The hidden state output from the last layer is taken as the feature vector for the text modality.

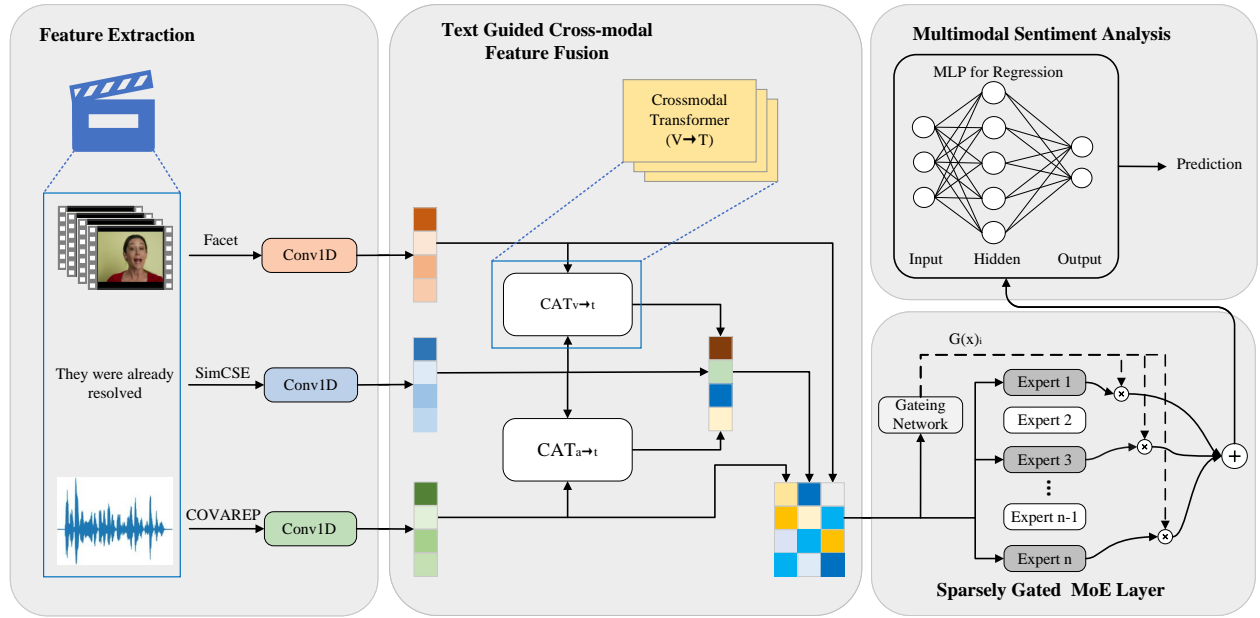

Fig. 1. The overall structure of the TGMoE model.

$$X'_t = \text{SimCSE}(X_t; \theta_t) \in \mathbb{R}^{s_t \times d_t} \quad (1)$$

Where X'_t represents the result of text modality feature extraction and θ_t is the SimCSE model's parameter. s_t means the sequence length and d_t is the feature dimension of text modalities.

For the audio modality, audio features are extracted using the COVEREP [14] acoustic framework. These features include pitch, volume, Mel-Frequency Cepstral Coefficients, and more, denoted as X_a . For the visual modality, visual features are extracted using Facet. These features include facial action units, facial landmarks, head pose, and other features, denoted as X_v . The features for audio and visual modalities can be obtained through the CMU-Multimodal SDK.

To achieve better fusion in the upcoming work, 1D temporal convolution is used to unify the feature dimensions of the three modalities while ensuring that each element of the input sequence has sufficient awareness of its neighboring elements. The features of the three modalities are fed into a 1D temporal convolutional layer:

$$f_m = \text{Conv1D}(X'_m, k_m) \in \mathbb{R}^{s_m \times d_m}, m \in \{t, v, a\} \quad (2)$$

where k_m is the size of the convolutional kernel. f_m is output of 1D temporal convolutional layer.

C. Text Guided Cross-Modal Feature Fusion Module

In the traditional Transformer model, changing the positions of the input sequence does not alter the final output. To enable the model to capture the sequential information of the input sequence, positional embeddings (PE) are added to the representation of each modality based on the practice outlined in Transformer [15]:

$$H_m = f_m + \text{PE}_m \in \mathbb{R}^{s_m \times d_m}, m \in \{t, v, a\} \quad (3)$$

where PE_m means the PE of each modal, H_m represents the feature vector after each modal adds PE.

The text modality is the most basic and intuitive form of reflecting the speaker's sentiment, containing more sentiment-related information compared to video and audio modalities. Therefore, based on the idea of MulT [16], this paper presents a text guided cross-modal fusion module, which utilizes cross-modal attention mechanisms to calculate the attention weights between the text modality and the audio-visual modalities. This promotes the reception of information from the other two modalities by the text modality, potentially integrating emotion-related features from the audio and visual modalities into the text features for better encoding of emotional information across all three modalities. Additionally, considering the characteristics of the sentiment analysis task, the dominant role of the text modality in the feature fusion process is reinforced to incorporate emotional information from different modalities. The text-guided cross-modal feature fusion is illustrated in Fig. 2. Each cross-modal Transformer consists of L layers of cross-modal attention.

$$\text{CAT}_{v \rightarrow t} = \text{Softmax}\left(\frac{W_Q H_t \times W_K^T H_v}{\sqrt{d_k}}\right) W_V H_v \quad (4)$$

$$\text{CAT}_{v \rightarrow t} = \text{LN}(\text{CAT}_{v \rightarrow t}) \quad (5)$$

Where $\text{CAT}_{v \rightarrow t}$ indicates the visual modality transmission of information to the text modality. $\text{Softmax}(\cdot)$ represents a normalized exponential function, it can compress a K-dimensional vector z containing arbitrary real numbers into another K-dimensional vector $\sigma(z)$ such that the range of

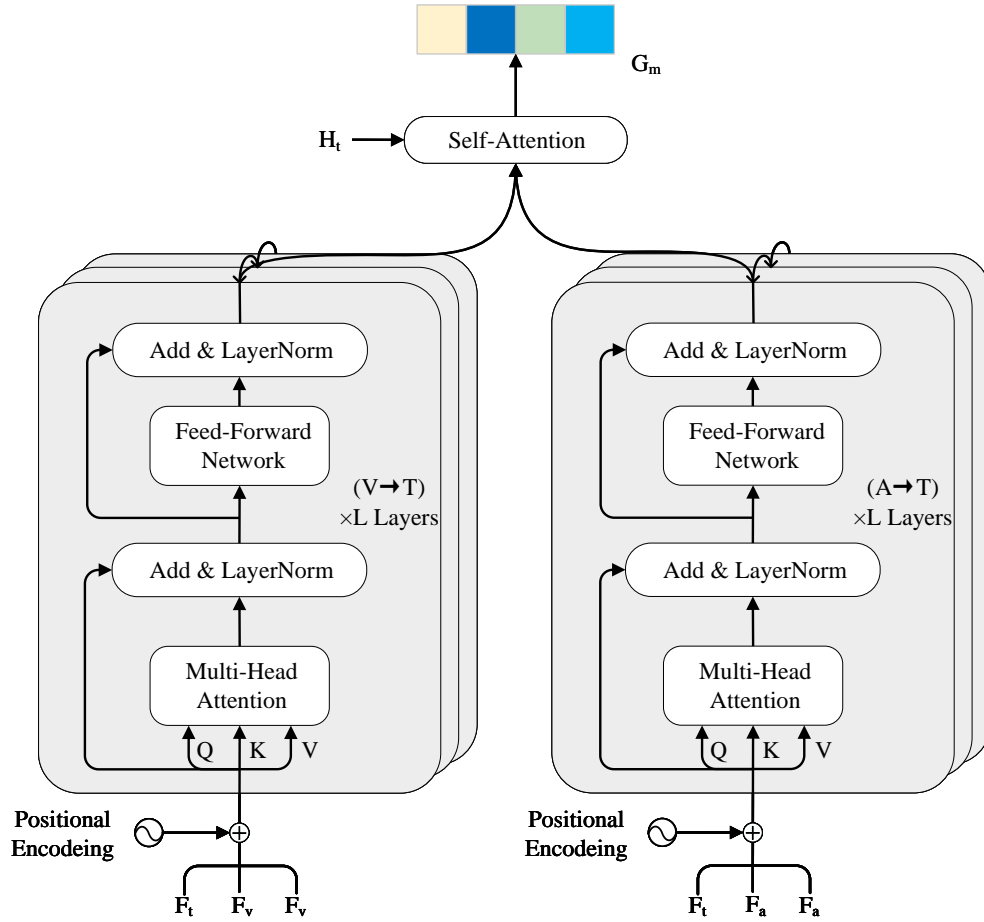

Fig. 2. Text guided cross-modal feature fusion module.

each element is between (0,1), and the sum of all elements is 1. The attention mechanism uses numbers between 0 and 1 to represent the importance of different data blocks. Where $Q = W_Q H_t$, $K = W_K^T H_v$, $V = W_V H_v$.

As each layer of the network can capture different abstract levels of input data, we stack L layers of cross-modal Transformers to learn hierarchical sentimental information within the features. Subsequently, cross-modal attention is further computed between the audio modality and the text modality, as exemplified by $(A \rightarrow T)$ in Fig. 2. The two fusion results are then concatenated with the text features and passed through self-attention blocks to capture the interactive information between the text features and the fusion features. Finally, the fusion features are combined with the features from the three modalities through convolutional layers to generate the ultimate fused feature representation. Adapting from the low-level features is beneficial for the model to retain the original information of each modality.

$$Z_m = H_t + \text{CAT}_{v \rightarrow t} + \text{CAT}_{a \rightarrow t} \quad (6)$$

$$G_m = \text{Self-Attention}(Z_m) \quad (7)$$

$$F_m = [G_m, H_a, H_v, H_t] \quad (8)$$

During the text guided cross-modal feature fusion process, the text modes constantly update their sequences through external information from multi-head cross-modal attention. By taking advantage of the fact that the text contains more sentiment-related information [17], the sentimental information of the text features is strengthened, and the sentimental information of the vision and audio modes is fully integrated into the text modes to obtain multi-modal features containing more sentimental information.

D. Sparsely Gated Mixture-of-Experts Module

During the process of text guided cross-modal feature fusion, sentiment may be expressed differently across different modalities. For example, in the sentence "You look beautiful today," the sentiment conveyed in the text modality is positive, but if accompanied by a pouting expression, the sentiment

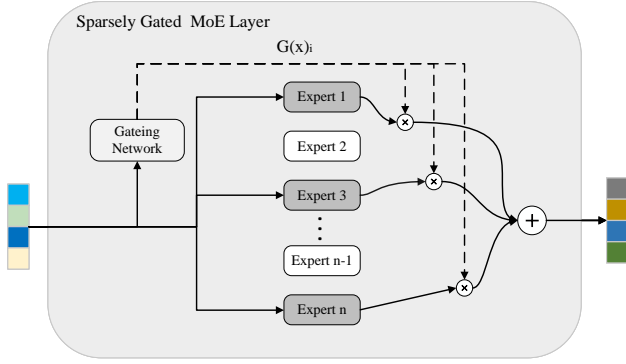

Fig. 3. Sparsely gated mixture-of-experts layer.

in the visual modality becomes negative. There are certain differences in the distribution of sentiment across different samples of data, so sentimental information in multi-modal features can be enhanced through a feed-forward network (FFN). However, for traditional deep learning models, activating the entire model for each sample when the training data is large can lead to significant spatial and time costs. To address this issue, the TGMoE model introduces a neural network component: the mixture of experts (MoE). By using gating mechanisms, the number of experts involved in the work can be effectively controlled, thus compressing the model's computational costs.

MoE is a special type of feed-forward network. In this structure, each model unit is referred to as an expert, and there is a gating network to select a combination of experts, combining the weight of each model as the final output. The difference from training data individually in traditional FFNs is that the mixture of experts' networks can enhance the non-linear representation capability of multi-modal features by allowing multiple experts to learn simultaneously. This enhances the distinctiveness of multi-modal features in terms of sentiments, thereby improving the classification accuracy of data samples.

The MoE layer in the TGMoE model consists of several experts and a trainable gating network. Each expert is an independent FFN that learns similar or different features from each other. The gating network learns parameters to select a sparse combination of numerous experts to process each input. The output of the gating network is a sparse n-dimensional vector, which is used to weigh the selected combination of experts. Each expert has the same architecture but distinct parameters. The structure of the MoE layer is illustrated in Fig. 3.

For a given input x , we define $G(x)$ as the output of the gating network; $E_i(x)$ is the output of the i -th expert network. Therefore, the output of the Sparsely Gated Mixture-of-Experts module is:

$$y = \sum_{i=1}^n G(x)_i E_i(x) \quad (9)$$

When $G(x)_i = 0$, the model does not need to compute

$E_i(x)$. Therefore, although the model includes numerous neural networks, only a small number of neural networks will be utilized for each sample, significantly reducing computational complexity and time cost.

Sparsely Gated Network: The input x is multiplied by a trainable weight matrix W_g , then the initial architecture of the gating network is completed by applying the Softmax function.

$$G(x) = \text{Softmax}(x \cdot W_g) \quad (10)$$

x represents the input of sparsely gated network, and W_g represents a randomly generated matrix. Constructed in this way, the gating network outputs a non-sparse vector. Therefore, to ensure the sparsity of the gated output, the top k values of the gated output are retained. In addition, adjustable Gaussian noise is introduced to ensure that each neural network receives roughly the same amount of training data. The amount of noise for each gate is controlled by another adjustable parameter matrix W_{noise} .

$$\text{KeepTopK}(v_i, k) = \begin{cases} v_i, & v_i \in \text{TopK}(k) \\ -\infty, & v_i \notin \text{TopK}(k) \end{cases} \quad (11)$$

$$H(x) = x \cdot W_g + \text{LN}(x \cdot W_{noise}) \quad (12)$$

$$G(x) = \text{Softmax}(\text{KeepTopK}(H(x), k)) \quad (13)$$

where $\text{LN}(\cdot)$ represents data standardization, $v_i \in \text{TopK}(k)$ means that v_i belongs to the top K elements.

The MoE layer is placed after the text guided cross-modal feature fusion module. After passing through the text guided cross-modal fusion module layer, each multimodal fusion feature will invoke the MoE once, thereby selecting different combinations of experts to enhance the sentimental information in the multimodal representation. For the multi-modal feature F'_m , multiple expert networks are simultaneously trained through the MoE layer to deeply explore the potential connections between data, as described below:

$$z = \sum_{i=1}^n \text{Softmax}(\text{KeepTopK}((F'_m \cdot W_g + \text{LN}(F'_m \cdot W_{noise})), k)) E_i(F'_m) \quad (14)$$

E. Model Prediction and Loss Function

The vector z output from the MoE layer is fed into a Multilayer Perceptron (MLP) for sentiment prediction. The MLP consists of three linear layers. The TGMoE model uses MAE as the basis for computing the loss function for the entire task.

$$Y'_m = \text{MLP}(Z_m; \theta_m), m \in \{t, v, a\} \quad (15)$$

$$\text{Loss}_m = \frac{1}{N} \sum_{i=1}^N (|\text{pred}^i - y^i|) \quad (16)$$

where N represents the number of training samples, and y represents the true labels of the multimodal data.

IV. EXPERIMENTAL RESULTS

A. Datasets and Evaluation Metrics

1) *Datasets*: This paper evaluates the performance of the TGMoE model using two publicly available datasets.

The CMU-MOSI dataset [18] is a commonly used dataset in the field of multimodal sentiment analysis. This dataset consists of 93 videos from YouTube where the reviews of movies are discussed. The dataset is divided into 2,199 subjective discourse-level video segments. Each segment has a real-valued sentiment score in the range of $[-3, +3]$ to express the intensity of the sentiment polarity of the characters.

The CMU-MOSEI dataset [19] is an extension of the CMU-MOSI dataset, with a larger number of utterances, more diverse samples, speakers, and topics. This dataset contains 23,453 video segments with sentiment-labeled tags from 5,000 videos. Each video segment in the MOSI and MOSEI datasets contains a sentiment score in the range of $[-3, 3]$, where a higher value indicates a stronger positive sentiment polarity.

2) *Evaluation metrics*: When considering sentiment analysis on the CMU-MOSI and CMU-MOSEI datasets as a regression task, the predictive performance of the models is measured using Mean Absolute Error (MAE) and Pearson correlation (Corr). When viewed as a classification task, evaluation methods include seven-class accuracy (Acc-7), binary accuracy (Acc-2), and F1 score. Here, Acc-7 represents the accuracy of predicting values falling into seven intervals within $[-3, +3]$, while Acc-2 and F1 represent the accuracy and F1 score of the binary classification task, respectively.

B. Experimental Settings

We developed the TGMoE model in the PyTorch framework, using Mean Absolute Error (MAE) as the loss function, Adam as the optimizer, and PyCharm as the integrated development environment. All experiments in this study were conducted on an RTX 4090 GPU, and multiple validations and analyses were performed to obtain the best set of hyperparameters.

We set the batch size to 32, epochs to 50, learning rate to $1e-3$, and sequence length to 50 for all three modalities. The text feature dimension is 768, the visual feature dimension is 35, the audio feature dimension is 74, the dropout rate is 0.1, and the number of heads in multi-head attention is set to 5. The number of stacked layers in the attention layer is set to 5.

C. Baselines

To assess the relative performance of the TGMoE model, we will compare it with the following baseline models.

TFN [1]: Tensor fusion network decomposes unimodal vectors into tensors through the Cartesian product, then fuses the outer product of tensors to learn interactions within and between modes.

LMF [6]: Efficient low-rank multimodal fusion decomposes stacked high-order tensors into many low-rank factors,

then efficiently fuses them based on these low-rank factors to improve efficiency.

MFM [20]: Multimodal representation learning factors link a multi-modal discriminative network with a generative network possessing intermediate modality-specific factors to facilitate the reconstruction of the fusion process and optimize the discriminative loss.

MuT [16]: Multimodal Transformer constructs a Transformer between modalities through attention mechanisms, integrating multimodal information and optimizing the fusion process.

MAG-BERT [12]: The multimodal adaptive gate designs an alignment gate for integrating visual and audio information and integrates it into a standard BERT model.

MISA [21]: The modality invariance and specificity of multimodal sentiment analysis project features into two separate independent spaces with specific constraints, taking into account the invariance and specificity of modalities, and then complete fusion on the features of both spaces.

BIMHA [22]: Enhancing bimodal information for arbitrary pairs of modalities using a multi-head attention mechanism, utilizing tensor fusion to capture interactions between modalities, effectively integrating information carried by different modalities, and improving sentiment prediction.

SELF-MM [23]: Self-supervised multi-task learning assigns a single-modal training task with self-generated labels to each modality, aiming to learn the consistency between modalities and the specificity within each modality.

CubeMLP [24]: By mixing relevant modality features on three axes using three independent MLP units and flattening the mixed multimodal features for task prediction.

TETFN[4]: By utilizing visual features extracted by the Vision Transformer, combined with audio features, learning text-oriented cross-modal mappings in pairs, in order to obtain efficient multimodal representations for emotion prediction.

D. Results

1) *Comparison experiment with the baseline model*: Tables I and II provide the experimental results of various models on the CMU-MOSI and CMU-MOSEI datasets. For Acc-2 and F1 values, there are two sets of evaluation results: on the left, positive and neutral sentiment samples are considered positive examples, and negative samples are considered negative examples to calculate accuracy. On the right, positive sentiment samples are considered positive examples, and negative samples are considered negative examples to calculate accuracy. Similarly, F1 values are calculated accordingly to obtain the corresponding F1 scores.

It can be seen that the proposed TGMoE model achieved the best performance on both datasets. On the CMU-MOSEI dataset, the Acc-2 and F1 scores were improved by 1.11%/0.33% and 1.4%/0.59%, respectively compared to previous methods. On the CMU-MOSI dataset, Acc-7, Acc-2 (left), and F1 scores (left) were improved by 0.1%, 1.32%, and 1.4% compared to previous methods. This indicates that the TGMoE model can adequately integrate different modalities of sentimental information, enhance non-textual modality

sentimental information to contribute more to textual modality sentiment representation in sentiment analysis, and effectively balance the semantic gap between different modalities.

2) *Ablation studies*: In the field of sentiment analysis, compared to audio and visual modalities, the text modality contains more sentimental semantic information. Therefore, the model proposed in this paper is text-centric, where the sentimental information from audio and visual modalities is extensively extracted and integrated into the text modality. Subsequently, a sparsely gated MoE network is utilized to select different expert combinations to analyze and process the sentimental information.

To validate the rationality of the proposed fusion approach, we further explored the impact of different modalities and sparsely gate MoE on sentiment analysis results of the CMU-MOSEI dataset. Experimental results are shown in Tables III and IV, where T, V, and A, respectively represent text, visual, and audio modalities. TGMoE-NoMoE indicates the TGMoE model without the hybrid expert module, where the extracted multimodal features are directly connected to a fully connected layer for sentiment prediction. This leads to the model being unable to learn sufficient nonlinear representations from multimodal features. TGMoE-FFN represents the TGMoE model replacing the hybrid expert module with an FFN layer, where the multimodal features output by the text guided cross-modal feature fusion module are input into the FFN layer to strengthen the multimodal features. This results in the model only being able to learn limited sentimental information, directly impacting the accuracy of sentiment analysis results.

TABLE IV. EXPERIMENTAL RESULT OF THE EFFECTIVENESS EXPERIMENT OF MOE MODULE ON THE CMU-MOSEI DATASET

Num	Model	MAE	Corr	Acc-7	Acc-2	F1
1	TGMoE-NoMoE	0.587	0.714	50.88	81.28/83.73	82.13/83.65
2	TGMoE-FFN	0.564	0.729	52.09	83.62/84.36	83.65/84.58
3	TGMoE	0.535	0.757	53.70	85.36/85.51	85.58/85.86

E. Discussion

From the perspective of the number of modalities, information from each modality can complement each other, and the addition of more modal information will lead to better sentiment analysis results. For the single modality baseline, the performance of the text modality is superior to the audio and visual modalities, indicating that the text modality contributes more to multimodal sentiment analysis than the audio and visual modalities. In real life, people also prefer to use language to express their direct sentiments.

From the perspective of model modules, when the MoE module is removed, all metrics of the model are lower compared to the complete model. Substituting the MoE module with an FFN (Feedforward Neural Network) layer leads to an improvement in model performance compared to TGMoE-NoMoE, indicating that FFN can strengthen the sentimental information in multimodal features, but with limited performance. The complete TGMoE model outperforms all metrics. Experimental results suggest that MoE plays a crucial role in multimodal fusion, and removing or simply replacing MoE results in the model's inability to learn sufficient nonlinear representations from multimodal features, thereby failing to guarantee that the final fused features contain abstract sentimental information, consequently affecting sentiment prediction performance.

In conclusion, the experiments above validate the efficacy of the text guided mixture of experts model TGMoE. This model adeptly harnesses sentimental data across various modalities, facilitating efficient fusion, mitigating the impact of sentimental information discrepancies across modalities on the final sentiment, and bolstering the efficacy of multimodal sentiment analysis.

V. CONCLUSION

To address the issue that the obtained multimodal fusion representation may be defective in capturing sentimental information due to ignoring the different contributions of various modalities to sentiment analysis, this paper proposes a

text guided mixture-of-experts model TGMoE for multimodal sentiment analysis. The TGMoE model is structured around three key modules. Firstly, features are extracted for each of the three modalities respectively to capture the inherent consistency within each modality. Secondly, a text guided cross-modal fusion mechanism is proposed: cross-modal attention mechanisms are used for text-visual and text-audio modalities, respectively, to capture the interactive information of visual and audio modalities with the text modality, supplementing the text modality with the sentimental information from the visual and audio modalities. Finally, a sparsely gated mixture of expert networks is employed to fortify the nonlinear representational capacity within multimodal features, engender more abstract fusion features, and elevate the precision of sentiment polarity classification. Comparative evaluations against existing multimodal sentiment analysis frameworks demonstrate a pronounced performance boost, underscoring the efficacy of the proposed text guided cross-modal interactive approach and the utility of employing mixture of expert networks for sentiment analysis enhancement.

In real-world scenarios of multimodal sentiment analysis, users may not provide information from all modalities simultaneously. For example, they might only provide text while missing audio or visual data. Therefore, our future research will focus on effectively handling cases of missing modalities, developing more robust sentiment analysis models, and enhancing the practical application value and user experience of these models.

Abstract—An object hierarchy in images refers to the structured relationship between objects, where parent objects have one or more child objects. This hierarchical structure is useful in various computer vision applications, such as detecting motorcycle riders without helmets or identifying individuals carrying illegal items in restricted areas. However, extracting object hierarchies from images is challenging without advanced techniques like machine learning or deep learning. In this paper, a simple and efficient method is proposed for extracting object hierarchies in images based on object detection results. This method is implemented in a standalone package compatible with both Python and C++ programming languages. The package generates object hierarchies from detection results by using bounding box overlap to identify parent-child relationships. Experimental results show that the proposed method accurately extracts object hierarchies from images, providing a practical tool to enhance object detection capabilities. The source code for this approach is available at <https://github.com/saravit-soeng/HiExtract>.

Keywords—Object hierarchy; object relationship; object detection; computer vision

I. INTRODUCTION

Computer vision, particularly object detection and hierarchy extraction in digital images, plays a crucial role in enabling computers to perceive and understand digital images similarly to humans. These technologies facilitate a range of tasks, such as image classification, object detection, and instance segmentation, by allowing the classification of images, identification of objects within images, and segmentation of objects from images [1], [2]. These tasks have been successfully accomplished using advanced deep learning techniques, notably Convolutional Neural Networks (CNNs). By leveraging big data and powerful computational resources, CNNs have significantly enhanced prediction performance and accuracy [3], elevating the field of computer vision. In the current digital era, computer vision tasks have uncovered applications across a broad spectrum of research areas [2], [4].

Object detection is a computer vision task that deals with identifying instances of objects such as humans, cars, motorcycles, or animals in digital images [5], [6], [7]. The results of object detection can be applied in various contexts and fields, including facial recognition, medical image analysis, surveillance systems, robotics, and autonomous driving. Consequently, object detection is one of the most ubiquitous

tasks in these diverse applications [6], [7], emphasizing its critical importance in real-world scenarios.

However, obtaining an object hierarchy from images or videos is a challenging task without the assistance of advanced techniques like machine learning or deep learning. Existing object detection methods primarily focus on identifying individual objects within an image and do not establish hierarchical relationships. For example, algorithms such as YOLO (You Only Look Once), SSD (Single Shot MultiBox Detector), Fast R-CNN, and Faster R-CNN offer state-of-the-art approaches for identifying various objects in digital images or videos but do not provide a hierarchical structure that elucidates relationships between objects. This gap in existing methodologies highlights the need for a novel approach to extract hierarchical relationships among detected objects.

This study aims to extract object hierarchies by leveraging the unique combination of object detection results and hierarchical structuring techniques. The task of object hierarchy extraction focuses on establishing parent-child relationships between identified objects within digital images. To construct the object hierarchy, a simple method based on the criteria of overlapping bounding boxes obtained from object detection results is employed. Objects with overlapping bounding boxes are considered to have a parent-child relationship. Thus, object detection serves as a fundamental component of the proposed approach. The study implements the proposed approach as a standalone package compatible with both Python and C++ programming languages, facilitating easy integration into various applications.

This research significantly contributes to the field of computer vision by providing a novel and efficient method for extracting object hierarchies using object detection results. The approach is practical due to its implementation as a standalone package compatible with Python and C++. The versatility of this approach allows it to be integrated into a wide range of applications. The significance of this research lies in its potential to offer new possibilities for understanding and processing digital images in a more structured and relational manner. This work not only extends object detection technology but also opens up possibilities for more complex and nuanced computer vision tasks, marking an important advancement in the field of computer vision.

This paper is organized as follows: Section II reviews related work in object detection and visual relationship extraction. Section III details our proposed method for hierarchical structuring of detected objects. Section IV presents

experimental results demonstrating the effectiveness of our approach across various scenarios. Section V explores practical applications and use cases for the extracted object hierarchies. Section VI provides insights, discusses limitations, and offers future research directions. Finally, Section VII concludes the paper.

II. RELATED WORK

Object detection and visual relationship extraction have been active areas of research in computer vision. This section provides an overview of recent advancements in these fields and identifies the gap that our research aims to address.

A. Object Detection

Recent years have seen significant progress in object detection algorithms, with several state-of-the-art methods emerging:

1) *YOLO (You Only Look Once)*: Introduced by Redmon et al. [8], YOLO revolutionized object detection by treating it as a regression problem, enabling real-time detection with high accuracy.

2) *SSD (Single Shot MultiBox Detector)*: Liu et al. [9] proposed SSD, which improved upon YOLO by using multi-scale feature maps for detection, enhancing accuracy for objects of various sizes.

3) *Fast R-CNN and Faster R-CNN*: Girshick [10] and Ren et al. [11] developed these region-based convolutional network methods, which significantly improved detection speed and accuracy.

While these algorithms excel at identifying individual objects, they do not establish hierarchical relationships between detected objects, which is the focus of our research.

B. Visual Relationship Detection

To bridge this gap, several novel frameworks have been proposed to detect visual relationships between objects. Dai et al. [12] introduced a deep relational network that leverages statistical dependencies between objects to detect visual relationships, demonstrating superior performance on two large datasets compared to other state-of-the-art methods. Kolesnikov et al. [13] proposed a model utilizing a Box Attention mechanism to detect visual relationships such as "person riding motorcycle" or "bottle on table," enabling the modeling of pairwise interactions between objects using standard object detection pipelines.

Lu et al. [14] incorporated language priors from semantic word embedding to guide model predictions, training separate models for objects and predicates independently before combining them to predict multiple relationships per image. Zhu et al. [15] introduced deep structured learning for visual relationship detection, employing both feature-level and label-level predictions to learn relationships, thereby capturing dependencies between objects and predicates and enhancing the understanding of visual relationships.

Additional research [16], [17], [18], [19], [20], has contributed various approaches for extracting visual relationships

between objects in digital images and videos, achieving notable results. These studies typically formulate visual relationships as <subject-predicate-object> structures.

C. Research Gap and Our Contribution

While existing research has made significant strides in object detection and visual relationship extraction, there remains a gap in efficiently extracting hierarchical relationships among objects in images. Most current methods focus on identifying individual objects or pairwise relationships, but do not provide a comprehensive hierarchical structure.

Our research addresses this gap by proposing a simple yet effective method for extracting object hierarchies from images based on object detection results. Unlike previous work that focuses on complex visual relationships, our approach simplifies the task by establishing a parent-child hierarchy among objects. This method provides a novel perspective on object detection and structuring in computer vision, with potential applications in scene understanding, image captioning, and visual question answering.

By leveraging the output of existing object detection algorithms and introducing a hierarchical structuring technique, our approach offers a practical solution that can be easily integrated into various computer vision applications. This research thus bridges the gap between individual object detection and complex visual relationship extraction, providing a middle ground that captures essential object hierarchies in a computationally efficient manner.

III. HIERARCHICAL STRUCTURING METHOD OF DETECTED OBJECTS

The proposed research provides a novel method for efficiently creating a hierarchy of detected objects in a digital image. This method simplifies the process of understanding object relationships and interactions, improving accuracy and reducing computational resources. It utilizes a unique combination of object detection algorithms and a hierarchical structuring technique that distinguishes it from existing methods. The proposed method leverages the output of an object detection algorithm, which identifies and locates objects within an image. The object detection results provide bounding boxes and confidence scores for each detected object. These bounding boxes represent the spatial locations of the objects, while the confidence scores indicate the likelihood that the detected objects are actually present in the scene [8].

The proposed method for extracting object hierarchies from object detection results has been implemented as a versatile, cross-platform package, facilitating seamless integration into diverse applications across multiple domains. The package is available for both Python and C++ programming languages, ensuring wide accessibility and compatibility with the preferred development environments of a vast range of developers. To leverage the capabilities of this package, users simply need to provide the object detection results as input, typically comprising predicted object classes and their corresponding bounding box coordinates. The package then processes this input data, employing sophisticated algorithms to analyze the spatial relationships between the detected objects and construct

29: end function

```

a hierarchical representation of the scene. The object hierarchy extraction process is illustrated in Fig. 1.

The given pseudo-code in Algorithm 1 describes a function called `extract_object_hierarchy` that takes two inputs: `base_objects` and `result`. The core algorithm accepts only two primary inputs:

1) *Base_objects*: This parameter specifies the parent objects from which we aim to extract the hierarchy. It allows flexibility in defining the root nodes of our hierarchical structure.

2) *Result*: This parameter encompasses the complete object detection results, typically including bounding box coordinates and class predictions for all detected objects in the image.

The purpose of this function is to analyze the output of an object detection algorithm and organize the detected objects into a hierarchical structure based on their spatial relationships (overlapping) and their predicted classes.

Initially, the package combines the predicted object classes and their associated bounding boxes into a unified data structure. The package then iterates over each detected object, referred to as the "base object," retrieving its corresponding class index from the original set of classes. If the detection results contain overlapping objects, the package performs an additional loop to identify objects whose class indices match that of the current base object. For each matching object, the package creates a new list to store objects that spatially overlap with the base object. It iterates over the detection results once more, comparing the bounding boxes of the objects against the base object's bounding box. If an overlap is detected, the current object is appended to the 'children' list.

Upon completing the overlap detection process, if the 'children' list is not empty, a new "parent object" is constructed, encapsulating the base object and its associated children objects. This parent object is then added to the 'result_list', effectively building the hierarchical structure.

After processing all base objects and their corresponding overlapping objects, the package consolidates the 'result_list' data into a final results object, which is then returned to the user. This results object represents the complete hierarchical structure of the detected objects, enabling users to seamlessly integrate and leverage this information within their applications.

IV. EXPERIMENTAL RESULTS

The experiments were conducted on various images in different scenarios to evaluate the proposed approach's effectiveness in extracting object hierarchies. The proposed method demonstrated impressive performance in extracting object hierarchies from images. However, the accuracy of the object hierarchy extraction process heavily relies on the object detection results.

The first experiment involved an image of a person holding a cell phone and a cup. Based on the proposed method, the person was defined as the single base or parent object, while the cell phone and cup were detected as child objects. This experiment utilized the YOLOv8s [21] model for object detection from images, as illustrated in Fig. 2.

Fig. 2. An experimental result on single base object.

Another experiment was conducted on an image containing multiple common base objects. In this case, a custom YOLOv5 model was employed to detect objects from the image. The custom model identified three distinct objects: rider, helmet, and non-helmet. The rider was defined as the base object, and through the extraction process, multiple parent-child relationships were established between the rider object and the helmet or non-helmet objects. Fig. 3 illustrates the results obtained in this experiment.

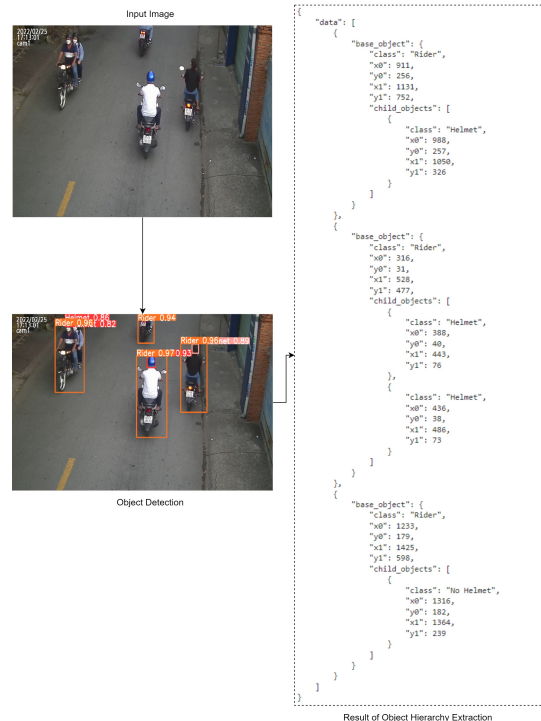

Fig. 3. An experimental result on multiple common base objects.

In addition to defining a common base object, the proposed approach was tested on multiple base objects. Fig. 4 shows the results obtained from an image featuring a person, a dog, and a tennis ball. In this test, both the person and the dog were defined as base objects.

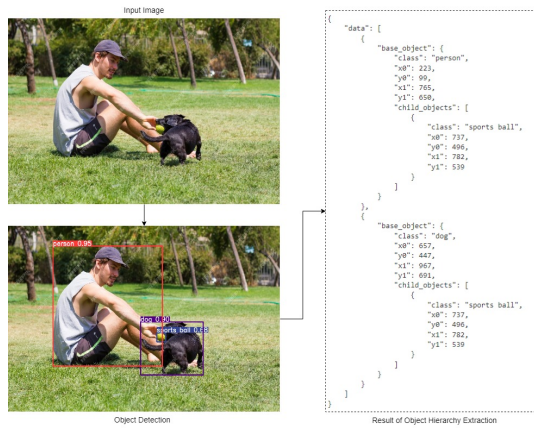

Fig. 4. An experimental result on different base objects.

The proposed approach demonstrated its versatility by handling various object hierarchies, ranging from a single base object to multiple base objects coexisting within an image. However, it is crucial to acknowledge that the accuracy of the extracted object hierarchy heavily depends on the performance of the underlying object detection model. Improvements in object detection algorithms could further enhance the accuracy and robustness of the proposed object hierarchy extraction method.

V. APPLICATION USE CASES

The extracted object hierarchy results can be leveraged in a variety of research and practical applications. In this research, we explored two distinct use cases to demonstrate the utility of the proposed object hierarchy extraction method.

The first use case involved the detection of motorcycle riders without helmets, a critical safety concern. We employed a custom YOLOv5-based model to detect three distinct objects: rider, helmet, and non-helmet. Leveraging the proposed method, a standalone package was developed to generate object hierarchy results from the object detection outputs. These object hierarchy results enabled the identification of illegal actions by motorcycle riders, specifically those not wearing helmets. Fig. 5 illustrates an example of detecting motorcycle riders without helmets using the generated object hierarchy results.

In this application, the object hierarchy played a crucial role in distinguishing between riders wearing helmets and those without helmets. By establishing the parent-child relationships between the rider object and the helmet or non-helmet objects, the system could effectively identify instances where a rider was associated with a non-helmet object, indicating a potential safety violation.

The second use case explored the application of object hierarchy results in a different domain or scenario, leveraging the versatility of the proposed approach. In this use case, the object hierarchy results enable the determination of whether specific items belong to a particular person within a defined area. By establishing the parent-child relationships between the person object and the item objects (e.g., handbag, backpack, or any other prohibited item), the system can effectively identify

instances where an individual is carrying a restricted item into a prohibited area.

Fig. 6 demonstrates an example of detecting a person carrying a handbag into a banned area based on the proposed method. The object hierarchy results allow the system to associate the handbag object with the person object, indicating that the individual is in possession of the item while entering the restricted area.

The versatility of the proposed object hierarchy extraction method allows for its application in diverse domains, showcasing its potential for enhancing situational awareness, decision-making processes, and automated analysis of complex visual data.

VI. DISCUSSION

The proposed method for extracting object hierarchies from images based on object detection results offers a novel approach to understanding spatial relationships between objects. This section discusses the implications of our findings, limitations of the current study, and potential directions for future research.

A. Implications of the Findings

Our approach demonstrates the feasibility of extracting meaningful hierarchical relationships between objects in images using a straightforward method based on bounding box overlap. This finding carries several important implications:

1) *Simplified scene understanding*: By organizing detected objects into a hierarchical structure, our method provides a more intuitive representation of the scene, potentially simplifying downstream tasks such as image captioning or visual question answering.

2) *Computational efficiency*: Compared to more complex visual relationship detection methods, our approach is computationally efficient, making it suitable for real-time applications.

3) *Versatility*: As demonstrated in our use cases, the extracted hierarchies can be applied to various domains, from traffic safety to security applications.

B. Limitations of the Study

While our method demonstrates potential, it is important to acknowledge its limitations:

1) *Dependence on object detection accuracy*: The quality of the extracted hierarchy is heavily dependent on the accuracy of the underlying object detection algorithm. Errors in object detection can propagate to the hierarchy extraction process.

2) *Simplistic relationship model*: Our method primarily relies on spatial overlap to determine relationships, which may not capture more complex or abstract relationships between objects.

3) *Lack of semantic understanding*: The method does not incorporate semantic knowledge about object classes, which could potentially improve the accuracy of the extracted hierarchies.

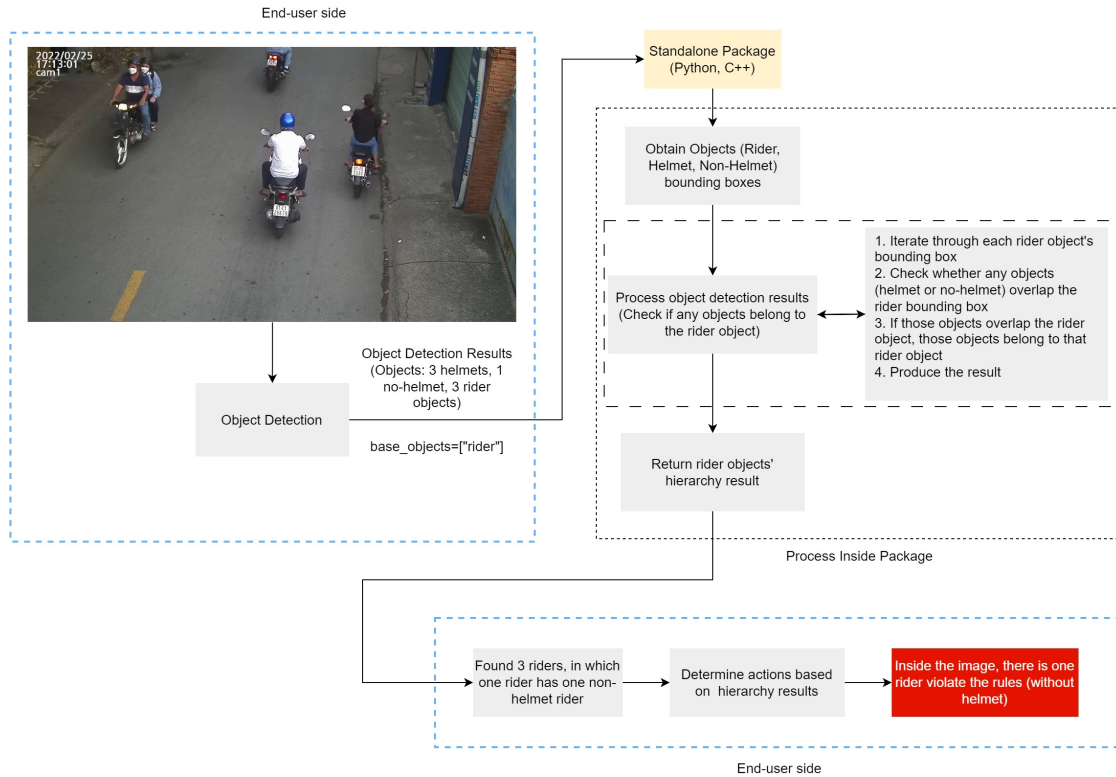

Fig. 5. An example of detecting motorcycle riders without wearing helmets using the object hierarchy results.

Fig. 6. An example of detecting a person carrying a handbag into a banned area based on the proposed method.

C. Future Research Directions

Based on the findings and limitations of this study, several avenues for future research emerge:

1) *Integration with semantic knowledge:* Incorporating class-specific semantic information could enhance the accuracy of the hierarchy extraction process.

2) *Temporal hierarchies:* Extending the approach to video data to capture temporal relationships between objects over time.

3) *Machine learning enhancement:* Developing a machine learning model to predict hierarchical relationships based on both spatial and semantic features could improve the method's accuracy and robustness.

4) *Expanding object detection compatibility:* Future versions of the standalone package should support a wider range of object detection algorithms beyond YOLO.

While our proposed method offers a simple and efficient approach to extracting object hierarchies, there is significant potential for further refinement and expansion of this technique. Future research should focus on addressing the current limitations and exploring more sophisticated approaches to understanding object relationships in visual data.

VII. CONCLUSION

In conclusion, this research has significantly contributed to the field of computer vision by introducing a novel approach for extracting object hierarchies from digital images. Utilizing the results of object detection, the proposed research presents a unique method that identifies parent-child relationships between objects based on overlapping bounding boxes criteria. This approach is also practical, as it has been implemented as a standalone package compatible with both Python and C++ programming languages. The versatility of this approach allows it to be integrated into a wide range of applications. The implications of this research are solid, offering new possibilities for understanding and processing digital images in a more structured and relational manner. This work not only expands object detection techniques but also opens up possibilities for more complex and subtle computer vision tasks, marking a significant step forward in the field. Based on the experiments, the results have demonstrated the effectiveness of the proposed approach in extracting the object hierarchy from the images. However, in terms of standalone package implementation, object detection is limited to the YOLO algorithms. In the next release version, we intend to expand to other object detection algorithms and improve the approach to work on more complexities of hierarchy extraction.

Abstract—The integration of Multi-access Edge Computing (MEC) and Dense Small Cell (DSC) infrastructures within 5G and beyond networks marks a substantial leap forward in communication technologies. This convergence is critical for meeting the stringent low latency demands of services delivered to Smart Devices (SDs) through lightweight containers. This paper introduces a novel split-duplicate-cache technique seamlessly embedded within a secure blockchain-based edge-cloud architecture. Our primary objective is to significantly shorten the service initiation durations in high density conditions of SDs and ENs. This is executed by meticulously gathering, verifying, and combining the most optimal chunk candidates. Concurrently, we ensure that resource allocation for services within targeted ENs is meticulously evaluated for every service request. The system challenges and decisions are modeled then represented as a mixed-integer nonlinear optimization problem. To tackle this intricate problem, three solutions are developed and evaluated: the Brute-Force Search Algorithm (BFS-CDCA) for small-scale environments, the Simulated Annealing-Based Heuristic (SA-CDCA) and the Markov Approximation-Based Solution (MA-CDCA) for complex, high-dimensional environments. A comparative analysis of these methods is conducted in terms of solution quality, computational efficiency, and scalability to assess their performance and identify the most suitable approach for different problem instances.

Keywords—Multi-access Edge-cloud Computing; container base image chunks; replication; fragmentation; service provision; blockchain; Markov approximation

I. INTRODUCTION

A. Preliminary

Multi-access Edge Computing (MEC) [1], [2] represents a distributed computing framework, fostering a distributed computing environment at the network edge. By meticulously placing computational resources at access points, edge routers, gateways, base stations or dedicated edge servers, MEC enables the efficient deployment of high-speed, real-time systems and solutions for end-users or Smart Devices (SDs). This approach is optimized for latency-critical, high-capacity data processing, making it ideal for emerging mobile apps and IoT devices.

MEC presents a transformative range of applications, notably within the Internet of Things (IoT) domain, alongside augmented and virtual reality, autonomous vehicles, and smart factories [3]. It empowers localized data processing and analysis, reducing reliance on centralized cloud data centers and effectively addressing latency and bandwidth challenges.

Moreover, MEC architectures seamlessly integrate with a wide spectrum of wireless technologies, including next-generation cellular networks, legacy cellular and wireless local area networks. This integration ensures that MEC solutions are versatile and adaptable across different network environments, whether public or private.

Dense Small Cell (DSC) networks, characterized by a high density of small cell base stations within a limited geographic area, have emerged as a critical component of modern cellular architectures. These networks are designed to deliver high-capacity, high-speed connectivity to users. However, the surge in user demands necessitates rapid service provisioning and virtualization [4] to maintain seamless and superior user experiences. Virtualization offers substantial benefits, including enhanced service delivery, scalability, simplified management, and improved performance. This is especially advantageous in the constrained physical environments and dynamic traffic patterns of Dense Small Cell (DSC) networks. By optimizing resource utilization and enabling on-demand provisioning, virtualization helps DSC networks effectively meet the growing demands of users [5]. In addition, containerized applications enable service virtualization, which provides a more sophisticated method for effective service deployment and management in resource-constrained environments. Containerization enables to create lightweight, self-contained service instances that improve operational flexibility and streamline management procedures. This method not only makes resource allocation easier but also supports advanced interference mitigation techniques like network slicing, which guarantee optimal performance and scalability in dynamic network conditions. Nevertheless, Delivering swift service provisioning in DSC environments necessitates a combination of high-speed network connectivity for rapid data transfer, advanced service orchestration to optimize network performance, and low-latency data processing to support real-time applications. These essential components work together to ensure timely and reliable service accessibility for end-users.

Furthermore, by integrating blockchain technology with caching mechanisms [6], [7], [8], containers data can be fragmented and dispersed within multiple ENs. This distribution not only enhances data availability but also reinforces data integrity through distributed verification. Thus, initiating container-based MEC services using splitting/duplicating/caching entails distributing container image fragments across multiple secure nodes using the blockchain technology [9]. Subsequent verification, orchestration, and

service delivery to the user ensure privacy, confidentiality, reliability, and fault tolerance. This decentralized fragmentation approach also alleviates network congestion and improves performance by caching and replicating frequently requested service data.

B. Motivation

This paper aims to optimize service delivery by minimizing container-based service data collection time, bandwidth consumption, and network hops between the user and the target Edge Node (EN). The service data comprises base image chunks of service containers, which require optimal caching, replication, and transfer to the designated target EN. To address this, we formulate an optimization problem considering chunks transfer paths and the availability of diverse resources at each Edge Node. Three solution approaches are proposed: a brute-force search algorithm (BFS-CDCA) for small-scale environments, a simulated annealing-based heuristic (SA-CDCA), and a Markov approximation-based solution for larger, more complex scenarios.

C. Contributions

The distinctive features of this paper can be enumerated as follows:

- A method based on reputation and blockchain for secure service provision, emphasizing the strategic optimized collection of containers' base image from multiple edge nodes, was introduced within a multi-user MEC network.
- An adaptive approach for Containers' Base Image Chunks (CBIC) collection is proposed, ensuring efficient service provision by strategically considering CBIC with the possibility of duplication across Edge Nodes (ENs). The focus is placed on security and efficiency within a dense small cell network environment.
- An optimization problem was formulated to minimize a derived cost function, considering constraints imposed by network bandwidth, cached chunk availability, and strict service initiation deadlines. Notably, the availability of critical resources was enhanced through the implementation of service penalization based on priority.
- Given the NP-hard nature of the formulated optimization problem, a time-efficient heuristic scheme was proposed, incorporating a simulated annealing-based algorithm and a Markov approximation-based solution, with a thorough evaluation of their respective performances.

D. Paper Organization

The remaining sections of this paper are detailed following the structure : Section II presents relevant works related to the study. Section III elaborates on the framework under examination. Section V outlines the formulation of the optimization problem. Following that, Section VII provides an overview of resolution methods, and Section VIII offers an overview of the main evaluation results. Finally, Section IX serves as the conclusion, offering insights into future directions.

II. RELATED WORKS

Recent studies, such as [10], have shown a rising interest in using edge computing for the Internet of Things (IoT). Many, like the authors in [11], have investigated how it can enhance performance, primarily by optimizing resources. The authors of [10] focused on reducing costs related to task completion, and employed specialized techniques to lower energy use during tasks. Meanwhile, in [11], wireless charging and task offloading were combined to save energy. Liu et al. developed a new strategy for data storage in edge computing, aiming to boost service providers' profits [12]. Yet, studies such as [13], [14] took a broader view, improving system performance through task offloading and data storage techniques. However, these studies highlight the limitations of individual Edge Nodes (EN) in providing services.

Addressing these shortcomings, the authors of [15]-[16] advocated for EN collaboration to enhance resource utilization and equitably distribute workloads. Specifically, [15] and [17] centered on diminishing task completion durations. While [15] explored collaborative methodologies, [17] added resource allocation to its examination. Feng et al. in [18] concentrated on minimizing user delays and conserving energy. On a different note, [16] embarked on ascertaining the optimal count of collaborating ENs. However, a shared assumption across these studies is that providers freely extend their services, leading to potential reservations about their spontaneous participation absent of incentives.

The subsequent works have primarily centered on enhancing data caching and data sharing by mobile devices. In this context, a plethora of contemporary studies have delved into issues related to edge caching for content sharing. For example, Huang et al. [19] tackled the specific issue of ensuring fairness in data sharing for caching within MEC environments. In a related vein, Asheralieva et al. [20] probed the data caching dilemma using D2D-based method, allowing users to transparently reveal their content sharing costs, diminish average network expenses, and stabilize the queuing framework. Yin et al. [21] put forth a hierarchical strategy for data sharing applications within the same environments, focusing on the challenge of efficient sharing management in MEC networks to enhance user device mobility and heterogeneity.

Progressing further, the authors of [22], [23] amalgamated machine learning methodologies with secure computing techniques to redress the limitations observed in antecedent models. Specifically, in [22], devices were harnessed to execute federated calculations, with an accent on fine-tuning task offloading choices. Concurrently, Cui et al., in their study [23], synergistically integrated secure data storage mechanisms with a blockchain framework, solidifying data integrity. Notwithstanding these innovative strides, it's worth noting that conventional mathematical approaches might grapple when faced with intricate network configurations. To elevate system performance to its zenith, striking a harmonious equilibrium between competitive and collaborative paradigms is paramount. In recent work by [24], a model was proposed concentrating on a singular container-based service. However, this study overlooked the significance of considering the blockchain block size as a crucial parameter, limiting its scope. In contrast, our investigation delves into the integration of multiple container-based services, addressing their specificities

and intricacies. Additionally, we explore the impact of the blockchain operational delay as a critical parameter, considering its implications on the overall system dynamics and performance.

III. THE MULTI-TIER FRAMEWORK UNDER STUDY

In this section, the foundational framework upon which our study is built is outlined. A comprehensive overview of the framework's architecture, components, and key methodologies is provided. The framework aims to provide Container-based Services (CSs) to smart devices (SDs) by offering Container Base Image (CBI) caching with intelligent fragmentation and duplication. It employs a blockchain network to secure the exchange of the resulting Container Base Image Chunks (CBICs) among the ENs constituting a DSC network situated within a two-dimensional geographical area.

Afterwards, the main components of the proposed framework, as illustrated in Fig. 1, are presented in this section.

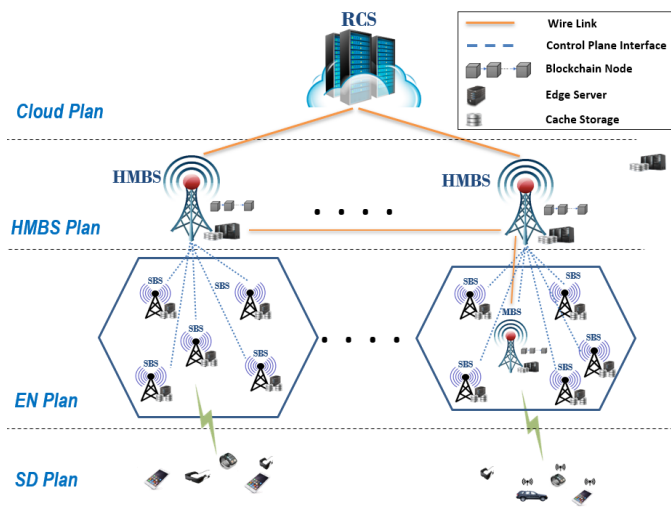

Fig. 1. Overview of the framework's main components.

A. Cloud Server and Edge Nodes

The framework handles a Remote Cloud Server (RCS) and several Small/Macro Base Stations. The RCS is expected to have extensive resources, including virtually unlimited capacities for disk storage, memory, CPU, GPU, etc. The base stations, acting as Edge Nodes (EN), provide wireless network access for smart devices (SDs) within their coverage areas. Additionally, interconnections between ENs are established through wired connections, utilizing high-bandwidth Ethernet cables or fiber-optic connections. Furthermore, each EN supports many users/subscribers and is provisioned with a dedicated edge server that has finite resources, thereby enhancing their capacity to perform localized data processing and service provisioning.

The set of all ENs is organized into multiple regions, each orchestrated by a designated Head Macro Base Station (HMBS) serving as the region head. The clustering of ENs into distinct regions, overseen by HMBSs, enables streamlined network operation and facilitates the delivery of services to end-users, resulting in improved reliability and performance.

Additionally, HMBSs take on the role of caching nodes, overseeing image and transaction management to ensure the reliability and security of CBICs while disseminating them across the network. They orchestrate the geographical distribution of published containers' CBICs and handle service initiation requests by refining collection procedures to reduce service initiation time.

B. Container-based Service and Reputation

Each EN can provide only a limited set of independent CSs, due to limited capacities, where each running service uses a container instance and serves one SD only. Advancing further, the base image of the i -th CS, is partitioned into multiple chunks according to the specified chunk size, and subsequently, each CBIC is replicated D_i times.

Furthermore, a reputation management model is integrated, playing a crucial role in fostering trust among entities and enabling secure and informed caching decisions. This model dynamically allocates a reputation score to each CS i within each region r based on its historical usage and interactions. This reputation reflects the size of the demand for the service within that specific region. As a result, the degree of duplication of a CS within a region is closely tied to its reputation. Essentially, the more reputable a CS is perceived to be, the higher the likelihood of it being duplicated within that region. This approach is driven by the principle that services with a stronger reputation are in higher demand and therefore benefit from having more duplicates available to meet user requests promptly and efficiently.

Practically, the reputation scores are computed based on all pertinent trust information and feedback provided by the network entities. These scores serve to establish trust relationships among caching entities, including service providers and edge nodes.

C. Blockchain Network

The blockchain network operations in the proposed secure caching framework comprises the following four phases:

1) *System initialization*: During this phase, the Trusted Authority (TA) executes a Setup procedure to compute public parameters. TA generates cyclic groups with a prime order, selects random exponents and hash functions, computes essential parameters to release the public parameters to all involved entities of the blockchain network.

2) *Entity registration*: Upon joining the blockchain network, both the Service Provider (SP) and the ENs undergo a registration phase, during which the Trusted Authority (TA) authenticates their identities. TA executes a key generation procedure to generate random values and computes secret keys for encryption, signing, and verification. TA assigns the signing key to SP and the decryption key to edge nodes (EN) through a secure communications channel.

3) *Block creation and validation*: Registered SPs encrypt message chunks with a randomly generated symmetric secret key and define access structures to control access to encrypted messages by target edge nodes (ENs). SPs then signcrypt the secret key under the access structure and send the resulting ciphertext to the blockchain network for validation. This record

includes the SP's public key, pseudo identity, block hash, and signcrypted ciphertext along with the SP's signature. All registered SPs are considered authority candidates for validation. A genesis block is created at the initiation of the permissioned chain, and time intervals are allocated for affixing single blocks to the chain. In the case of multiple authorities, one leader per interval collects and validates records before passing them to other candidate authorities. Validated records are included in new blocks along with blockheaders containing relevant metadata.

4) *Chunks distribution*: Upon receiving a new block, the network may opt to forward the blockchain header to the edge nodes (ENs), allowing them to decide whether to request the signed ciphertext (ST) and signature (π) from specific blocks via a pull request. Upon receiving ST and π from the blockchain, ENs decrypt to recover the symmetric key (keysym), then decrypt the chunk message and verify its integrity and signature. After obtaining keysym, ENs use it to decrypt the message and calculate verification parameters, comparing them to π to confirm that the message has not been altered.

IV. SYSTEM MODEL

This section offers a comprehensive overview of the modelization of the primary components essential to our study. Here, to simplify our notation, we will assign the variables i, j, k, n, p, r and m to refer container-based services, chunks, chunks' duplicates, edge nodes, paths, regions and resources, respectively.

A. Nodes and Resources

The CSs are denoted by the set $\mathcal{S} = \{S_1, S_2, \dots, S_i, \dots, S_{\sigma_s}\}$, distributed among the Edge Nodes (ENs) represented by the set $\mathcal{N} = \{N_1, N_2, \dots, N_n, \dots, N_{\sigma_n}\}$. Each EN is equipped with an edge server which in turn offers a diverse array of resources across multiple categories, encompassing CPU, GPU, TPU, FPGA, memory, storage, network bandwidth, etc. Here, the set of possible σ_z resources is denoted $\mathcal{Z} = \{r_1, r_2, \dots, r_{\sigma_z}\}$. Accordingly, every node n is characterized by its capacity set in terms of resources which we denote $\mathcal{Z}_n^{cap} = \{Z_{n,1}^c, Z_{n,2}^c, \dots, Z_{n,\sigma_z}^c\}$. Here, $Z_{n,m}^c$ denotes the maximum quantity of resource r_m that node n can provide. Furthermore, its current resource utilization is represented by: $\mathcal{Z}_n^{use} = \{Z_{n,1}^u, Z_{n,2}^u, \dots, Z_{n,\sigma_z}^u\}$, where $Z_{n,m}^u$ indicates the amount of resource r_m utilized in node n .

B. Container-based Service and Chunks

For convenience, we will interchangeably use the term Container-based Service (CS) or its user, and denote CS S_i as i . Then, to summarize the operational parameters related to CS i , we use the notation Ω_i , defined as:
 $\Omega_i \triangleq \langle R_i, \pi_i, \pi_i^{min}, \pi_i^{max}, \rho_i, N_i^t, \mathcal{M}_i, B_i^{ser}, \mathcal{Z}_i^{dem}, D_i, t_i^{trans}, A_i \rangle$.
 As shown in Table I, the operational parameters for CS i encompass essential details regarding its initiation and execution.

TABLE I. SUMMARY OF OPERATIONAL PARAMETERS FOR CS i

Parameter	Description
Ω_i	The operating parameters of CS i
R_i	Region receiving the service initiation request for CS i .
C_i	The set of chunks related to CS i with the size σ_i
D_i	Number of duplicates of the CS i .
A_i	Total data amount of CS i .
π_i	Priority score of CS i .
π_i^{min}, π_i^{max}	Priority score bounds of CS i .
ρ_i	Reputation score of CS i .
N_i^t	EN receiving the service initiation request for CS i .
\mathcal{M}_i	Localization matrix of all available duplicates of chunks associated with CS i .
B_i^{ser}	Minimum permissible data rate for the available bandwidth between the node hosting CS i and N_i^t .
\mathcal{Z}_i^{dem}	Resource demand of CS i , quantified by the number of standardized virtual resource units.
t_i^{trans}	Maximum permissible deployment delay for CS i .

Specifically, $\mathcal{Z}_i^{dem} = \{Z_{i,1}^d, Z_{i,2}^d, \dots, Z_{i,\sigma_z}^d\}$ denotes the resource demand of CS i in terms of resources, where the resources are quantified by the number of standardized virtual resource units. Here, σ_z denotes the number of resource types, and $z_{i,m}^d$ indicates the required quantity of resource r_m .

Afterwards, the set of chunks of CS i is denoted $C_i = \{C_{i,1}, C_{i,2}, \dots, C_{i,\sigma_i}\}$ where σ_i is the chunks count of CS i . For ease of use the j chunk of C_i is denoted as $C_{i,j}$ ($j \in C_i = \llbracket 1; \sigma_i \rrbracket$) and defined by the following key parameters: $\Omega_{i,j} \triangleq \langle I_{i,j}, D_{i,j} \rangle$. Here, $I_{i,j}$ is the identifier used to determine the order of the chunk within the CS i , and $D_{i,j}$ denotes the total data size of the chunk, measured in bytes. Moreover, in region R_i the σ_i duplicates of all chunks belonging to CS i are distributed across its ENs. The location information is provided by a set of σ_i matrices that are continually updated by the HMBS. This set specifies, for each CS i , the identifiers of the ENs caching all its chunk duplicates. The matrix \mathcal{M}_i linked to CS i is of dimensions $(\sigma_i \times D_i)$. For convenience, the k -th duplicate ($k \in \mathcal{K} = \{1, 2, \dots, D_i\}$) of the j -th chunk of CS i is denoted as $C_{i,j,k}$ and located in EN $\mathcal{M}_{i,j,k}$.

C. Service Priority and Reputation

Penalization of services in dense small cell networks is an unavoidable challenge, often stemming from users diversity and resource constraints such as limited bandwidth, computational capabilities, or storage/memory availability. Capacity constraints within a system may lead to the prioritization of certain users over others, achieved through a deliberate reduction in the pace at which their service requests are fulfilled. This selective prioritization strategy is implemented to effectively manage resource limitations, ensuring that critical users or tasks receive timely attention while acknowledging and potentially delaying less urgent requests. Such prioritization mechanisms play a crucial role in optimizing resource utilization and maintaining system stability under high demand scenarios. In response to these challenges, we adopt a prioritization model wherein users with higher priorities are subjected to lesser penalties, if necessary. Accordingly, a priority π_i is attributed to CS i such that:

$$\pi_i \in \{\pi_i^{min}, \dots, \pi_i^{max}\} \cup \{M, M + \rho_i\} \quad ; i \in \mathcal{S} \quad (1)$$

Here, π_i^{min} and π_i^{max} respectively represent the minimum and maximum allowable priority scores for CS i . M is a very

big number such that $\pi_i^{max} \ll M, \forall i \in \mathcal{S}$. The priority factors are used to favour the transfer of CS. In particular, CS with priority at least $\pi_i = M$ are high priority containers that are solicited for urgent transfer. Other priorities are determined according to the service continuity requirement in terms of downtime or the service level agreement.

Simultaneously, users who have been penalized in one round may be perceived as potential priority users in subsequent rounds. This dynamic approach recognizes that users experiencing penalties in a time slot might require special attention or resource allocation in subsequent slots to ensure fair access and equitable long term treatment. By adapting priorities based on historical user interactions, the system aims to efficiently handle specific needs and requirements of individual users over time. As a result, within our model, the penalization score undergoes adjustments based on the following criteria:

- If user i holds high-priority score $M + \rho_i$, its priority score remains unchanged. Here, ρ_i , referred the reputation score which is introduced to establish a hierarchical order among high-priority users to ensuring their precedence.
- Alternatively, if user i does not possess high-priority status:
 - If its request is fulfilled during the current time slot, its priority π_i is reset to its initial value π_i^{min} .
 - If its request remains unsatisfied during the current slot, its priority in the subsequent time slot is either incremented by 1 or set to M : if π_i reaches the maximum allowable value π_i^{max} , π_i is set to M , otherwise it is elevated to $\pi_i + 1$.

D. Network Model

The network model is given by $\mathcal{P} = \{\mathcal{P}_{n \rightarrow n'} / n \in \mathcal{N}; n' \in \mathcal{N} \setminus \{n\}\}$ composed of all sufficient paths connecting all pairs of distinct nodes (n, n') . Also, we use $\mathcal{P}_{i,j,k}^n$ to denote the set $\mathcal{P}^{\mathcal{M}_{i,j,k} \rightarrow n}$ of paths connecting EN $\mathcal{M}_{i,j,k}$ housing chunk $C_{i,j,k}$ to node n . Without loss of generality, we assume that the set $\mathcal{P}_{i,j,k}^n$ is precalculated and given at the decision time slot.

Moreover, each available path $p \in \mathcal{P}_{n \rightarrow n'}$ that is used for multi-hop data transmission is characterized by [5], [25]:

- its hop count $\mathcal{H}_{n \rightarrow n'}^p$
- its allocatable bandwidth $\mathcal{B}_{n \rightarrow n'}^p$
- traversing delay $\mathcal{D}_{n \rightarrow n'}^p$

Thus, if EN n is the transfer destination of the CS i 's chunks, the backhaul bandwidth between n and the target node N_i^t , serving the user of CS i 's, is given by:

$$\mathcal{B}_i^n = \begin{cases} \infty & ; n = N_i^t \\ \max_{p \in \mathcal{P}_{n \rightarrow N_i^t}} \left\{ \mathcal{B}_{n \rightarrow N_i^t}^p \right\} & ; n \neq N_i^t \quad ; i \in \mathcal{S}; n \in \mathcal{N} \end{cases} \quad (2)$$

E. Delays

The cumulative delay while transferring a data byte of chunk $C_{i,j,k}$ using path p in the set $\mathcal{P}_{i,j,k}^n$ is denoted $\mathcal{D}_{i,j,k}^{n,p}$.

In this study, the service collection process involves transferring the base image of its container from the most suitable caching ENs to the nearest node possible to node N_i^t to cater to the user's request. According to the specific service being requested, the provider's CBI might be exclusively stored in the RCS, completely located on an EN, or distributed as multiple chunks across regional ENs. Upon receiving a new service request, the associated node acquires necessary instructions from the HMBS. The MBS selects the most appropriate procedure from three potential options based on specific circumstances. Notably, the focus of this study is the third option, which encompasses the characteristics of the other two scenarios. Consequently, the transfer latency experienced by a specific chunk, denoted as $C_{i,j,k}$, to EN n is determined by the cumulative transfer delays of all selected chunks from their respective caching nodes. These delay are influenced by the underlying blockchain network architecture and prevailing transfer conditions. As such, they can be decomposed into the following components:

1) *Blockchain-related operational delays*: [26], [27] this delay encompasses the time it takes for a node to respond and send a requested block back to the requester. This delay is intricately tied to factors like node processing power, data volume, network bandwidth, and the blockchain protocol employed. In our approach, we extend this modeling by incorporating the block size as an additional parameter, recognizing its influence on delay. Specifically, we characterize this delay as a linear function of both the chunk size and block size, introducing two parameters associated with the hosting EN and the HMBS. This refinement allows for a more comprehensive representation of the operational delay in the blockchain network.

2) *Network-related transfer delays*: which refers to the time it takes for the transfer of the CBIC to propagate through the network from its holding node to its final decided node. This duration is influenced by several factors, including network topology, congestion, and the number of hops.

The first delay, denoted $^{BC}T_{i,j,k}$, is given in the next formula where $a_{i,j,k}$, $b_{i,j,k}$ and $c_{i,j,k}$ are the delay-related parameters associated with the hosting EN $\mathcal{M}_{i,j,k}$:

$$^{BC}T_{i,j,k} = a_{i,j,k} * D_{i,j} + b_{i,j,k} * L^{Bloc} + c_{i,j,k} \quad (3)$$

Here, $i \in \mathcal{S}$, $j \in \mathcal{C}_i$, $k \in \mathcal{K}$, $D_{i,j}$ is the total data amount of chunk $C_{i,j}$, the term $b_{i,j,k} * L^{Bloc}$ represents the delay overhead related to the adopted block-chain block size L^{Bloc} .

Achieving precise estimates for the parameters $a_{i,j,k}$, $b_{i,j,k}$ and $c_{i,j,k}$ within the blockchain edge-cloud network involves a comprehensive strategy. Initial empirical experiments provide a foundational dataset for response time with varying chunk sizes. Employing regression analysis offers initial parameter estimates. To enhance precision, integrate machine learning (ML) techniques, utilizing supervised learning algorithms and considering features like hosting EN attributes, blockchain protocol, and chunk characteristics. Advanced ML methods, including neural networks, contribute to capturing intricate

relationships. Continuous monitoring and adaptation based on real-world performance data ensure ongoing accuracy. This hybrid empirical-ML approach establishes a robust framework for dynamic and precise estimation of the delay-related parameters in the blockchain edge-cloud network.

The second delay depends on the decided target node n and it is given by:

$${}^{NET}T_{i,j,k}^{n,p} = \begin{cases} 0 & ; n = M_{i,j,k} \\ D_{i,j} \times \mathcal{D}_{i,j,k}^{n,p} & ; n \neq M_{i,j,k} \end{cases} \quad (4)$$

where $i \in \mathcal{S}; j \in \mathcal{C}_i; k \in \mathcal{K}; n \in \mathcal{N}; p \in \mathcal{P}_{i,j,k}^n$.

Deploying a CS in this work refers to the transfer of all its CBICs from the distributed hosting nodes to the decided MEC server in order to make it ready to start serving the requester user. Thus, a new incoming service request from a user trigger the service deployment from their hosting nodes to the best available nearby EN.

Hence, the transfer process delay of duplicate $C_{i,j,k}$ to EN n is composed of the blockchain operational delay as well as the transfer delay from the storing nodes to the decided hosting node n . Using Eq. 3 and 4 we can formulate the overall transfer delay $T_{i,j,k}^{n,p}$ related to the duplicate $C_{i,j,k}$ as follows:

$$T_{i,j,k}^{n,p} = {}^{BC}T_{i,j,k} + {}^{NET}T_{i,j,k}^{n,p} \quad (5)$$

Lastly, Table II provides an inventory of the primary notations employed in this paper.

TABLE II. MAIN NOTATIONS

Notation	Definition
\mathcal{N}	The set of edge-cloud nodes
\mathcal{S}	The set of container-based services
$\sigma_n, \sigma_c, \sigma_r$	The the total number of nodes, CS and resources
$\mathcal{P}_{n \rightarrow n'}$	The set of available paths connecting nodes N_n and $N_{n'}$
$\mathcal{B}_{n \rightarrow n'}$	The bandwidth of path $p \in \mathcal{P}_{n \rightarrow n'}$
$\mathcal{H}_{n \rightarrow n'}$	The hop count of path $p \in \mathcal{P}_{n \rightarrow n'}$
$D_{i,j}$	The total data amount of the container, chunk $C_{i,j}$
$\mathcal{P}_{i,j,k}^n$	The set of available paths connecting nodes N_n and $N_{n'}$
$\mathcal{D}_{i,j,k}^n$	The transfer cumulative delay using path $p \in \mathcal{P}_{i,j,k}^n$
Z_i^d	The CS i 's demand in terms of resource r_m
$Z_{n,m}^u$	The available resource of node N_n in terms of resource r_m

V. THE OPTIMIZATION PROBLEM

In this section, the fundamental problem that serves as the focal point of our study is articulated. The variables, objectives, and constraints are clearly defined to establish a comprehensive formulation and delineate the overarching objective that requires optimization.

A. Decision Variables

To accurately represent the operations within our system, the decision variables employed in our model are introduced as follows:

The transfer binary decision variable of CS i to node n is denoted α_i^n where $\alpha_i^n = 1$ refers to the decision to deploy C_i to node n , otherwise, $\alpha_i^n = 0$.

$$\alpha_i^n \in \{0; 1\} \quad ; i \in \mathcal{S}; n \in \mathcal{N} \quad (6)$$

The duplicate choice binary decision variable of chunk duplicate $C_{i,j,k}$ is denoted $\beta_{i,j,k}$ where $\beta_{i,j,k} = 1$ refers to the decision to transfer $C_{i,j,k}$, otherwise, $\beta_{i,j,k} = 0$.

$$\beta_{i,j,k} \in \{0; 1\} \quad ; i \in \mathcal{S}; j \in \mathcal{C}_i; k \in \mathcal{K} \quad (7)$$

Additionally, when transferring chunk $C_{i,j,k}$ from its caching node $M_{i,j,k}$ to node n the decision variable to select the migration path p among the possible paths set $\mathcal{P}_{i,j,k}^n = \mathcal{P}_{M_{i,j,k} \rightarrow n}$ is the binary variable $\gamma_{i,j,k}^{n,p}$ where $\gamma_{i,j,k}^{n,p} = 1$ refers to the decision to use the p -th path in $\mathcal{P}_{i,j,k}^n$ to migrate $C_{i,j,k}$ from node $M_{i,j,k}$ to n , otherwise $\gamma_{i,j,k}^{n,p} = 0$.

$$\gamma_{i,j,k}^{n,p} \in \{0; 1\} \quad ; i \in \mathcal{S}; j \in \mathcal{C}_i; k \in \mathcal{K}; n \in \mathcal{N}; p \in \mathcal{P}_{i,j,k}^n \quad (8)$$

In situations where the available system resources are insufficient to support the initiation of a CS, our proposed model offers the option to defer the initiation of this CS. To represent this penalization decision for C_i , we utilize the binary variable δ_i , where $\delta_i = 0$ indicates penalization, while $\delta_i = 1$ denotes no penalization.

$$\delta_i \in \{0; 1\} \quad ; i \in \mathcal{S} \quad (9)$$

B. The Cost Model

In this section, we present the proposed Cost Model, a fundamental component of our system design aimed at comprehensively assessing and optimizing the framework decisions.

1) *Delay cost*: In our model, when deploying CSs to the designated hosting nodes, the delay cost incurred during the transmission of data transfer flows is contingent on the congestion levels of the network's links. Consequently, with a placement decision vector α , a duplicates selection vector β , and a path selection vector γ as well as using Eq. 5 we can formulate the transfer delay related to the CS i s as follows:

$$T_i(\alpha, \beta, \gamma) = \sum_{j \in \mathcal{C}_i} \sum_{k \in \mathcal{K}} \sum_{n \in \mathcal{N}} \sum_{p \in \mathcal{P}_{i,j,k}^n} \alpha_i^n \beta_{i,j,k} \gamma_{i,j,k}^{n,p} (T_{i,j,k}^{n,p}) \quad (10)$$

As a result, the comprehensive delay-related cost can be calculated as follows:

$$\Psi^{delay}(\alpha, \beta, \gamma, \delta) = \sum_{i \in \mathcal{S}} \delta_i T_i(\alpha, \beta, \gamma) \quad (11)$$

Additionally, for normalization purpose we use the total maximal allowable transfer delay for all CS given by:

$$\Psi_{max}^{delay} = \sum_{i \in \mathcal{S}} t_i^{trans} \quad (12)$$

2) *Backhaul cost*: Once all the required container chunks related to S_i have been transferred to destination EN n , the backhaul bandwidth between the connected EN N_i^t and n plays a crucial role in determining the service-related user's perceived delay. Ideally, the user's experience is best when $n = N_i^t$, and we aim to prioritize such decisions. To achieve this, our model takes into account two main costs related to EN n : the available bandwidth between EN n and N_i^t as well as the hop count between them. Utilizing a placement decision vector α and employing Eq. 2, the serving bandwidth for the user linked to CS S_i can be expressed as:

$$\mathcal{B}_i(\alpha) = \sum_{n \in \mathcal{N}} \alpha_i^n \mathcal{B}_i^n \quad ; i \in \mathcal{S} \quad (13)$$

The resulting backhaul cost function, denoted as $\Psi_{i,n}^{back}$, is defined in such a way that it equals 0 when $n = N_i^t$. However, in all other cases, it takes on a value as follows:

$$\Psi_{i,n}^{back} = \min_{p \in \mathcal{P}_{n \rightarrow N_i^t}} \left\{ W_r \frac{\min_{p' \in \mathcal{P}_{n \rightarrow N_i^t}} \mathcal{B}_{n \rightarrow N_i^t}^{p'}}{\mathcal{B}_{n \rightarrow N_i^t}^p} + W_h \frac{\mathcal{H}_{n \rightarrow N_i^t}^p}{\max_{p' \in \mathcal{P}_{n \rightarrow N_i^t}} \mathcal{H}_{n \rightarrow N_i^t}^{p'}} \right\} \quad (14)$$

Here, $i \in \mathcal{S}$, $n \in \mathcal{N}$ and the weights W_r and W_h are two adjustable weights to fine-tune the optimization process for different scenarios, where W_r represents the weight associated with available bandwidth, and W_h represents the weight associated with hop count costs, with the constraint that $W_r + W_h = 1$. Moreover, the cost function $\Psi_{i,n}^{back}$ falls within the range $[0,1]$, and the use of the max and min expressions for fractions serves the purpose of normalization.

Therefore, with the decision vector α , the overall user backhaul cost can be obtained as:

$$\Psi^{back}(\alpha, \delta) = \sum_{i \in \mathcal{S}} \left\{ \delta_i \sum_{n \in \mathcal{N}} \alpha_i^n \Psi_{i,n}^{back} \right\} \quad (15)$$

3) *Load balancing cost*: The load balancing procedure targets an equitable distribution of the incoming service workloads, aiming to minimize deviations from the average value. Within our model, the associated cost must consider the processing workloads across all ENs. This includes the current workload of running services on each EN, along with anticipating the additional load expected from services that will be selected to run on them.

Initially, following the CS deployment, the anticipated resource utilization $Z_{n,m}^u$ of processing resource r_m on node n can be determined using the following equation:

$$Z_{n,m}^a(\alpha, \delta) = Z_{n,m}^u + \sum_{i \in \mathcal{S}} \alpha_i^n \delta_i Z_{i,m}^d \quad ; n \in \mathcal{N}; m \in \mathcal{Z}^p. \quad (16)$$

Next, we establish the processing load ratios $\theta_{n,m}$ associated with resource r_m in EN n , along with their mean value $\bar{\theta}_m$, defined as follows:

$$\theta_{n,m}(\alpha, \delta) = \frac{Z_{n,m}^a(\alpha, \delta)}{Z_{n,m}^c} \in [0, 1] \quad ; n \in \mathcal{N}; m \in \mathcal{Z}^p \quad (17)$$

$$\bar{\theta}_m(\alpha, \delta) = \sum_{n \in \mathcal{N}} \frac{\theta_{n,m}(\alpha, \delta)}{\sigma_n} \in [0, 1] \quad ; m \in \mathcal{Z}^p \quad (18)$$

Subsequently, the processing load concerning EN n across all processing resource types in \mathcal{Z}^p is defined as:

$$\Psi_n^{load}(\alpha, \delta) = \sum_{m \in \mathcal{Z}^p} \frac{|\theta_{n,m}(\alpha, \delta) - \bar{\theta}_m(\alpha, \delta)|}{\sigma_z} \quad ; n \in \mathcal{N} \quad (19)$$

Finally, the resulting overall processing load is as follows:

$$\Psi^{load}(\alpha, \delta) = \sum_{n \in \mathcal{N}} \sum_{m \in \mathcal{Z}^p} \frac{|\theta_{n,m}(\alpha, \delta) - \bar{\theta}_m(\alpha, \delta)|}{\sigma_n \sigma_z} \in [0, 1] \quad (20)$$

C. The Multi-Objective Function

The adopted multi-objective function, to be elaborated upon, consists of two components: the overall cost and the degree of penalization for users. We begin by introducing the overall cost model below. It is constructed using a multi-objective function, which combines the detailed cost metrics into a weighted sum using the weight aggregation approach:

$$\Psi(\alpha, \beta, \gamma, \delta) = W_d \frac{\Psi^{delay}(\alpha, \beta, \gamma, \delta)}{\Psi_{max}^{delay}} + W_b \frac{\Psi^{back}(\alpha, \delta)}{\sigma_c} + W_l \Psi^{load}(\alpha, \delta) \quad (21)$$

Here, W_d , W_b , and W_l serve as regulatory weight constants that determine the priority attributed to each cost. Their values range between 0 and 1, satisfying the condition $W_d + W_b + W_l = 1$. Furthermore, the denominators in this function act as normalization factors for each cost function. The metrics normalizing procedure involves transforming the values of the three studied metrics into dimensionless costs between 0 and 1. This ensures the ability to addition and comparison within the cost function by standardizing the metrics' scales.

Next, a penalty function is introduced in order to minimize the number of penalized users. It is proposed such that high-priority users could be penalized, if necessary, only if all non priority users are penalized. Accordingly, we adopt the following penalty function given by:

$$\Pi(\delta) = \sum_{i \in \mathcal{S}} (1 - \delta_i) \pi_i \quad (22)$$

The formulation of this function establishes a penalization hierarchy among the users, where the decision to penalize any CS guarantees that high-priority containers are penalized last, if required.

At this point, we can finally state the following equation, which defines the adopted overall multi-objective function, referring to the objective function targeted for minimization:

$$\Theta(\alpha, \beta, \gamma, \delta) = \Psi(\alpha, \beta, \gamma, \delta) + \Pi(\delta) \quad (23)$$

D. The Constraints

In our model, the case when CS i is not transferred (penalized by setting $\delta_i = 0$) is represented by setting $\alpha_i^n = 0$ for $n \in \mathcal{N}$ and if transferred, only one target node is selected. Accordingly, the transfer decision of CS i has to meet the following constraint:

$$\sum_{n \in \mathcal{N}} \alpha_i^n = \delta_i \quad ; i \in \mathcal{S} \quad (24)$$

Additionally, if i is not penalized, only one duplicate of chunk $C_{i,j,k}$ must be selected, resulting in the following constraint:

$$\sum_{k \in \mathcal{K}} \beta_{i,j,k} = \delta_i \quad ; i \in \mathcal{S}; j \in \mathcal{C}_i \quad (25)$$

Also, all the σ_i chunks of CS i , if not penalized, must be transferred to the selected node which lead to the following constraint:

$$\sum_{j \in \mathcal{C}_i} \sum_{k \in \mathcal{K}} \beta_{i,j,k} = \delta_i \sigma_i \quad ; i \in \mathcal{S} \quad (26)$$

By selecting only one path p in $\mathcal{P}_{i,j,k}^n$ to serve the transfer flow of chunk $C_{i,j,k}$, if i is not penalized, from its node $\mathcal{M}_{i,j,k}$ to target node n , the next constraint has to be satisfied:

$$\sum_{p \in \mathcal{P}_{i,j,k}^n} \gamma_{i,j,k}^{n,p} = \delta_i \quad ; i \in \mathcal{S}; j \in \mathcal{C}_i; k \in \mathcal{K}; n \in \mathcal{N} \quad (27)$$

Therefore, the anticipated demand for each resource r_m on each node n must fulfill every resource type requirement. This can be formally formulated as:

$$Z_{n,m}^a(\alpha, \delta) \leq Z_{n,m}^c \quad ; n \in \mathcal{N}; m \in \mathcal{Z} \quad (28)$$

The subsequent constraint ensures that the total delay incurred during the collection of all chunks associated with CS i does not surpass its tolerated transfer delay t_i^{trans} .

$$\delta_i T_i(\alpha, \beta, \gamma) \leq t_i^{trans} \quad ; i \in \mathcal{S} \quad (29)$$

Finally, the bandwidth constraint associated with CS i , utilizing the maximum available bandwidth specified in Eq. (13), is formalized as follows:

$$\mathcal{B}_i(\alpha) \geq \delta_i B_i^{ser} \quad ; i \in \mathcal{S} \quad (30)$$

E. The Problem Formulation

Based on the elucidated problem context, the following optimization problem, designated as $\mathcal{P}1$, aims to optimize the aforementioned dual objectives. The solution aims to maximize user benefits while respecting resource constraints, meeting transfer delay and bandwidth requirements, and minimizing penalties associated with priority.

$$\mathcal{P}1 : \text{minimize } \Theta(\alpha, \beta, \gamma, \delta)_{\{\alpha, \beta, \gamma, \delta\}}$$

$$\text{s.t. (6), (7), (8), (9), (24), (25), (26), (27), (28), (29), (30)}$$

VI. PROBLEM DECOMPOSITION

The general problem $\mathcal{P}1$ involves making decisions regarding CSs placement (α decision variables), selecting CBICs along with path determination (β and γ decision variables) as well as the final penalization decision (δ decision variables). Next, $\mathcal{P}1$ is decomposed into sub-problem as well as a general problem. The sub-problem (CSPDP) deals exclusively with the aspect concerning the selection of CBICs along with path determination and penalization decisions. It is assumed that the decisions regarding container placement have been made. Subsequently, the general problem (GCP) iterates over the placement possibilities and employs the solution from the CSPDP to derive the overall solution.

A. CSPDP Sub-Problem

The formulation of this problem can be presented as follows:

$$\begin{aligned} \text{CSPDP} : & \text{minimize } \Theta^\alpha(\beta, \gamma, \delta^\alpha)_{\{\beta, \gamma, \delta^\alpha\}} \\ & \text{s.t. (7), (8), (9), (25), (26), (27), (29)} \end{aligned}$$

In this formulation, with fixed decisions α , the objective function value is obtained using Eq. (23). Additionally, the penalty vector δ^α pertains only to containers for which resource and bandwidth constraints ((28) and (30) respectively) are satisfied based on decisions α . That is to say, if a certain container i is penalized with decisions α ($\delta_i = 0$), then δ_i^α always equals 0 and is not considered a variable for the CSPDP problem. The remaining penalty decisions of δ^α are related to transfer time constraints that depend on selecting CBICs along with path determination (β and γ decision variables).

Subsequently, a proposition related to the set of feasible solutions of the problem will be demonstrated.

Proposition 1. The set \mathcal{S}_f^α of feasible solutions of CSPDP is non-empty.

Proof: By utilizing binary decisions, constraints (7), (8), (9) are fulfilled. Additionally, $\forall \alpha$, with a penalty vector $\delta^+ = \mathbf{0}$, resource constraints ((28) and (30)) will be satisfied. Let the decision vectors β^+ and γ^+ be constructed such that $\beta^+ = \mathbf{0}$ and $\gamma^+ = \mathbf{0}$. Since $\delta_i^+ = 0 \forall i$, all remaining constraints (25), (26), (27), (29) are satisfied. Therefore, $(\beta^+, \gamma^+, \delta^+) \in \mathcal{S}_f^\alpha \Rightarrow \mathcal{S}_f^\alpha \neq \emptyset$. ■

B. GCP Global Problem

The general problem $\mathcal{P}1$ involves traversing all possible decisions given by the containers placement α and solving the sub-problem CSPDP at each iteration. This means that for each potential configuration α , problem CSPDP is solved to obtain a corresponding optimal solution. This iterative process is repeated until all possibilities of α are explored, thereby determining the best global solution for problem $\mathcal{P}1$.

Thus, by using the next constraint, this challenging placement problem, denoted \mathcal{GCP} , can be further formulated:

$$(\beta, \gamma, \delta^\alpha) \in \mathcal{S}_f^\alpha \quad (31)$$

and the GCP Global Problem is as follows:

$$\begin{aligned} \mathcal{GCP} : & \text{minimize } \Theta^\alpha(\beta, \gamma, \delta^\alpha) \\ & \{\alpha\} \\ \text{s.t. } & (6), (24), (28), (30), (31) \end{aligned}$$

However, this problem's placement decisions lies in optimally placing σ_s containers within σ_n edge nodes. This placement must consider resource constraints, including available resources and bandwidth capacity, which contribute to the inherent complexity of the problem. Consequently, the next proposition 2 is derived.

Proposition 2. The optimization problem \mathcal{GCP} is NP-hard.

Proof: Given σ_s services to place within σ_n ENs. To find the best placement solution for problem \mathcal{GCP} , even when all resources are sufficient, the problem remains one of determining the optimal placement of σ_s services among σ_n nodes, the computation complexity of \mathcal{GCP} can reach $O(\sigma_n^{\sigma_s})$. Therefore, problem \mathcal{GCP} is NP-hard and cannot be well solved in polynomial time. ■

Subsequently, an efficient resolution of $\mathcal{P}1$ (or its equivalent form \mathcal{GCP}) will be presented in the next section.

VII. PROBLEMS RESOLUTION

Now, the resolution of the obtained optimization problem $\mathcal{P}1$ is explored. The identified optimization-related challenges will be tackled through a detailed approach, and the derived solutions will be presented. The end of this section will provide insights into our efforts to effectively address the problem and demonstrate our commitment to achieving optimal results.

A. GCP Problem Resolution

Initially, two conditions are established regarding the ENs that can potentially serve as candidates for the placement of service i . The first condition (32) ensures that each EN must satisfy the resource constraints (28) and the service bandwidth constraints (30).

$$\left\{ \begin{array}{l} Z_{i,z}^d + \sum_{i' \in \mathcal{C}^i} \alpha_{i'}^n Z_{i',z}^d \leq Z_{n,z}^c \quad z \in \mathcal{Z} \\ \max_{p \in \mathcal{P}_{n \rightarrow N_i^t}} \left\{ \mathcal{B}_{n \rightarrow N_i^t}^p \right\} \geq B_i^{ser} \end{array} \right. \quad (32)$$

Based on this first condition (32), we can define the next set $E_i(\alpha)$ associated with CS i as the collection of candidate ENs with their minimum hop count to target node N_i^t .

$$E_i(\alpha) = \left\{ \left(n, \min_{p \in \mathcal{P}_{n \rightarrow N_i^t}} \left\{ \mathcal{H}_{n \rightarrow N_i^t}^p \right\} \right); n \in \mathcal{N} \text{ and (32) is satisfied} \right\} \quad (33)$$

A tuple (n, h) is included in this set if EN n is reachable from target node N_i^t with a hop count h and satisfies the conditions in (32).

Then, using $E_i(\alpha)$, we define a second condition to identify a refined set $\mathcal{E}_i(\alpha, \Delta_h)$ of candidate placement ENs relevant to CS i . This condition use a threshold Δ_h to ensure that the minimum number of hops between each potential node in

$E_i(\alpha)$ and the target node N_i^t is less than Δ_h . If no nodes satisfy this condition, the set will instead comprise the node from the set $E_i(\alpha)$ that is closest to N_i^t , regardless of this condition, provided such node exist. Since an empty subset signifies an unavoidable penalty for the associated service, this condition guarantees that the set $\mathcal{E}_i(\alpha, \Delta_h)$ is empty only when $E_i(\alpha)$ is also empty. Moreover, the use of the threshold Δ_h is primarily driven by the need to restrict the solution search space, thus excluding trivially non-feasible combinations. Additionally, it serves the purpose of maintaining control over the execution time, particularly in scenarios involving non-feasible configurations.

Accordingly, and in relation to all services, we define a general vector $\mathcal{E}(\alpha, \Delta_h)$ containing all subsets $\mathcal{E}_i(\alpha, \Delta_h)$ as follows:

$$\mathcal{E}(\alpha, \Delta_h) = \{ \mathcal{E}_i(\alpha, \Delta_h) / i \in \mathcal{S} \} \quad (34)$$

Subsequently, the total number $\chi(\alpha, \Delta_h)$ of placement possibilities for "not yet penalized" services can be derived as:

$$\chi(\alpha, \Delta_h) \leftarrow \prod_{\{x \in \mathcal{E}(\alpha, \Delta_h) \text{ and } x \neq \emptyset\}} (|x|) \quad (35)$$

Now that we've established these key concepts, let's delve into the solution implementation. Here's the Algorithm 1, named GSPA, that outlines the steps involved:

Algorithm 1 : Global Service Placement Algorithm (GSPA)

Require: $\mathcal{S}, \mathcal{N}, \mathcal{C}, \mathcal{K}, \mathcal{P}, \mathcal{M}, \Omega, \mathcal{D}$ and Δ_h .

Ensure: Global solution $\alpha^*, \beta^*, \gamma^*, \delta^*$ with cost $Cost^*$

```

1:  $Cost^* \leftarrow \infty$ ;
2: build  $\mathbf{E}^0 = \mathcal{E}(\mathbf{0}, \Delta_h)$  using (34);
3:  $N \leftarrow \chi(\mathbf{0}, \Delta_h)$  using (35);
4: for  $l = 0$  to  $N - 1$  do
5:   for each service  $i$  in  $\mathcal{S}$  do
6:      $\alpha_i \leftarrow \mathbf{0}$ ;
7:     if  $|\mathbf{E}_i^0| = 0$  then
8:        $\delta_i \leftarrow 0$ ; //service  $i$  penalization
9:     else
10:       $\delta_i \leftarrow 1$ ; //no penalization of service  $i$ 
11:       $n_i$  is the node within  $\mathbf{E}_i^0$  at index  $(l \bmod |\mathbf{E}_i^0|)$ ;
12:       $\alpha_i^{n_i} \leftarrow 1$ ; // service  $i$  placement at node  $n_i$ 
13:       $l \leftarrow l \div |\mathbf{E}_i^0|$ ;
14:     end if
15:   end for
16:    $(\beta, \gamma, \delta, X) \leftarrow subSolution(\alpha, \delta)$ ;
17:   if  $X < Cost^*$  then
18:      $(\alpha^*, \beta^*, \gamma^*, \delta^*, Cost^*) \leftarrow (\alpha, \beta, \gamma, \delta, X)$ 
19:   end if
20: end for
21: return  $(\alpha^*, \beta^*, \gamma^*, \delta^*, Cost^*)$ 

```

In the outer for loop (line 4), all feasible placements are iterated over, with each iteration involving the construction of the placement vector α and the initial penalization decisions δ (lines 5 to 15). Subsequently, the CSPDP sub-problem is resolved, and the current solution along with its cost are updated (lines 16 to 19).

B. CSPDP Sub-Problem Resolution

In this subsection, the process of solving this sub-problem is demonstrated. Three solutions are proposed and detailed: The first involves an exact solution based on a Brute Force Search (BFS) method, while the remaining two utilize approximate solutions based on Simulated Annealing (SA) and Markov Approximation (MA) methods, respectively.

1) *Brute-force-search-based scheme*: To determine the optimal chunks duplicate Transfer decisions provided by the placement decisions α , we conduct an exhaustive search across all potential solutions using a Brute Force Search for Chunks Duplicates Collection, denoted as BFS-CDCA. Algorithm 2 presents this solution. An exhaustive search over all possible combinations of chunk duplicates and paths is conducted with respect to the placement decision α . This search aims to identify the optimal solution $(\beta^*, \gamma^*, \delta^*)$ with the minimum cost S^* . The cost function is computed based on the decisions made for α, β, γ , and δ , considering the constraints of problem CSPDP. The algorithm iterates, evaluates and updates the optimal solution whenever a lower cost is encountered. The function *minPenalisation* facilitates the determination of the penalty vector that minimizes the overall objective function Θ , considering that the decisions α, β , and γ have already been established. Finally, the algorithm returns the intermediate optimal solution $(\beta^*, \gamma^*, \delta^*)$ along with the corresponding cost S^* .

Algorithm 2 Brute Force Search based CBIC Distributed Collection Algorithm (BFS-CDCA)

Require: $\mathcal{S}, \mathcal{N}, \mathcal{C}, \mathcal{K}, \mathcal{P}, \mathcal{M}, \Omega, \mathcal{D}$ and α .
Ensure: Intermediate solution $(\beta^*, \gamma^*, \delta^*)$ with cost S^* ;

- 1: $S^* \leftarrow \infty$
- 2: $N \leftarrow$ combinations count;
- 3: **for** $l = 0$ to $N - 1$ **do**
- 4: construct decisions vectors β, γ from l ;
- 5: $\delta \leftarrow \text{minPenalisation}(\alpha, \beta, \gamma)$
- 6: **if** constraints of CSPDP are satisfied **then**
- 7: $S \leftarrow \Theta(\alpha, \beta, \gamma, \delta)$ according to (23);
- 8: **if** $S < S^*$ **then**
- 9: $(\beta^*, \gamma^*, \delta^*, S^*) \leftarrow (\beta, \gamma, \delta, S)$
- 10: **end if**
- 11: **end if**
- 12: **end for**
- 13: **return** $(\beta^*, \gamma^*, \delta^*, S^*)$

2) *Simulated-annealing-based scheme*: In Algorithm 3, the proposed heuristic solution based on simulated annealing is introduced. Simulated annealing, a widely utilized optimization technique, is renowned for its simplicity, general applicability, and efficiency compared to alternative methods.

Algorithm 3 uses a probabilistic approach that allows for potential degradation in cost to prevent being trapped in local minima. It utilizes a cost function as an analogy to the energy of a thermodynamic system. Throughout the iteration in the solution space, the acceptance of the current state depends on whether the new state has lower energy. If the new state has higher energy, acceptance is probabilistic, determined by a temperature parameter and the Boltzmann distribution. As the temperature decreases, the system becomes less likely to

Algorithm 3 : Simulated Annealing based CBIC Distributed Collection Algorithm (SA-CDCA)

Require: $\mathcal{S}, \mathcal{N}, \mathcal{C}, \mathcal{K}, \mathcal{P}, \mathcal{M}, \Omega, \mathcal{D}, \Delta, L^{max}, T_0$ and α .
Ensure: Intermediate solution $(\beta^*, \gamma^*, \delta^*)$ with cost S^* ;

- 1: Generate initial decisions (β, γ)
- 2: $\delta \leftarrow \text{minPenalisation}(\alpha, \beta, \gamma)$;
- 3: $S^* \leftarrow \Theta(\alpha, \beta, \gamma, \delta)$ according to (23);
- 4: **for** $l=1$ to L^{max} **do**
- 5: $T \leftarrow T_0 e^{-0.5l \frac{1}{\Delta}}$;
- 6: $\beta' \leftarrow \text{rand_neighbour}(\beta)$;
- 7: $(\gamma', \delta') \leftarrow \text{bestTransfer}(\alpha, \beta')$;
- 8: **if** constraints of CSPDP are satisfied **then**
- 9: Calculate $S' = \Theta(\alpha, \beta', \gamma', \delta')$ using 23;
- 10: $\Delta_S \leftarrow S' - S$
- 11: **if** $\Delta_S < 0$ or $e^{\frac{-|\Delta_S|}{T}} \geq \text{random}(0,1)$ **then**
- 12: $(\beta, \gamma, \delta, S) \leftarrow (\beta', \gamma', \delta', S')$
- 13: **if** $S < S^*$ **then**
- 14: $(\beta^*, \gamma^*, \delta^*, S^*) \leftarrow (\beta, \gamma, \delta, S)$
- 15: **end if**
- 16: **end if**
- 17: **end if**
- 18: **end for**
- 19: **return** $X^* = (\beta^*, \gamma^*, \delta^*, S^*)$

accept higher energy states. This adjustment in the probability of accepting a penalizing transition seeks a balance between exploring new solutions and exploiting known solutions in the space.

The algorithm enters a simulated annealing loop (line 4), where it iterates over a specified number of iterations L^{max} . In each iteration, the temperature T is updated based on the current iteration l , and a random neighbor solution β' is generated. The corresponding best γ' is then determined using β' . The penalty vector δ' for the new solution is obtained by minimizing penalization. If the constraints of problem CSPDP are satisfied, the cost S' is calculated, and a decision is made based on the Metropolis criterion to accept or reject the new solution. If accepted, the current solution is updated, and if it improves the global solution, it is recorded. Finally, the algorithm returns the global intermediate solution $X^* = (\beta^*, \gamma^*, \delta^*)$ along with the corresponding cost S^* .

3) *Markov approximation-based scheme*: Markov Approximation is a technique used in optimization to approximate complex problems by simplifying them into a Markov chain model. It is particularly useful for problems with large solution spaces where exact methods become computationally infeasible. In this method, the problem is represented as a Markov decision process, where each state corresponds to a possible solution, and transitions between states are determined by a stochastic process based on the problem's constraints and objectives. By iteratively updating the probabilities of transitioning between states, the algorithm converges towards an optimal or near-optimal solution.

a) *Log-sum-exp approximation*: Now, we delve into a Log-sum-exp method aimed at approximating the mathematical expression of the obtained problem. Let the configuration $c = \{\alpha; \beta; \gamma; \delta\} \in \mathcal{S}_f^\alpha$ be a solution, where \mathcal{S}_f^α is the Feasible Solution Set (FSS) of problem CSPDP with objective

function Θ^α . Sure, problem \mathcal{CSPPD} is equivalent to:

$$\min_{c \in \mathcal{S}_f^\alpha} \Theta^\alpha(c) \quad (36)$$

According to Appendix A of [28], by associating a probability p_c with the adoption of a configuration c , the optimal solution of the problem $\max_{c \in \mathcal{S}_f^\alpha} \Theta^\alpha(c)$ is the same as that of the problem $\max_{p \geq 0} \sum_{c \in \mathcal{S}_f^\alpha} p_c \Theta^\alpha(c)$ where $\sum_{c \in \mathcal{S}_f^\alpha} p_c = 1$. It follows that the optimal solution of problem \mathcal{CSPPD} is the same as that of the following problem:

$$\min_{p \geq 0} \sum_{c \in \mathcal{S}_f^\alpha} p_c \Theta^\alpha(c) \text{ subject to } \sum_{c \in \mathcal{S}_f^\alpha} p_c = 1. \quad (37)$$

Here $p = (p_c)_{c \in \mathcal{S}_f^\alpha}$ is a probability distribution associated with the possibility universe \mathcal{S}_f^α .

Subsequently, the formulation of the log-sum-exp approximation can be derived such that [29]:

- Firstly, for any strictly positive constant τ , we have:

$$0 \leq \min_{c \in \mathcal{S}_f^\alpha} \Theta^\alpha(c) + \frac{1}{\tau} \ln \left(\sum_{c \in \mathcal{S}_f^\alpha} e^{-\tau \Theta^\alpha(c)} \right) \leq \frac{\ln |\mathcal{S}_f^\alpha|}{\tau} \quad (38)$$

- Secondly, let g_τ be the log-sum-exp function defined on \mathbb{R}^m by:

$$g_\tau(x_1; \dots; x_m) = \frac{1}{\tau} \ln \left(\sum_{1 \leq i \leq m} e^{\tau x_i} \right) \quad (39)$$

where $m = |\mathcal{S}_f^\alpha|$. As $\tau \rightarrow \infty$ and according to Eq. (38), the approximation gap $\frac{\ln |\mathcal{S}_f^\alpha|}{\tau} \rightarrow 0$, and thus the proposed approximation in Eq. 38 becomes exact.

- Thirdly, by using the conjugate function of g_τ and according to [30]-p.93, we can find that:

$$g_\tau(x) = \max_{\left\{ p \geq 0 \text{ s.t. } \sum_{1 \leq i \leq m} p_i = 1 \right\}} \sum_{1 \leq i \leq m} p_i x_i - \frac{1}{\tau} \sum_{1 \leq i \leq m} p_i \ln(p_i) \quad (40)$$

- Finally, the approximation defined by Eq. 40 is also the solution to the following optimization problem:

$$\min_{\left\{ p \geq 0 \text{ s.t. } \sum_{c \in \mathcal{S}_f^\alpha} p_c = 1 \right\}} \sum_{c \in \mathcal{S}_f^\alpha} p_c \Theta^\alpha(c) + \frac{1}{\tau} \sum_{c \in \mathcal{S}_f^\alpha} p_c \ln(p_c) \quad (41)$$

b) The Markov chaine: : In this subsection, the Metropolis-Hastings algorithm will be employed to construct an irreducible Markov chain $(X_n)_{n \geq 0}$ with state space \mathcal{S}_f . This chain will have p^* as its reversible probability distribution, thereby ensuring its stationarity.

Firstly, the Lagrangian of problem (41) is given by:

$$L(p, \lambda) = \sum_{c \in \mathcal{S}_f^\alpha} p_c \Theta^\alpha(c) + \frac{1}{\tau} \sum_{c \in \mathcal{S}_f^\alpha} p_c \ln(p_c) + \lambda \left(\sum_{c \in \mathcal{S}_f^\alpha} p_c - 1 \right) \quad (42)$$

where λ is the Lagrange multiplier [29].

Secondly, solving the Karush-Kuhn-Tucker conditions yields the following two equations $\sum_{c \in \mathcal{S}_f^\alpha} p_c^* = 1$ and $\Theta^\alpha(c) + \frac{1}{\tau} (\ln(p_c^*) + 1) + \lambda^* = 0 \left(\forall c \in \mathcal{S}_f^\alpha \right)$, where $(p_c^*)_{c \in \mathcal{S}_f^\alpha}$ is the optimal solution of the primal problem and λ^* is the optimal solution of the dual problem. Thus, from the second equation we can get:

$$p_c^* = e^{-\tau(\Theta^\alpha(c) + \lambda^*) - 1}; \forall c \in \mathcal{S}_f^\alpha \quad (43)$$

This result and the condition $\sum_{c \in \mathcal{S}_f^\alpha} p_c^* = 1$, give the result:

$$\lambda^* = \frac{1}{\tau} \left(\ln \left(\sum_{c \in \mathcal{S}_f^\alpha} e^{-\tau \Theta^\alpha(c)} \right) - 1 \right) \quad (44)$$

Finally, combining Eq. (43) and (44) leads to the following probability distribution:

$$p_c^* = \frac{e^{-\tau \Theta^\alpha(c)}}{\sum_{u \in \mathcal{S}_f^\alpha} e^{-\tau \Theta^\alpha(u)}}; \forall c \in \mathcal{S}_f^\alpha \quad (45)$$

here p_c^* represents the optimal solution of problem (Eq. 41) and thus a quasi-optimal solution of problem (Eq. 36).

c) MA-CDCA algorithm: Our problem-solving process starts with constructing an initial configuration, denoted as c_0 . Once c_0 is established, we employ the Metropolis-Hastings algorithm to create an irreducible Markov chain, represented by $(X_n)_{n \geq 0}$. This Markov chain has the desirable property of converging to a specific stationary probability distribution, denoted by p^* . The core of the algorithm lies in a probabilistic approach based on the Metropolis-Hastings principle, which is described in detail next as follows :

if at time t , we have $X_t = c \in \mathcal{S}_f^\alpha$, a state c' is randomly drawn from \mathcal{S}_f^α according to the distribution $q_{c,c'}$ given by:

$$q_{c,c'} = \frac{p_c^* + p_{c'}^*}{|\mathcal{S}_f^\alpha| - 1} \quad (46)$$

then we calculate the acceptance probability $A_{c,c'} = \min \left\{ \frac{p_{c'}^* q_{c',c}}{p_c^* q_{c,c'}}; 1 \right\}$ simplified as:

$$A_{c,c'} = \min \left\{ e^{-\tau(\Theta^\alpha(c') - \Theta^\alpha(c))}; 1 \right\} \quad (47)$$

Hence, we accept the transition $X_{t+1} = c'$ with probability $A_{c,c'}$ and reject it with probability $1 - A_{c,c'}$.

The pseudo-code of the solution is presented in Algorithm 4.

Algorithm 4 : Markov Approximation based CBIC Distributed Collection Algorithm (MA-CDCA)

Require: $\mathcal{N}, \mathcal{C}, \mathcal{K}, \mathcal{P}, \mathcal{M}, \Omega, \mathcal{D}, T^{max}$ and α .
Ensure: Intermediate solution $X^*=(\beta^*, \gamma^*, \delta^*)$;
1: Generate an initial chunks selection (β_0) based on α ;
2: $(\gamma_0, \delta_0) \leftarrow bestTransfer(\alpha, \beta_0)$;
3: Build the initial solution $X_0=(\alpha, \beta_0, \gamma_0, \delta_0)$;
4: **for** $t=0$ to T^{max} **do**
5: Select CS i such that $CS_Gain(X_t, i) > 0$;
6: Generate a chunks selection $\beta_i(t+1)$ related to CS i such that $Chunk_Gain(X_t, i, \beta_i(t+1)) > 0$;
7: Update β' according to shift $\beta_i(t) \rightarrow \beta_i(t+1)$;
8: $(\gamma', \delta') \leftarrow bestTransfer(\alpha, \beta')$;
9: Build the new configuration $c' \leftarrow (\alpha, \beta', \gamma', \delta')$
10: Calculate acceptance probability $A_{X_t, c'}$ using 47;
11: **if** $A_{X_t, c'} > random(0,1)$ **then**
12: Accept the new transition $X_t \rightarrow c'$ and set $X_{t+1} = c'$
13: **else**
14: Reject the new transition $X_t \rightarrow c'$ and set $X_{t+1} = X_t$
15: **end if**
16: **end for**
17: **return** $X^* = X_{T^{max}+1}$

VIII. EVALUATION

To evaluate the proposed solutions, we conducted a series of experiments using a range of metrics. These experiments were meticulously designed to test each solution under various conditions, ensuring a comprehensive assessment.

A. Simulation Setup

All the experiments were conducted on a personal computer running Windows 10, equipped with a 2.4GHz Intel Core i5 processor and 16GB of RAM. This setup ensured a consistent and controlled environment for testing, minimizing the potential influence of hardware variability on the performance metrics.

The parameters of the simulation experiments are detailed in Table III. These parameters were meticulously chosen to reflect realistic and challenging conditions for the proposed solutions.

TABLE III. SIMULATION PARAMETERS

Parameter	Values
$\sigma_s; \sigma_n; \sigma_i; D_i$	variable
σ_r	3 resource types: CPU, RAM, Storage
$ \mathcal{P}_{n \rightarrow n'} $	$\in [3; 5]$
τ	10^{10}
$W_r; W_h$	0.5; 0.5
$W_d; W_b; W_l$	0.5; 0.5; 0.5
L^{Loc}	10.0 MB
$a_{i,j}$	$\in [5, 30] \times 10^{-3}$ s/MB
$b_{i,j}$	$\in [1, 5] \times 10^{-3}$ s/MB
$c_{i,j}$	$\in [1, 10] \times 10^{-4}$ s

B. Cost and Execution Time Analysis

This section presents a comparative analysis of the three solutions: BFS-CDCA, MA-CDCA, and SA-CDCA focusing on their normalized cost and execution time under varying

conditions. In this analysis, we consider a scenario with 8 services (users) and a variable count of edge nodes σ_n ranging from 2 to 9. For all services i , a duplication factor $D_i = 2$ is used and two settings for chunks fragmentation are considered, $\sigma_i \in \{3; 5\}$, and these values are used as suffixes in the names of each solution to denote their specific configurations. For example, MA-CDCA-3 and MA-CDCA-5 refer to the Markov Approximation-based solution with a chunk fragmentation settings of $\sigma_i = 3$ and $\sigma_i = 5$, respectively.

Fig. 2 shows how the average total cost changes with the number of edge nodes.

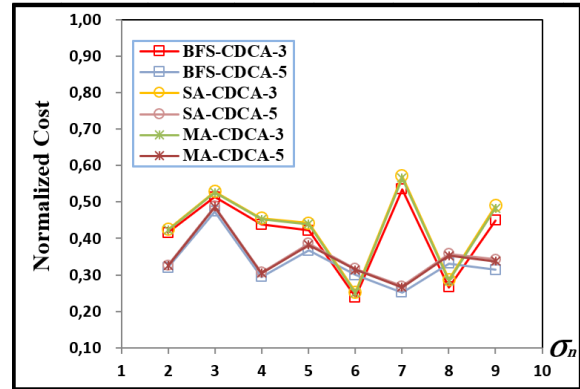

Fig. 2. Normalized Cost; $\sigma_s = 8, D_i = 2, \sigma_i \in \{3; 5\}$.

The results indicate a significant similarity between the three solutions' performance, particularly for $\sigma_n \in \{2; 3; 4\}$ across both settings of σ_i . Furthermore, for $\sigma_c \in \{5; 6; 7; 8; 9\}$, the experiment demonstrates that both MA-CDCA and SA-CDCA solutions achieve costs within 1.1% and 1.3% margin of difference compared to the exact BFS-CDCA solution, respectively.

Likewise, Fig. 3 shows how average execution time changes with the number of edge nodes σ_n .

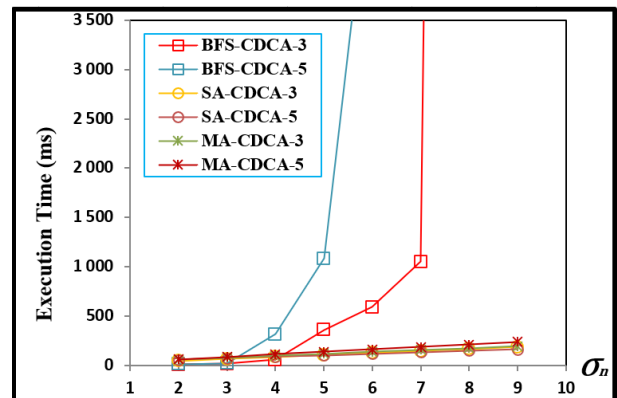

Fig. 3. Execution Time; $\sigma_s = 8, D_i = 2, \sigma_i \in \{3; 5\}$.

The trend in Fig. 3 is confirmed by the data. Execution time increases with the number of edge nodes σ_n , particularly for the BFS-CDCA solution, which exhibits exponential growth. In contrast, the MA-CDCA and SA-CDCA solutions demonstrate stable execution times. For example, with a fragmenta-

tion parameter σ_i of 3 and 9 edge nodes, MA-CDCA-3 and SA-CDCA-3 require only 210.0ms and 229.0ms, respectively, while the exact BFS-CDCA solution reaches impractically high execution times of 6452677.1ms. Similarly, with a fragmentation parameter of 5 and 9 edge nodes, MA-CDCA-5 and SA-CDCA-5 require only 320.0ms and 389.0ms, respectively, whereas the exact BFS-CDCA solution reaches impractically high execution times of 10877142.4ms.

While the number of edge nodes σ_n has the most significant impact on execution time, the results also reveal the influence of the fragmentation parameter σ_i . As σ_i increases, all solutions show a trend of requiring more execution time. This suggests that careful consideration must be given to the fragmentation parameter σ_i to avoid additional processing overhead for the adopted solutions.

C. Service Provision Analysis

Now, this section examines the satisfaction rate for service provision requests, focusing on three main factors: fragmentation, duplication, and service priority. The influence of these factors is analyzed to determine their effects on the overall performance of both the system and the proposed solutions.

1) *Chunks count and duplication factors:* In this experiment, the impact of fragmentation on request satisfaction rates is investigated. This is achieved by controlling two factors related to each service: the per-service duplication factor D_i and The chunk count factor σ_i . In essence, the experiment examines how dividing services into smaller chunks (fragmentation) affects service requests satisfaction. For each service i , the D_i factor is set in $\{1; 3\}$ while the chunk count was varied from $\sigma_i = 1$ (where only a single piece of service data is considered) to $\sigma_i = 8$. Also, the number of services is set to either $\sigma_s = 8$ or $\sigma_s = 16$. These services are deployed across 10 edge nodes ($\sigma_n = 10$) and are assigned equal priority. Moreover, considering the significant impact of data size on the studied timing metric, the CSs' data sizes A_i are generated within the range of $[1, 8]$ MB. For the configuration where $\sigma_s = 8$, the obtained average data size A_i is 4.6 MB, whereas for the $\sigma_s = 16$ configuration, the average is 5.7 MB.

Fig. 4 shows how the Average Collection Time of the selected chunks changes with the number of chunks.

Fig. 4. Average Chunks Collection Time; $\sigma_s \in \{8; 16\}$, $\sigma_n = 10$, $D_i \in \{1; 3\}$.

A preliminary analysis of the results reveals a high degree of similarity between the SA-CDCA and MA-CDCA solutions across most configurations examined. This suggests that both approaches achieve comparable efficiency. For fragmentation levels (σ_i) ranging from 1 to 4, the average collection time consistently decreases across all combinations of service count (σ_s) and duplication factor (D_i). This suggests that a moderate level of fragmentation may improve efficiency in collecting data. In fact, regardless of the service count (σ_s), increasing the duplication factor (D_i) from 1 to 3 consistently reduces the average collection time. This implies that data redundancy introduced by duplication might be beneficial for faster collection. Interestingly, the behavior changes beyond a fragmentation level of 4. Indeed, when $D_i = 1$ (no duplication), the collection time tends to increase regardless of the service count (σ_s). This suggests that excessive fragmentation without redundancy becomes detrimental for collection efficiency. Conversely, with three duplicates of each chunk ($D_i = 3$), the collection time continues to decrease until a fragmentation level of 6, after which it slightly increases. This implies that a higher level of redundancy can tolerate a wider range of fragmentation levels before seeing a performance drop. These observations highlight the importance of considering both fragmentation and duplication when optimizing data collection strategies.

2) *Service priority factor:* The next experiment investigates the influence of service priority under critical resource limitations, where the available resources can meet the requirements of only two CS. Twenty services, all requiring the same resources, were divided into two groups of ten. The first group (GU) received a uniform priority ($\pi_i = 1$). The second group (GG) received graded individual priorities assigned from 10 (highest) to 1 (lowest). The experiment was conducted over five rounds, with served services removed from the pool for subsequent rounds. This setup allowed the study of the global penalization function, which evaluates the overall penalty incurred due to unmet service requests based on priority levels. Additionally, the obtained average normalized cost was analyzed to understand how the changing priority of the variable service affects the efficiency of service delivery.

Fig. 5 illustrates how the Average Normalized Cost and the overall penalization evolve as the rounds progress.

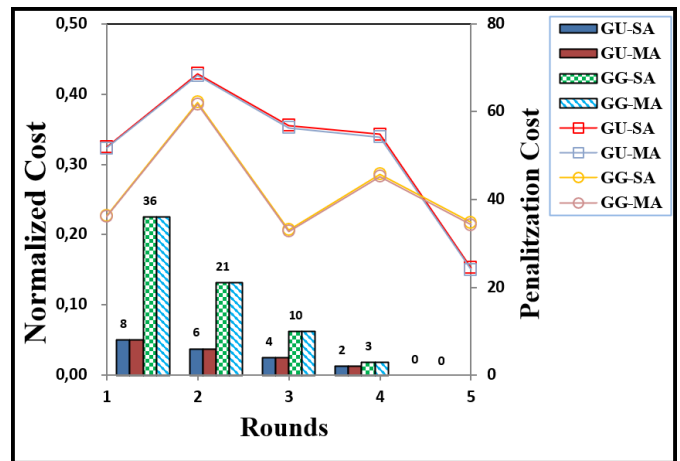

Fig. 5. Normalized cost (line chart), penalization cost (bar chart); $\sigma_s = 20$, $\sigma_n = 12$, $D_i = 2$, $\sigma_i = 2$.

In terms of Normalized Cost, the two algorithms, SA-CDCA and MA-CDCA, yield nearly identical costs for the cost related objective function. However, the MA-CDCA algorithm has a minor edge in terms of cost making it slightly more effective. Furthermore, the penalization cost for all priority groups (GU, GG) and algorithms (SA, MA) consistently decreases across the rounds. This indicates a general improvement in performance over execution rounds in terms of penalized CS. Indeed, in the GU group, where all equipment possesses a uniform priority ($\pi_i = 1$), the consistent decrease in penalization cost by 2 units per round implies that two CS are being served consistently each round. Similarly, in the GG group, the decreasing rate in penalization cost implies that the highest priority equipment is being served consistently, leading to a reduction in penalties. In other words, the adopted prioritization strategy effectively prioritizes high-priority CS.

D. Blockchain-based Caching Analysis

The third experiment investigates how replicating services influences time overhead. To understand the effect of varying fragmentation levels, four different chunks' count scenarios ($\sigma_i = 1$ to $\sigma_i = 4$) are considered, each with 1 and 3 duplicate scenarios for each of the σ_s services ($\sigma_s \in \{8, 16\}$). This experiment aims to analyze how different levels of fragmentation and duplication impact the overall time overhead. Throughout the experiment, all services are assigned the same priority, and a fixed number of edge nodes ($\sigma_n = 10$) is maintained. For each service, the Blockchain-related (BC) Time Overhead is calculated as the maximum operational time across all the involved blockchain nodes, as given by equation 3. The maximum is taken because BC operations are performed in parallel. Then, the total time overhead for the system is obtained by summing these maximum times for all σ_s services.

Fig. 6 shows how the Overall Blockchain-related Time Overhead changes as the fragmentation progresses.

Fig. 6. Overall blockchain-related time overhead; $\sigma_s \in \{8; 16\}$, $\sigma_i \in \{1; 2; 3; 4\}$, $\sigma_n = 10$, $D_i \in \{1; 3\}$.

As the services are divided into an increasing number of chunks (σ_i), the time overhead associated with the blockchain operations decrease. Indeed, with lower fragmentation levels, the time overhead is relatively high due to fewer parallel operations being performed. However, as the fragmentation

level increases, more chunks are processed in parallel across the blockchain nodes, resulting in a reduction in processing time. This trend is observed consistently, regardless of the number of services or duplicates involved. Additionally, the total time overhead clearly increases with a higher number of services, as more cache blocs are processed. Conversely, the total time overhead decreases with an increase in the number of duplicates, as the redundant data allows for more flexible decisions regarding the timing characteristics of the caching blockchain nodes. Hence, the results clearly highlight the positive impact of service fragmentation and replication on reducing the time overhead caused by blockchain-related operations. These insights are essential for the development of efficient cache management mechanisms within the investigated blockchain-based systems.

IX. CONCLUSIONS AND PERSPECTIVES

This paper investigates the fusion of Multi-access Edge Computing (MEC) capabilities with blockchain technology to address the low-latency and safety requirements of Smart Devices (SDs). The emphasis was placed on examining the role of a split-duplicate-cache method within a secure blockchain-enhanced MEC system, with the objective of enhancing service provision. An optimization problem was derived and solved with the objective to reduce the backhaul bandwidth and the number of hops between the serving node and the selected deployment node. The experimentation assessed the performance of the three proposed solutions: MA-CDCA, SA-CDCA, and BFS-CDCA. The analysis revealed that BFS-CDCA performed best in smaller-scale settings, while MA-CDCA and SA-CDCA showed efficient execution times, especially in configurations with a high number of CBICs, replicas, ENs, and CSs. Additionally, it was demonstrated that the fragmentation-replication methodology positively impacts the Blockchain operational time overhead.

Future research could focus on evaluating the scalability of MA-CDCA and SA-CDCA in larger, more complex scenarios and assessing their real-world deployment in smart cities and IoT networks. Additionally, exploring the security implications, energy efficiency, and impact on end-user experience could provide valuable insights into the practical benefits and limitations of these solutions.

Abstract—To address the lack of Chinese online course review corpora for aspect-based sentiment analysis, we propose Semantic Token Augmentation and Replacement (STAR), a semantic-relative distance-based data augmentation method. STAR leverages natural language processing techniques such as word embedding and semantic similarity to extract high-frequency words near aspect terms, learns their word vectors to obtain synonyms and replaces these words to enhance sentence diversity while maintaining semantic consistency. Experiments on a Chinese MOOC dataset show STAR improves Macro-F1 scores by 3.39%-8.18% for LCFS-BERT and 1.66%-8.37% for LCF-BERT compared to baselines. These results demonstrate STAR's effectiveness in improving the generalization ability of deep learning models for Chinese MOOC sentiment analysis.

Keywords—Data augmentation; sentiment analysis; MOOC; natural language processing; deep learning

I. INTRODUCTION

The rise of information technology has facilitated the sharing of experiences via online platforms, leading to significant growth in User Generated Content (UGC). Researchers have utilized Natural Language Processing (NLP) and machine learning to extract valuable insights from UGC on topics such as product attribute extraction [1], [2], [3], consumer preference patterns [4], [5], [6], and public sentiment monitoring [7], [8]. These studies enhance text mining applications and support data-driven consumer behavior analysis, product improvement, and market strategies.

Massive Open Online Courses (MOOCs) have generated extensive online course reviews, providing insights into learner preferences and teaching effectiveness. Analyzing these reviews aids educators in improving courses. Automated sentiment analysis, using machine learning algorithms, efficiently processes large volumes of review data, offering insights for student feedback [9], course evaluation [10], and teaching quality assessment [11]. These techniques facilitate data-driven decision-making in education.

Despite the growing interest in sentiment analysis for Chinese MOOC review data, challenges still exist including a scarcity of annotated corpora, leading to overfitting and class imbalance issues. Data augmentation (DA) techniques can expand training datasets while preserving labels. Although DA techniques have been applied in various NLP tasks, including natural language inference [12], [13] and sentiment analysis [14], [15], [16], there remains a research gap in DA strategies for Chinese educational review data.

This paper proposes a novel approach, Semantic Token Augmentation and Replacement (STAR), to address Chinese text augmentation challenges in the educational domain. STAR uses semantic relative distance calculation to augment training datasets and balance sentiment polarity in Chinese MOOC reviews.

The main contributions of this work are as follows:

- 1) We propose STAR, a novel augmentation method that utilizes external knowledge bases and semantic relative distance calculation to rapidly augment small sample datasets. STAR maintains the semantic accuracy of original review sentences while balancing sentiment distribution in augmented samples. We demonstrate its effectiveness across three BERT model variants (LCFS-BERT, LCF-BERT, and BERT-SPC) for Chinese MOOC sentiment analysis.
- 2) We conduct a comparative analysis of Word2Vec and BERT Encoding for word vector generation in STAR, employing uniform sampling for synonym replacement. This comparison provides insights into the optimal word embedding approach for data augmentation in aspect-based sentiment analysis of Chinese MOOC reviews.
- 3) To the best of our knowledge, we first present the synonym replacement-based data augmentation to Chinese review datasets, demonstrating its effectiveness in improving aspect-based sentiment analysis performance in this specific domain.

The rest of this paper is organized as follows: Section II presents related work. Section III and Section IV describe the proposed method in detail. The experimental results and analysis are presented in Section V and Section VI. Section VII concludes our study and points out the research work in the future.

II. RELATED WORK

Data augmentation aims to increase the diversity of training samples by synthesizing new data from existing datasets [17], [18]. It has been widely applied in various NLP tasks, including named entity recognition [19], [20], natural language inference [21], and sentiment analysis [22], [23]. Wei et al. [24] introduced an Easy Data Augmentation (EDA) that employs methods like synonym replacement, random insertion, deletion, and swapping. Their experiments improved significantly performance on text classification tasks, especially for smaller datasets. To address the limitations of random insertion

and swapping approaches, Karimi et al. [25] introduced an Easier Data Augmentation (AEDA), which randomly inserts punctuations into the original text while maintaining word order. This method offers easier implementation and preserves all input information, leading to enhanced generalization performance. For sentence-level named entity extraction, Dai et al. [18] improved experimental results through label-oriented token and synonym replacement, demonstrating their approach using Transformer models on biomedical and materials science datasets.

Synonym Replacement (SR) stands out as a simple yet effective data augmentation method. It replaces selected words with synonyms from WordNet or similar words from word embeddings, maintaining the original sentence semantics [26], [27]. Claude et al. [28] implemented synonym replacement and spell checking via Cloud API, achieving 4.3%-21.6% accuracy improvements in deep networks like LSTM and BiLSTM. For Aspect-Based Sentiment Analysis (ABSA), Zhang Rong et al. [29] developed Multi-Level Data Augmentation (MLDA), improving Accuracy and Macro-F1 by 1.2% 3% on the Rest dataset compared to LSA-BERT.

However, most studies have focused on English text, with limited exploration of Chinese text augmentation, particularly for educational review data. To address this gap, we propose Semantic Token Augmentation and Replacement (STAR), a novel approach leveraging semantic relative distance calculation for Chinese MOOC course reviews. STAR utilizes external corpus knowledge to augment training data and balance sentiment polarity distribution. We evaluate STAR using three BERT variants (LCFS-BERT, LCF-BERT, and BERT-SPC), demonstrating significant improvements in model performance and generalization capability for educational data mining tasks.

III. METHODOLOGY

Let $S = \{t_1, t_2, \dots, t_n\}$ denote a sentence of n tokens, where t_n represents the n th token. We define the aspect term set $A = \{t_{m+1}, \dots, t_{m+k}\}$ and the opinion term set $O = \{t_{n-k+1}, \dots, t_n\}$, where $A, O \subseteq S$. The sentiment polarity set is given by $P = \{\text{positive}, \text{negative}\}$. The sentiment classification model computes the sentiment polarity of various aspect terms within a review. It computes a function $f: A \times O \rightarrow P$, which maps aspect terms and their associated opinion terms to sentiment polarities based on local context analysis.

For instance, in the sentence, as shown in Fig. 1, *The course is really good, but the picture is blurred.* we have aspect terms $A = \text{"course", "picture"}$ and opinion terms $O = \text{"good", "blurred"}$. The model would classify $f(\text{"course", "good"})$ as positive and $f(\text{"picture", "blurred"})$ as negative, demonstrating its ability to discern different sentiment polarities for various aspects within a review.

The lack of annotated corpus resources presents a significant challenge in training deep learning models, especially in specialized domains requiring expert evaluation of annotation quality. To address this limitation and enhance the generalization capability of neural network models, researchers have employed various data augmentation techniques, including word transformation, sentence order alteration, and back-translation

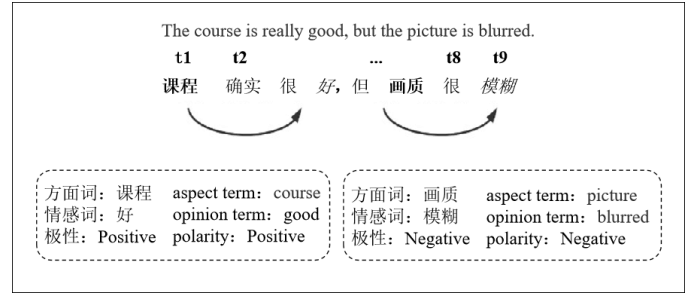

Fig. 1. Course aspect sentiment analysis example.

[16], [24], [30], [31]. These techniques aim to generate diverse training sentences while preserving semantic integrity.

To address these challenges, we propose three data augmentation approaches tailored specifically to Chinese MOOC course review data. These approaches aim to expand the training sample size while preserving the original labels, thereby reducing the loss function value during the deep learning model training process, as shown in Eq. 1. This approach seeks to enhance the extraction and identification of course-related content and its associated sentiment polarities.

$$\arg \min_{\theta} \frac{1}{N} \sum_{i=1}^N L(y_i, f(x_i, \theta)) \quad (1)$$

Where $L(\cdot)$ denotes the cross-entropy loss function, θ represents the optimization parameter set, $f(x_i, \theta)$ is the decision function, and N is the number of training samples.

Due to the imbalance in the distribution of sentiment polarity in the training data, we employ Eq. 2 to keep the number of positive and negative samples the same size, thereby addressing the overfitting issue during the training process.

$$N' = (1 + N) \times rate \quad (2)$$

Here, N represents the original dataset sample size, $rate$ denotes the augmentation rate, and N' indicates the sample size in the new dataset after augmentation, accounting for the augmentation rate and sentiment polarity distribution ratio.

IV. PROPOSED DATA AUGMENTATION METHODS

We propose and implement three augmentation methods, namely, Semantic Token Augmentation and Replacement (STAR), Aspect Replacement (AR), and Token Replacement TF-IDF (TRT). We first focus on the STAR method, followed by AR and TRT. The STAR method is the core augmentation approach in this study, leveraging semantic relative distance calculations to enhance the training dataset. The AR method focuses on aspect word replacement, while the TRT method utilizes TF-IDF values to identify replacement candidates. These methods aim to expand the training dataset while preserving original labels, thereby improving model performance in sentiment analysis tasks.

A. Semantic Token Augmentation and Replacement (STAR)

This approach employs token replacement based on semantic relative distance, utilizing Word2Vec to identify similar words and generate a new training dataset. To preserve semantic integrity, the augmentation process avoids replacing words near core words, as these typically better express sentiment or opinion. Our analysis revealed that 75% of sample sentences exceed 18 words in length. Consequently, we set the Semantic-Relative Distance (SRD) threshold to 5. When a non-stop word's semantic relative distance from the core word surpasses this threshold, it is replaced with a similar word, generating a new sentence as shown in Fig. 2.

Fig. 2. STAR augmentation approach.

To maintain the semantic relationships of sentiment polarity words in the original sentence, adjective and adverb tokens outside the aspect word area remain unchanged during augmentation.

The SRD calculation process involves the following steps:

- 1) Initialize the SRD threshold to 5 and set the augmented quantity $augNumI$ to 0. While $augNumI$ is less than the specified augmentation quantity $augNum$, iterate through the original data and calculate the quantity to be augmented.
- 2) Designate aspect words from the specified area as stop words. Use the Jieba word segmentation tool to annotate parts of speech and add adjectives to the stop word set. The remaining words become the *randomWords* for augmentation. During candidate word traversal, replace words using similar words from the augmentation dictionary via uniform sampling.
- 3) Regulate the sample augmentation quantity to ensure the training set's augmentation meets requirements. Save results in *augData* and return the augmented dataset.

Algorithm ?? presents the STAR algorithm's pseudo-code, with input parameters including *index* (augmentation dictionary), *dataframe* (data to be augmented), and *augNum* (augmentation quantity). The algorithm outputs the augmented dataset.

B. Aspect Replacement (AR)

This approach leverages BERT for aspect word semantic similarity matching. It randomly selects aspect words from a synonym dictionary using uniform sampling, replaces original aspect words in the sentence with these selections, and updates the corresponding aspect words in the training data.

Algorithm 1 Semantic Token Augmentation and Replacement (STAR) algorithm pseudo-code

```

1: Input: index, dataframe, augNum;
2: Output: Augment dataset augData
3: srd = 5
4: augNumI = 0
5: while augNumI < augNum do
6:   for each rowi in dataframe do
7:     augProportion = maxNum of augment per sentence
8:     left = aspectindex - srd
9:     right = aspectindex + srd
10:    srdWords = words[left : right + 1]
11:    adjWords = Filter tags starting with A by jieba
12:    stopWords = stopWords ∪ srdWords ∪ adjWords
13:    randomWords = Wordlist ∉ stopWords
14:    rowAug = 0
15:    for each wordi in randomWords do
16:      if word not in index or similar words is NULL
17:    then
18:      continue
19:    end if
20:    synonymsList = synonym for wordi in index
21:    for each synonyms in synonymsList do
22:      sentencen = Replace word in sentence with
23:      synonyms
24:      augData = sentence ∪ augData
25:      augNumI = augNumI + 1
26:      rowAug = rowAug + 1
27:      if augNumI = augNum then
28:        return augData
29:      end if
30:      if rowAug ≥ augProportion then
31:        break
32:      end if
33:    end for
34:    if rowAug ≥ augProportion then
35:      break
36:    end if
37:  end for

```

C. Token Replacement TF-IDF (TRT)

Token Replacement TF-IDF (TRT) follows these steps:

- 1) Calculate the TF-IDF value for each token.
- 2) Identify replacement candidates: non-stop words, non-aspect words, with a distance greater than 1 from aspect words.
- 3) For each candidate, compute its weight as $w_i = \text{tfidf}_{\max} - \text{tfidf}$.
- 4) Determine each candidate's position in the sentence.
- 5) Using the synonym dictionary in the augmentation index, uniformly sample one token from 10 candidate synonyms for each replacement candidate. If no synonyms are available, retain the original token.
- 6) Save the augmented dataset and return the results.

These data augmentation methods expand the training dataset while preserving original labels, thereby enhancing model performance in downstream tasks.

V. EXPERIMENTAL SETTINGS

We conducted experiments on a real-world dataset of Chinese MOOC course comments to evaluate the effectiveness of our proposed data augmentation methods. Our experiments focused on aspect-level sentiment classification, comparing the performance of LCFS-BERT, LCF-BERT, and BERT-SPC models across different training set sizes. We analyzed the impact of our data augmentation methods on model performance and evaluated the effectiveness of these methods in enhancing model generalization capability.

A. Data Source

The data used in this study is sourced from course reviews on the China University MOOC website. After data cleaning and annotation, we obtained 1,971 valid data points, which were classified into positive and negative categories based on sentiment polarity. Among them, there are 1,550 positive reviews and 421 negative reviews, with a positive-to-negative sample ratio of approximately 3.7:1. Due to this imbalance in the number of positive and negative samples, there is a certain degree of imbalance in the performance of the training samples across these categories.

We analyzed the distribution of positive and negative polarities across various course aspects, as detailed in Table I. For sentences containing multiple aspect words, we split them into multiple samples to ensure that each sample contains only one aspect word.

B. Experimental Procedure

In the experiment, we first randomly shuffle the original data and then split it into training and testing sets at an 8:2 ratio. To ensure that the testing set and training set are mutually exclusive, meaning that testing samples do not appear during training, we implemented strict data partitioning measures.

Subsequently, we extract 50, 150, 300, and 500 samples from the training set to form new training subsets, ensuring that the sentiment polarity ratio in the new training subsets remains consistent with the original training set. For each new training subset, we use three data augmentation methods to expand it, ensuring that the augmented training data remains balanced in terms of sentiment polarity.

To compare the effectiveness of different data augmentation methods, we kept the sentiment polarity ratio unchanged in the testing set. For example, STAR_150_3 indicates that 150 samples are extracted according to the sentiment polarity ratio in the original training set. Using the STAR augmentation method, we expand it to 600 samples, including the original samples. After replacing aspect terms with $ST\$$, these data are input into the deep learning model for training.

C. Parameter Configuration

To balance the training efficiency and generalization ability of each model, ensuring good performance on MOOC data, training stops when the loss function value on the validation set is minimal for the LCFS-BERT, LCF-BERT, and BERT-SPC models.

In terms of model training, the Chinese BERT [32] is used as the pre-trained language model, with the Adam optimizer updating the model weights. The learning rate is set to 0.00002 to control the rate at which the model weights are updated. The training dataset is iterated for 10 epochs, with a batch size of 16 for each iteration. To reduce the risk of overfitting and improve the model's generalization ability, a dropout rate of 0.5 is used. Additionally, to control sequence length, reduce the model's computational complexity, and avoid negative impacts on the loss function from overly long sequences, the maximum sequence length is set to 80.

D. Experimental Results

In the experiment, aspect-based sentiment classification models based on BERT were selected: LCFS-BERT [33], LCF-BERT [34], and BERT-SPC [35]. We compared the performance of our three proposed augmentation methods against the baseline results from training on the original dataset. Furthermore, we analyzed the performance of these models across different training set sizes, using Macro-F1 as the evaluation metric for the model's effectiveness.

As shown in Table II, we can see the performance of the three augmentation methods across different sample sizes and models. Bold underlined values indicate the highest score in the current training batch.

With the increase in training data, different augmentation methods showed the varying performance improvement on each model. For instance, after applying the STAR method, the Macro-F1 score of the LCFS-BERT model improved from 71.9% to 92.27%. Models trained with augmentation methods outperformed those trained with original data alone. For the LCFS-BERT model, after using STAR, AR, and TRT methods, the Macro-F1 scores were 92.27%, 78.92%, and 78.2%, respectively. However, for the BERT-SPC model, the original dataset's Macro-F1 score was better than the results with data augmentation methods at 150 training samples. It was mainly due to the introduction of excessive noise text in the augmentation experiment, weakening the semantic correlation between aspect words and sentiment words.

To comprehensively evaluate and compare the effectiveness of the STAR augmentation method across different models and dataset sizes, the model performance curve shown in Fig. 3 visually demonstrates the improvement effect of the STAR augmentation method on model performance.

Fig. 3. Model performance comparison chart.

As shown in Fig. 3, the STAR method consistently outperforms the other two augmentation techniques, particularly in enhancing model generalization on small datasets. Compared

TABLE I. STATISTICS FOR SENTIMENT POLARITY OF COURSE ASPECTS

Sentiment Polarity	Teaching Evaluation	Teaching Content	Teaching Cost	Platform Health	Teaching Interaction	Teacher	Course Structure	Course Video
Positive (count)	62	571	16	11	639	76	117	58
Negative (count)	74	133	3	38	65	23	33	52
Total	136	704	19	49	704	99	150	110
Positive Ratio	45.59%	81.11%	84.21%	22.45%	90.77%	76.77%	78.00%	52.73%

TABLE II. COMPARISON OF MODELS' PERFORMANCE(%)

Model	Method	50	150	300	500
LCFS-BERT	STAR	71.90	87.72	88.72	92.27
	AR	78.92	82.84	84.93	91.41
	TRT	78.20	82.46	81.12	88.46
	No_Aug	64.23	79.54	85.33	87.48
LCF-BERT	STAR	71.90	86.78	88.22	92.26
	AR	78.54	83.68	86.34	91.20
	TRT	78.32	80.26	85.09	89.69
	No_Aug	67.79	78.41	86.56	89.26
BERT-SPC	STAR	73.80	78.00	88.80	92.49
	AR	73.03	82.22	88.34	88.75
	TRT	69.62	84.04	87.35	91.58
	No_Aug	57.34	86.70	82.97	91.02

to training results without augmentation, all three augmentation methods generally improved Macro-F1 scores, with STAR showing outstanding comprehensive performance across all three model types.

VI. DISCUSSION AND ANALYSIS

This paper explores the application of augmentation methods in sentiment analysis tasks for text data. The analysis of experimental results indicates that augmentation methods positively impact model performance. The following analysis is conducted from two aspects: the implementation ideas of the augmentation methods and the performance of the models.

- From the perspective of the implementation ideas of the augmentation methods:
 - The AR augmentation method differs from the other two augmentation methods. It replaces aspect words in sentences and uses BERT Encoding for synonym generation, which can reduce the impact of replacement words on the context. According to experimental results,

AR improves the model's classification performance compared to the baseline model, but the improvement is not as significant as that of STAR. The main limitation of AR is that it only replaces aspect terms without altering other tokens in the sentence. Consequently, AR generates sentences with a uniform structure, offering less potential for improving the model's generalization capability compared to the other augmentation methods.

- For the TRT augmentation method, replacing words within the local context of a term can introduce textual noise. This can impact the model's ability to extract syntactic features, thereby affecting its classification performance.
- From the perspective of model performance:
 - The overall enhancement effect of the LCF-BERT model is slightly inferior to that of the LCFS-BERT model. Considering that the LCF-BERT model calculates semantic relative distance based on word distance, both AR and TRT methods perform word replacements close to aspect words, so the actual word distance does not change. However, for the LCFS-BERT model, which calculates semantic relative distance based on syntax trees, the model can better understand the local context related to aspect words.
 - Both AR and TRT methods perform word replacements within the local context of aspect words, introducing some noise in the model's recognition of local context. Therefore, their effectiveness is weaker than that of the STAR method.

According to experimental results, the STAR augmentation approach shows better enhancement effects on small sample training sets compared to AR and TRT methods and can also quickly augment according to the specified multiplier. Currently, the experimental results only provide a statistical analysis of the classification performance of each model when the original dataset is augmented by a single multiplier. However, for high-multiplier augmentation methods, further experimental verification is needed to compare the performance of

the three augmentation methods.

VII. CONCLUSION AND FUTURE WORK

In this paper, we propose a novel semantic relative distance-based augmentation method (STAR) to address the lack of labeled data corpus for Chinese course reviews. This method combines augmentation techniques with the BERT pre-trained model to mine the sentiment tendencies in the text. To improve the generalization ability of the deep learning model and discover more sentiment tendencies related to course teaching in the text, the STAR method integrates external knowledge and semantic relative distance calculation and then conducts experiments.

The experimental results show that after using the STAR method, the Macro-F1 values of the LCFS-BERT model and the LCF-BERT model increased by 3.39% to 8.18% and 1.66% to 8.37%, respectively, indicating the effectiveness of this augmentation method. Our experiments are based on aspect-level sentiment classification models using a local context attention mechanism.

In the future, it is necessary to further explore and validate the effectiveness of high-ratio data augmentation and the applicability of the STAR augmentation method under other language models. Additionally, it is essential to deeply explore and optimize data augmentation techniques to adapt to the characteristics of Chinese education review data, thus providing more accurate and effective support for data analysis and decision-making in the education field.

Abstract—The image style transfer operations are a kind of high-level image processing techniques, in which a target image is transformed to show a given style. These kind of operations are typically acquired with modern neural network models. In this paper, we aim to achieve the image style-transfer operations in real time, with the underlying computer games. We can apply the style-transfer operations to the all or part of rendering textures in the existing games, to change the overall feeling and appearance of those games. For a computer game or its underlying game engine, the style-transfer neural network models should be executed so fast to maintain the real-time execution of the original game. Efficient data management is also required to achieve deep learning operations while maintaining overall performance of the game as much as possible. This paper compares several aspects of style-transfer neural network models, and its executions in the game engines. We propose a design and implementation way for the real-time style-transfer operations. The experimental result shows a set of technical points to be considered, while applying neural network models to a game engine. We finally shows that we achieved real-time style-transfer operations, with the Barracuda module in the Unity game engine.

Keywords—Style transfer; neural network models; game engine; rendering textures; real-time operations

I. INTRODUCTION

Game engines are now general development tools, which help users develop games conveniently through providing the functionalities needed to develop any kind of computer games. A game engine typically includes a *rendering module* that draws objects on the screen, a *physics simulation module* for adding physically-simulating effects, such as collisions and/or gravity effects, a *sound module* for background music and/or sound effects, and an *event processing system* for user input and system events [1].

It can also support network communication features, external database connections, and on-line storage connections for storing or retrieving information about users or data for the game. A game engine is now typically a complex and heavy program, since it provides various sets of functions, as show here.

Recently, game engines are emerged to support machine learning features, typically as *add-on* modules. Actually, in artificial intelligence and machine learning fields, various researches and developments have drawn much attentions from general public persons. For example, *AlphaGo*[2] which is artificial intelligence in the game of *Go*, *AlphaStar*[3] which is artificial intelligence in the *StarCraft 2*, and *Vizoom* [4]

which is a study that trains neural networks to play the first-person shooter game *Doom* through visual information. These artificial intelligence works are implemented based on the *deep reinforcement learning* [5]. Due to the remarkable achievements of deep reinforcement learning, many studies of artificial intelligence used in the computer games are mainly focused on reinforcement learning.

In fact, the artificial intelligence methods can be used in a variety of ways, even in game-specific applications. Recently, artificial intelligence has also been used in the areas of creation, such as painting pictures as sophisticated as photographs [6], writing [7], or music composing [8]. Several major gaming companies carry out research on the generation of images, animations, music, etc. to be used in games across various neural networks. These game resources are usually created outside of the game engine, and the generated resources are provided in the general file formats. The game engines read those resource files, and then use them in the games.

We expect that it would be innovative to generate resources such as images, videos, and sounds through neural networks inside the game engine and apply them to the game in real-time. However, most generative neural networks are too slow for real-time applications. Thus, applications of neural network models to real-time games are limited to relatively simple neural network models to quickly generate game resources.

In this work, we focused on the convergence development of real-time games and artificial intelligence models, through applying generative neural networks in real-time. More precisely, we focused on the *image style transfers* [9] to generate the texture images in real-time, as game resources, as shown in Fig. 1.

The texture images are used for various purposes in the game, and thus, our work can also be extended to the various applications. In contrast, the style transfer is not possible to be implemented in other ways except machine learning methods. Thus, it is a good case study for game engines, which support machine learning features. The image style transfer is even more practical, since it can be easily adopted for the special effects in games.

Applying style transfer methods to the real-time games shows some technical issues. Firstly, the resulting images of the neural network models should be generated quickly so that it can be applied in real-time. Thus, efficient architectural models for running the game itself and also the neural network models simultaneously are needed.

Fig. 1. An example of the style-transfer operation.

Fig. 2. The overall structure of the feed-forward style-transfer neural network model [11].

In this paper, we will solve those technical issues. From the viewpoint of execution speeds, we aim to achieve real-time performance even with applying neural networks that perform style transfer. We will use a commercial game engine, as the case study, which provides machine learning model drivers to analyze and optimize the inter-working method to check performance and limitations.

II. RELATED WORKS

The *style transfer method* can be achieved by neural network models which create the resulting images by transferring the image styles of the given style images to the content images. The work performed by the neural network model can be checked through the resulting image created with the content image and style image, as shown in Fig. 1.

The key concept in the style transfer method is that it is possible to separate content and style from an image, by extracting features of the image through a set of trained convolution layers [10]. The initial style transfer method [9] operated by gradually transforming the input image through gradient descent, and it took a long time to obtain the resulting image, making it difficult to process video streams or real-time applications.

Later, the *Feed-Forward style transfer method* [11] was proposed, which solved the problem of slow conversion speed. This method generates the transformed image at once through the *encoder-decoder* networks. As shown in Fig. 2, this method creates a transformed image by receiving the content image from the *Image Transform Net*, which is actually an encoder-decoder network. The input image is separated into the content image and the style image. The trained VGG (Visual Geometry

Fig. 3. The overall structure of the AdaIN style-transfer neural network model [13].

Group) neural network [12] calculates content loss (L_c) and style loss (L_s), respectively, and then trains the *Image Transform Net* through the back-propagation. Since the entire neural network is trained on a single style image, it can be suitable for a single style transfer.

Style transfer methods with *Adaptive Instance Normalization* (AdaIN) [13] can be used for arbitrary number of style images, even in real-time or at least in pseudo real-time. The AdaIN layer calculates the *mean* and *variance* for each channel of the features extracted from the content images and the style images. Then, it normalizes the means and variances of the content images, with respect to the means and variances of the style images.

The *AdaIN* operations can be summarized as the following equation:

$$\text{AdaIN}(x, y) = \sigma(y) \frac{x - \mu(x)}{\sigma x} + \mu(y), \quad (1)$$

where μ is the mean and σ is the variance function, from statistics. The parameter x is the feature values extracted from the content image through the VGG encoder, while the parameter y is the feature values from the style image through the VGG encoder.

As shown in Fig. 3, VGG encoder is trained by classification tasks and network weights are fixed. Since AdaIN has no parameters used for learning, training is performed only on the VGG decoder part. There are two loss functions used for training: *content loss* (L_c) and *style loss* (L_s) functions. The differences between the results of applying VGG encoder to the images that has been constructed through VGG decoder, and the results obtained when the content images go through VGG encoder and the AdaIN layer, are defined as the content losses. Similarly, the differences between the results of applying VGG encoder to the images that has been constructed through VGG decoder and the style images are defined as the style losses. The final objective function is the sum of content losses and style losses, and the VGG encoder is trained to minimize it.

For a computer game or its underlying game engine, the style-transfer neural network models should be executed so fast to maintain the real-time execution of the original game. Unfortunately, the previous works are insufficient to get real-time results, and we aim to get the style-transfer operations in real-time or even in pseudo real-time. In the next sections, we will show our experimental details and the results.

Fig. 4. A typical execution order of Unity event functions.

III. EXPERIMENTAL ENVIRONMENT

A. System Configurations

Our system configuration for the experiments are as follows:

- CPU : Intel Core i7, 2.30 GHz
- GPU : NVIDIA GeForce RTX 2060
- Main Memory : 16GB
- Operating System : Windows 10 Pro 64bit Edition

As shown here, we used typical commercial PCs with mid-tire computing powers, rather than high-tire ones, for more practical uses and more real-world experimental results.

B. Game Engine Integration

Our work is carried out on the *Unity* game engine. It manages various functions necessary for game development in module units. Each module must be operated efficiently at an appropriate time, according to the characteristics of the game to be made, to obtain a positive response from game service users. Each module is controlled through *event functions*. Event functions perform actions that need to be handled at a specific point in time or situation in the game.

The *Unity* game engine provides many event functions to control modules in various situations, so it is inadequate to mention all of them in this paper. Taking it into consideration, the execution orders of the event functions are iterated in groups, according to their purpose, as shown in Fig. 4.

At the start of the event processing loop, event functions for *initializing* the game are called, and then event functions related to *physical effects* are called. Physical effects are updated separately from the main thread at a specified time through a reliable timer system. By applying this method, if the physical effects are not updated within a fixed time interval, it can be applied inaccurately unlike in reality, but it is possible to prevent unexpected situations, in which screen rendering is delayed until all the physical effects are applied.

TABLE I. COMPARISON OF *Unity* AND *Self-Engine* GAME ENGINES, ACCORDING TO THE MACHINE LEARNING FEATURES

game engine	Unity	Self-Engine
machine learning module	ML-Agents	Neuro
programming language	Python, C#	C++
training	Pytorch, Tensorflow	cuDNN
inferencing	Barracuda	cuDNN
additional features	support reinforcement learning	lightweight learning

Then, the *input* event functions are called to handle user inputs to interact with the game. Next, *game logic* event functions that perform calculations for various decisions to be performed in the game are called, and event functions that draw the screen with the data updated so far are called. Next, the event function that defines the action to be applied to the *end of the frame* is called, and the event function specifies the action to be performed when it is decided to make the object be *disabled or enabled* in the game scenario is called. Finally, when the game ends, event functions for resource *decommissioning* are called.

C. Machine Learning Modules for Game Engines

Before starting our full-scale experiments, we investigated several game engines, for their features which support machine learning models, and also the overall environment for the inference executions. At that time, the *Unity* engine is one of the best-suitable commercial game engines, and it officially supports machine learning features. We also compared those features with the *Self-Engine* [14], which is an open-source, lightweight game engine which supports machine learning models, as shown in Table I.

Unity supports the *Unity Machine Learning-Agents Toolkit* (or shortly, *ML-Agents*) [15], which is an add-on module to apply machine learning features to the games. In *ML-Agents*, the *C# scripting language* [16] is used to train neural networks in the game engine environment. *Python terminals* [17] work in conjunction with it, for neural network training.

For the general cases, the machine learning modules for neural network training in the Python environment can be selected from *PyTorch* [18] and *TensorFlow* [19], which are already familiar to AI researchers. In contrast, since we use *ML-Agents* for functional inferences, we had better to use *Barracuda* [20], which is a specialized module that executes pre-trained neural network models with C# scripts. Additionally, *ML-Agents* support other various functions to efficiently perform reinforcement learning.

Self-Engine uses *Neuro* [21] for its machine learning module. Both the game engine itself and the machine learning module are implemented in the same C++ programming language and thus, the machine learning module is naturally integrated into the game engine. With the integrated machine learning module, neural network training and inferences are performed in the similar manner. In the *Self-Engine*, the machine learning

Fig. 5. The internal structure of the ML-Agent module.

module of Neuro internally uses *cuDNN* [22] as its underlying deep neural network operation tools.

Actually, Self-Engine is a lightweight game engine implemented as an open-source, and its internal structure is less complex than that of commercial game engines. However, at least at this time, most of artificial intelligence researchers prefer PyTorch and TensorFlow, and Self-Engine has fewer convenient features compared to Unity, which officially supports machine learning modules. Conclusively, in our experiments, we use the Unity game engine, as our major target system.

IV. IMPLEMENTATION DETAILS

A. ML-Agents Features

The ML-Agents performs training between the *Unity editor* and the *Python terminal* via *Inter-Process Communication* (IPC), as shown in Fig. 5. The two processes conduct training by exchanging data with each other in socket communication. For this purpose, ML-Agents must be installed in both Unity editor and Python terminal respectively. ML-Agents installed on the Unity editor side is implemented in the C# programming language, which is part of the Learning Environment. ML-Agents installed on the Python side is the Python API part, as shown in Fig. 5.

After each installation, the Unity editor needs to set up a project to use ML-Agents. An object to be used as an agent must be placed in the scene of the Unity editor, and Behavior Parameters and Decision Requester script must be added to the object as components. In the Behavior Parameters script, the agent specifies the settings for the information the agent wants to observe in the environment, and when not used in the learning mode, the neural network model saved as an *ONNX file* [23] to be used for inference.

After that, we implemented the actions to be performed by the agent by inheriting the Agent Class, and also the observation data to be sent to the Python module during training and the processing to be performed when the data is received from the Python module. After implementing the internal functions by inheriting the Agent Class, write a Python script using the ML-Agent Python Low-Level API to access the Unity process from the Python terminal. Fig. 6 shows the

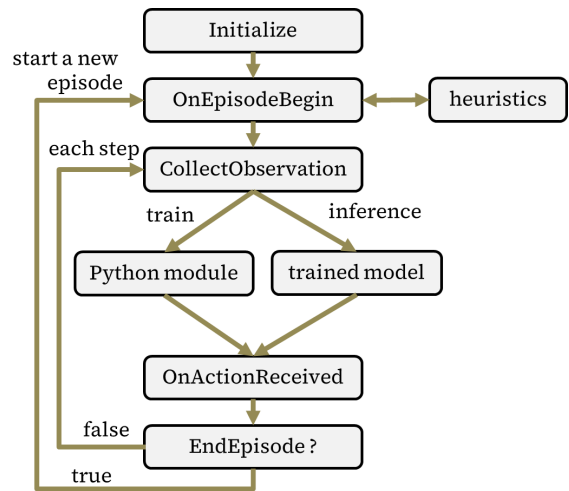

Fig. 6. The internal structure and function calling orders in the agent class.

overall structure of the agent class and its internal functions with their calling orders.

The *Initialize* function inside the *Agent Class* performs necessary works when the game starts. The *OnEpisodeBegin* function implements the initialization work to be performed when an episode starts at each time. After implementing the inside of the *CollectObservation* function that obtains observation information about the environment to be used for the training or the inference, it is divided into the training mode and the inference mode, and the next task to be performed is determined. Mode selection can be set in *Behavior Type* of the *Behavior Parameters* script.

The result from the neural network models being trained in Python terminals or the pre-trained neural network models used for the inference can be applied to the agent through the *OnActionReceived* function. When the episode ends by applying the action output from the neural network model, a new episode is started and training proceeds again. In other cases, the process of receiving observation data in the next step is repeated. The *heuristic* function is used when a user controls an agent directly, without using a neural network model or with the user-provided artificial intelligence.

After implementing the internal functions for inheriting the Agent Class, write a Python script using the ML-Agent Python low-level API to access the Unity process from the Python terminals. When a script is written using the Python low-level API of ML-Agents, the approximate structure of the script code is shown in Fig. 7.

The neural network training method in ML-Agents starts with selecting Unity environments to control with Python APIs. If the build completed executable is selected as an environment to use, the path to the executable must be specified, and if the path is left blank, it will automatically connect to the Unity editor. The successful connection to the Python terminals will result in the reset operation of the Unity environment at the first start. Then Unity conducts simulation by its agents and the Python terminal starts training either PyTorch or TensorFlow neural network models with the received observation data, as the *get observations* step in Fig. 7.

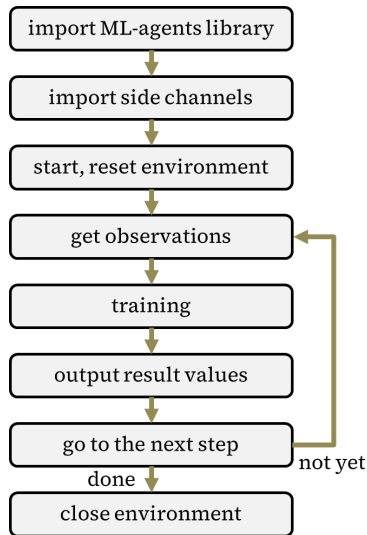

Fig. 7. The ML-Agent python API script structure.

After that, the training proceeds with repeating the number of steps set in the Python script. At each step during training, information about the agent that needs a decision on the next action to be performed and the agent whose episode has ended collects the output of the neural network results, as the *output result values* stage, and applies it to the next step for agents that need a decision, as the *go to next step* stage. During training, user input does not work in the Unity editors or the built environment, since the Python terminal controls input events in Unity.

Additional work is required to perform the *style-transfer* operations with the ML-Agents. ML-Agents can transmit the information observed through the camera sensors of agents in the Unity environment to the Python terminal. This feature is provided for training deep reinforcement learning networks with environmental observation data obtained from the camera sensors. Performing style transfer on this image is applying style transfer to the screen that the agent sees. However, the Python module of ML-Agents does not support sending images to the Unity process. Currently, ML-Agents only considered transmitting the behavior of the agent to be performed in the next step. To solve this problem, we inherited the Side channel class and used it for sending user-defined data.

The *side channel* is a supported function to transmit user-defined data or inform the user about a specific state during the neural network training process. To use this function, we need to implement the internal functions directly from inheriting the Side Channel class. The side channel implemented in this way can be used in the *import side channels* step, as shown in Fig. 7.

Similar to the structure of ML-Agents, *Side Channel Class* must be implemented in Unity and Python, respectively. On the Unity side, the *Side Channel C# class* is inherited, and on the Python side, the *Side Channel python class* is inherited. The process of data transmission through the side channel is shown in Fig. 8. In Python terminals, after converting the style-transferred image into a one-dimensional array of floating-point values, it is transmitted to the Unity side through the side

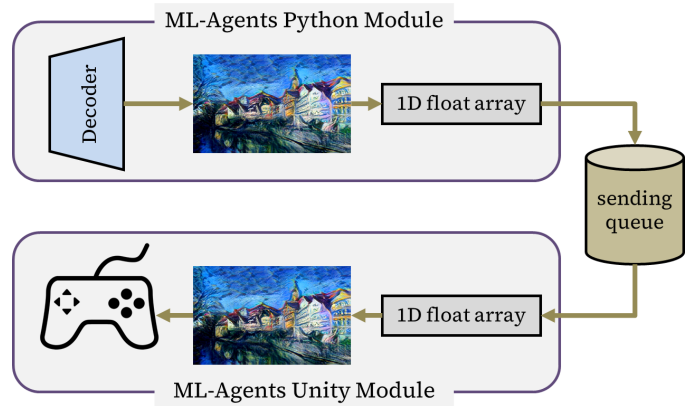

Fig. 8. Our data transmission model, with the side channel.

channel. In the Unity game engine, the received floating-point one-dimensional array is converted into a texture image, which will be rendered on the screen. However, this method transfers the image pixel-by-pixel through the send/receive queue and copies the received float array pixels one-by-one to the texture, which requires a large amount of CPU computing power.

Our style-transfer neural network model is based on the *AdaIN* layer. The model was implemented in PyTorch and used only for inference, when the training was completed. In the case of VGG encoder, the number of filters in the convolutional layer increased from 256 to 512 except for the end of the VGG19 neural network model.

In the VGG encoder, the feature map is extracted from the image by repeatedly stacking the Convolution (Conv2D) layers and the Rectified Linear Unit (ReLU) [24] activation function layers. The subsequent MaxPool2D operation reduces the horizontal and vertical resolution of the image by half. The ReflectionPad2D operation [25] adds spaces to the edges of the output tensors of the current layers, as if reflected in a mirror so that the inverted image appears repeatedly [26].

The VGG decoder also has a convolution layer and a ReLU activation function layer like the VGG encoder [27]. The difference is that the number of filters in the convolution layer is reduced by half, and the resolution of the output tensor is doubled through the added Upsample layer. If the mode of the Upsample layer is set to nearest, the extended part is filled with the same value as the element value of the nearest feature map.

B. Using the Barracuda Module

Barracuda is an inference-specific module built into the Unity game engine. Barracuda executes neural network models stored in ONNX file formats, through C# scripts. Barracuda internally uses the compute shaders [28] to handle the operations required for the neural network inference. These operations are quickly processed in parallel, using the multiple cores of the *Graphics Processing Unit* (GPU). Since Barracuda can run the neural network itself, there is no need to use PyTorch or TensorFlow, there is no cost required for inter-working between the two processes.

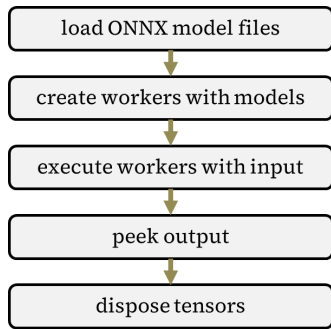

Fig. 9. Overall operations in the barracuda module.

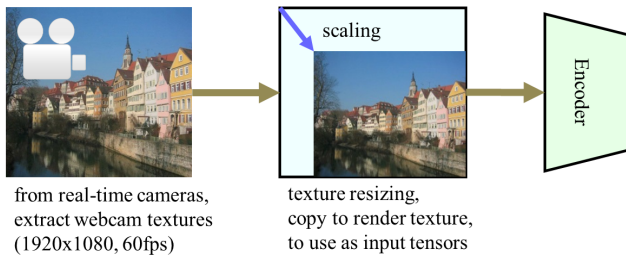

Fig. 10. Input data preprocessing process.

A neural network model executed with Barracuda can use `Texture2D` data types, which works as an input tensor in the Unity game engine, and vice versa. In the case of ML-Agents, the CPU reads pixel values from the resulting tensor, and injects them into the `Texture2D` object, actually in a step-by-step manner. In contrast, Barracuda runs faster by simultaneously processing multiple pixels at once, with the GPU. Since Barracuda was developed specifically only for the inference, it does not support any training of the neural network models.

The operating sequences of the Barracuda module are as shown in Fig. 9. A target neural network model will be stored in the ONNX file format, and it will be loaded through the C# script, at the *load ONNX model files* stage. The module creates a worker object corresponding to the loaded neural network model, at the *create worker with models* stage. A `Texture2D` object is passed as the input tensor to the neural network model, and also as an argument to the worker object, at the *execute workers with input* stage. The resulting tensor will be obtained with the *PeekOutput* function. The final result will be returned as a Tensor type, and can be converted to other types including `Texture2D` and floating-point number arrays.

To achieve the style-transfer operations with the Barracuda module, we provide the trained style-transfer neural network models as the ONNX files. Those files are imported into the Unity game engine. In our experiments, we use the ONNX files for the neural network models trained with a single style image, in a feed-forward manner [11].

To clearly check the performance of the style-transfer operations, we applied the style-transfer operation to the real-time texture images, from a webcam-based video stream. The video stream provides 60 frames per second, in the 1920×1080 resolution. Since the video resolution is too large

Fig. 11. Post-processing at the decoder.

Fig. 12. A brute-force implementation of the style-transfer operation, with the python terminal in the unity engine.

to achieve real-time style-transfer, the video streams are scaled down to the internal render-texture area, with lower resolution. We achieved the highly efficient texture transfers, by using Shader functions of Unity to modify texture images at high speed through GPU's parallel processing features, as shown in Fig. 10.

In addition, appropriate post-processing is needed to the resulting tensor, to be properly used in the games. For example, the final pixel values from the Barracuda module may be normalized floating-point numbers between 0.0 and 1.0, while the rendering module needs 8bit unsigned integer values, as the corresponding color values. We also integrated these kinds of post-processing operations into the Shader programs, for more efficient and faster operations, as shown in Fig. 11.

V. EXPERIMENT RESULT

A. Python-based Implementation

For comparison purposes, we implemented the style transfer operations in a brute-force way, to directly link the Unity editor to the Python terminals, as shown in Fig. 12. As the starting point, the underlying game shows 170 frames per second, without connecting to the Python terminals. Since it was expected that this direct connection would be inefficient, we use low-resolutions of 128×128 , for the input video streams. The style-transfer neural network model is executed on the Python side, as an AdaIN network. The resulting style-transferred image is in 256×256 resolution, and read directly from the Python terminal.

Even the style-transfer operations can be achieved efficiently in Python environment, we found that the bottleneck is the data transmission between the Python terminal and the Unity game engine. To check the transmission speed, we once used a dummy Python kernel, which just re-transmit the input data as the result. Since they use network sockets for the data transmission, it shows very slow result of even 3 frames per second, as shown in Fig. 12.

Fig. 13. An example of feed-forward style transfer.

Fig. 14. Applied style image.

Fig. 15. Experimental results from a sample AdaIN style-transfer implementation.

Fig. 16. Experimental results when applying the different style image.

Even worse, the received data need additional post-processing on the CPU side. For example, the color values should be converted from floating-point values to 8bit unsigned integer values for the graphics rendering. Although using shared memory seems more appropriate for the images, this simple use of Python terminals for the style-transfer purpose should consider the optimal connect of two different programming languages: Python and the C# programming language used in the Unity engine. Conclusively, we need another fully efficient way of providing style-transfer operations to the Unity engine.

B. Our Barracuda-based Implementation

In this work, we used a special device driver module, named Barracuda, in the Unity game engine. The Barracuda module is built into the Unity engine, and drives a trained neural network for inference. We first extracted input data of the real-time video streams, from our small size Web Cameras (or webcams). The input data stream is actually texture images extracted from the webcam video streams. It is then resized to be processed by the neural networks.

The style transfer neural networks are used in two aspects: a neural network trained on a single style image in a feed-forward manner, and another neural network with AdaIN, which can apply style images to the target texture, in real-time. The input images extracted from the video camera are converted into the 256×256 resolution render textures, which are used as inputs to the neural networks. The final resulting images are then used as surface textures for cube objects, which are actually a physically-simulated moving object, in our scenario, as shown in Fig. 13.

Fig. 14 shows our sample style image used for this experiment. Since there is little data transmission/reception cost, the final frame rate of the game engine is affected by the resulting texture image generation speed of the neural network models. In our experiment, we confirmed that the game engine works fast enough to be used in real-time.

VI. ANALYSIS OF EXPERIMENTAL RESULTS

In our experiments, we found that the *Barracuda* module is specialized in inference, and suitable for the game engines to use the neural network features. This module also shows some limitations: it currently works well with limited sets of neural network models. Actually, we used two style-transfer models: the *feed-forward model* and the *AdaIN model*. The feed-forward model shows fast conversion speeds, and also limitations of being best suitable for a single style image training. In contrast, the AdaIN model can be used for several style images even in real-time, as shown in Fig. 15 and 16.

However, the AdaIN model was suitable for small-size images, due to the real-time requirement. Fig. 17 shows the speed of the style transfer neural networks for input data of various sizes. In this case of the AdaIN models, we found that the size of the image used as the style image was best suitable with 256×256 resolutions. The style transfer performance was greatly decreased with the image sizes larger than this.

For the game engine, it can achieve about 170 frames per second, without any style-transfer operations. Applying the style-transfer operations, the maximum texture image size was 300×300 , with our experiment environment settings. Since we used mid-powered PCs, rather than the best-performance

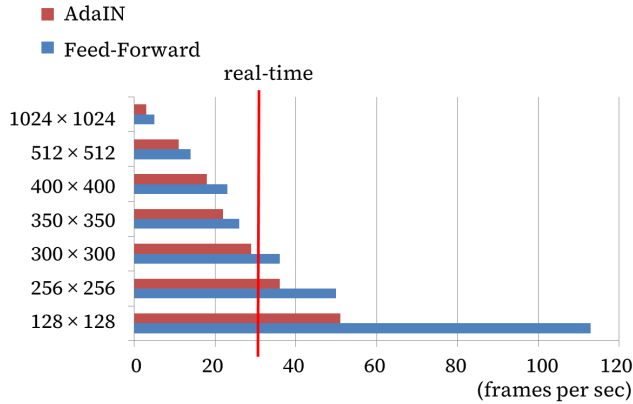

Fig. 17. Real-time style transfer performance based on input image sizes.

computing environment, we expect that the performance and also the size of the input texture would be improved with enhanced computing power machines.

VII. CONCLUSIONS AND FUTURE WORKS

Through this simulation, we examined the real-time style transfer performance in the game engine and efficient data processing methods. When interlocking a neural network that generates game resources in real-time with a game engine, the data transmission and reception method between the neural network and the game engine must be efficient. In addition, input and output data from neural networks must be fast and efficient when converted to game resources. In the paper, the Shader function of the game engine was used to efficiently convert and copy data through GPU parallel processing.

This paper shows a simulation of applying a deep neural network to textures on the game in real-time. Since the texture is used in various ways in the game, it will be possible to conduct various studies through future applications. It will also be necessary to study the performance optimization problems that may arise during game development using deep neural networks.

Additionally, research will be needed on performance optimization issues that may arise while developing games using neural network models. Just as the optimization techniques applied are different depending on the genre or characteristics of the game itself, optimizations based on the characteristics of the used neural network models should be investigated. Considerations for the mobile environment are also needed.

Abstract—Unbalanced data sets represent data sets that contain an unequal number of examples for different classes. This dataset represents a problem faced by machine learning tools; as in datasets with high imbalance ratios, false negative rate percentages will be increased because most classifiers will be affected by the major class. Choosing specific evaluation metrics that are most informative and sampling techniques represent a common way to handle this problem. In this paper, a comparative analysis between four of the most common under-sampling techniques is conducted over datasets with various imbalance rates (IR) range from low to medium to high IR. Decision Tree classifier and twelve imbalanced data sets with various IR are used for evaluating the effects of each technique depending on Recall, F1-measure, gmean, recall for minor class, and F1-measure for minor class evaluation metrics. Results demonstrate that Clusters Centroid outperformed Neighborhood Cleaning Rule (NCL) based on recall for all low IR datasets. For both medium, and high IR datasets NCL, and Random Under Sampling (RUS) outperformed the rest techniques, while Tomek Link has the worst effect.

Keywords—Clusters centroid; decision tree; neighborhood cleaning rule; random under sampling; Tomek Link under sampling; unbalanced datasets

I. INTRODUCTION

Machine learning and statistics have been used for classification in many fields such as security [1]–[8], medical [9]–[15], text classification [16]–[18], and others [19], [20]. Classifications are defined as building a training model based on previous experiences or examples. Recently, there has been a rapid growth in data that has been collected from different environments but, unfortunately, there is a lack of quality data.

The quality of the data means a balanced distribution for all classes, the range of values is normalized, and no missing values, and so on. The point is, that several traditional machine learning techniques assumed that the target classes have a balanced distribution in the data [21]–[23].

Multi-class classifiers such as Support Vector Machine (SVM), Decision Tree (DT), Logistic Regression (LR), and others are sensitive for imbalanced class distribution problems [24] while one class classifiers such as Isolation forest, local outlier factor (LOF), OC-SVM and other were not.

Due to the fact that, it is rare to find balanced datasets, that contain equal or nearly equal numbers of instances for each class in real-life classification problems; Building classification models under highly imbalanced datasets is an issue in machine learning algorithms.

In unbalanced datasets the most important class (class of interest) has fewer examples than other classes like rare disease datasets [25], therefore, the classification performance of the classifier will be affected by skewing to the majority class instances, which is usually not class of interest [26].

There are two main approaches for handling unbalanced dataset problems: “algorithm-driven approach”, and “data-driven approach”. The first approach concerns adjusting the classifier to improve its learning from the minority class samples [27].

On the other hand, the second approach concentrates on changing the data distribution in two ways either by adding new minor class examples (over-sampling) or removing some major class instances (under-sampling). Each way has its own advantages and disadvantages, where over-sampling is considered more overhead than under-sampling and can lead to overfitting problems while under-sampling causes the loss of important information [27].

In the literature, most researchers either propose some under-sampling techniques and commonly use these techniques in research, or compare these techniques using a specific dataset.

To our knowledge, there does not exist any research in the literature comparing the effects of specific under sampling techniques in the classification performance over datasets with low, medium, and high IR. This notice represents the rationale behind this paper where the main goal from this paper is to compare the influence of four common under sampling techniques called Tomek Link, NCL, Clusters Centroid, and Random Under Sampling (RUS) in the classification results for different datasets with various IR ranges from low to high IR datasets.

To accomplish this goal twelve datasets from the Keel collection with different IR variate between low, medium, and

high IR have been used for comparing the performance of the decision tree classifier using each one of the previous four under-sampling techniques based on average recall, average F1 measure, gmean, minor class recall, and minor class F1 measure.

The rest of this paper is organized as follows: Section II displays the most recent studies about handling imbalance datasets in the literature. Section III-A describes Tomek Link, NCL, Clusters Centroid, and RUS under-sampling techniques that are compared. methodology has been demonstrated in Section III. In Section III-B the datasets are displayed. In Section IV results are presented. Finally, Section V contains the conclusion.

II. RELATED WORK

A large number of domains with significant environmental, vital, or commercial importance encounter the class imbalance problem. The class imbalance problem means that there is a majority of one or more class spreads in the datasets [28], [29]. Moreover, it has been shown in some instances to significantly impede the performance achievable by conventional learning techniques that assume a balanced distribution of the classes and produce biased classifiers. Also, it degrades the performance of machine learning classifiers [30].

Many proposals have been presented in the literature to solve the imbalanced dataset. One of the most well-known techniques is the cluster-based under-sampling approach. It has been widely used to solve the imbalance of class distribution. In [31]–[35] a cluster-based under-sampling approach has been used to select the representative data as training data. Thus, the classification accuracy for minority classes will be improved. The experimental results show that the proposed approach outperforms other under-sampling techniques in the previous studies.

Random Under Sampling (RUS) is considered an under-sampling technique that is used for class imbalance problems. Many proposals used RUS to maintain a balanced class distribution [36]–[38]. In [39] a combination of T-Link and, Synthetic Minority Technique (SMOTE) and another sampling method such as RUS, and ROS in order to produce balance data.

Additionally, RUS has been used with different ratios to detect the performance of some of the machine learning classifiers as [40] eight random undersampling (RUS) ratios which are no sampling, 999:1, 99:1, 95:5, 9:1, 3:1, 65:35, and 1:1 have been used. Moreover, to show the performance of these ratios seven different classifiers are employed which are LightGBM (LGB), Decision Tree (DT), Random Forest (RF), Naive Bayes (NB), Logistic Regression (LR) CatBoost (CB), and XGBoost (XGB).

In [41] an ensemble feature selection has been proposed to classify the attack using the BoT-IoT dataset. The proposed approach is centered on the building of predictive models that are based on different classifiers. RUS has been used to solve the imbalance BoT-IoT dataset. The results show that the best RUS ratio was 1:1 or 1:3.

In [42] a new hybrid under sampling-based ensemble approach (HUSBoost) has been proposed. The main objective of

HUSBoost is to handle imbalanced data using three main steps which are data cleaning, data balancing, and classification. At first, we remove the noisy data using Tomek-Links. RUS has been applied to create several balanced subsets.

The neighborhood cleaning rule (NCL) method has been used in many proposals in literature to deal with imbalance data [43]–[45] while other studies used hybrid approaches instead of NCL alone [46]. In [47] a combination of under-sampling and oversampling methods have been used to solve imbalance cases. Their proposal used is NCL under-sampling method and Adaptive Semi unsupervised Weighted Oversampling (A-SUWO) for the oversampling method.

Tomek link Tomek link technique is used in many studies to overcome the challenges of data imbalances that affect the performance of supervised learning-based [48]. In [49] Synthetic minority oversampling technique (SMOTE) and T-link have been used for imbalanced data. In addition, a Naïve Bayes classifier, support vector machine, and k-nearest neighbors together have been used for performance evaluation.

In [50] Cluster Based, Tomek Link, and Condensed Nearest neighbours have been used to handle the class imbalance problem by equalizing the number of instances. This is done by under-sampling the majority class based on some particular criteria [51]–[54]. The performance evaluation was done based on applied different machine learning classifiers such as K-Nearest Neighbor, Decision Tree, and Naive Bayes. The results showed that Decision Tree outperformed other machine learning techniques using the proposed technique.

Up to our best knowledge and based on an extensive literature review search, we noticed that most of the previous works exist in the literature compare the performance of specific under sampling techniques versus a hybrid version of these techniques over specific datasets with specific IR. However, in this paper, four of the most common under sampling techniques were applied over three categories of datasets that were categorized based on IR into three categories (low IR, medium IR, and high IR), and the effects of each technique on the classifier performance were compared.

The main purpose of this paper is to conclude a standard relationship between the compared under sampling techniques and dataset IR value in order to guide researchers in choosing the most suitable under sampling technique from the compared ones based on the dataset IR. In this paper, twelve imbalanced data sets with various IR have been used for evaluation in addition to DT for classification.

III. METHODOLOGY

For each dataset Work starts by dividing the original file into two parts: 70% for learning the classifier (training data set) and 30% for evaluating the effectiveness of the constructed model (testing set) based on average recall, average F1 measure, gmean, minor class recall, and minor class F1 measure [55].

For the training dataset, four under sampling techniques have been applied in order to make it balanced for learning decision tree classifier then using the generated model for classifying the test set and evaluating its performance, as shown in Fig. 1.

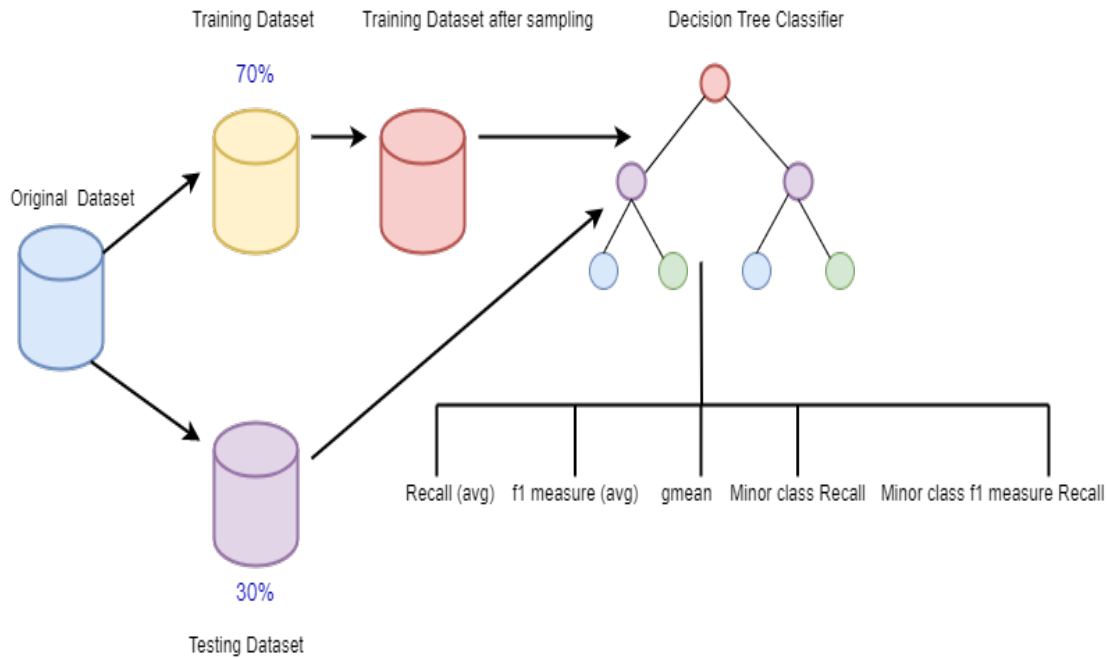

Fig. 1. Workflow for the used methodology

For each dataset, the best results that have been generated by DT classifier with each under sampling technique after adjusting its parameters are documented and compared.

In this paper, python is used for conducting all experiments through the PyCharm integrated development environment (IDE). Python libraries sci-kit-learn and imbalanced-learn are deployed for generating the results [56].

A. Under Sampling Techniques

- 1) Tomek link Tomek link refers to a pair of nearest neighbors where each one belongs to different classes. Under-sampling is done by removing all majority class samples from all Tomek Links [57].
- 2) Neighborhood Cleaning Rule (NCL) It was proposed by Laurikkala in 2001, where in this method for each sample in the training set three nearest neighbors for it must be defined then if it belongs to the major class while all of its selected neighbours belong to the minor class then it will be removed as a noise sample but if this sample belongs to the minor class and its three nearest neighbours belongs to the major class then these neighbours must be removed now. This method needs numerous computations with large-size datasets [58].
- 3) Clusters Centroid This method undersamples the majority class by replacing a cluster of majority samples as it finds the clusters of the majority class with the K-mean algorithm then it keeps the Cluster Centroids of the N clusters as the new majority samples [5].
- 4) Random Under Sampling (RUS) RUS works by removing some of the majority class samples randomly to change the distribution of data in the imbalanced dataset in order to convert it to a more balanced

one for improving the classifier learning process in machine learning but this method sometimes means losing important information which considered as one drawback according to using this technique [59].

B. Datasets

Twelve datasets from Keel [8] collection with different IR are used in this paper. Table I summarizes these datasets properties.

Datasets are divided into three groups based on their IR, where the first five datasets with IR smaller than 9 represent a low IR group while the medium IR group contains datasets with IR greater than 9 and smaller than 50. Finally, datasets with IR greater than 50 are members of the high IR group in this paper.

C. Evaluation Metrics

This section is devoted to displaying the evaluation metrics that are used for evaluating the effects of TL, RUS, NCL, and CC under sampling techniques in the classifier performance for different datasets from various IR.

- Recall or TPR: It measures how often the classifier correctly detects the positive instances from all positive instances [60], [61], as shown in Eq. (1)

$$Recall = \frac{TP}{(TP + FN)} \quad (1)$$

- F1-Score: It combines the effects of precision and recall together [62], as shown in Eq. (2).

TABLE I. PROPERTIES OF TWELVE IMBALANCED DATASETS WITH DIFFERENT IR FROM KEEL REPOSITORY

Imbalance Category	Dataset Num.	Dataset Name	features	examples	Minor class	Major class	imbalance rate
Low	D1	glass1	9	214	76	138	1.82
	D2	ecoli_0_vs_1	7	220	77	139	1.86
	D3	vehicle0	18	846	199	647	3.25
	D4	ecoli3	7	336	35	301	8.6
	D5	page-blocks0	10	5472	559	4913	8.79
Medium	D6	glass4	9	214	13	201	15.47
	D7	car-good	6	1728	69	1659	24.04
	D8	kr-vs-k-one_vs_fifteen	6	2244	78	2166	27.77
High	D9	kr-vs-k-zero_vs_eight	6	1460	27	1433	53.07
	D10	Winquality	11	691	10	681	68.1
	D11	kr-vs-k-one_vs_fifteen	6	2193	27	2166	80.22
	D12	abalone19	8	4174	32	4142	129.44

$$F1 - Score = \frac{(2TP)}{(2TP + FP + FN)} \quad (2)$$

- gmean: It is a combination of TPR, and TNR metrics, as shown in Eq. (3).

$$gmean = \sqrt{(TPR * TNR)} \quad (3)$$

All metrics depend on four main parameters explained below:

- True Positive (TP): represents a number of actually positive instances classified as “positive”.
- True Negative (TN): represents a number of actually negative instances classified as “negative”.
- False Positive (FP): represents a number of actually negative instances classified as “positive”.
- False Negative (FN): represents a number of actually positive instances classified as “negative”.

IV. EXPERIMENTAL RESULTS AND ANALYSIS

This section discusses the results that are generated from comparing the effects of Tomek Link, NCL, Clusters Centroid, and RUS in the performance of Decision Tree (DT) classifier for all groups of low, medium, and high IR datasets based on average Recall in subsection IV-A, then based on average F1 measure in subsection IV-B. Later the results of gmean, recall of minor class, and F1 measure of minor class results were discussed and analyzed in subsections IV-C, IV-D, and IV-E, consequently.

A. Recall

From Table II, we can conclude the following results by comparing the effects of the selected under sampling techniques in decision tree classifier average recall value for low, medium and high IR groups of datasets. From Fig. 2 we can concludes the following points for all low IR dataset groups recall value

- NCL provides better performance based on recall than Tomek link for all datasets.
- Also we concluded that NCL provides better recall value than RUS for first three datasets.

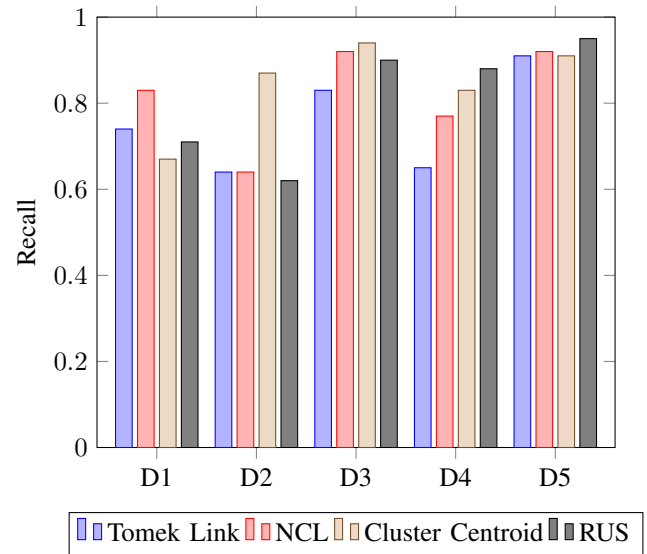

Fig. 2. Recall results for all low imbalance rate datasets.

- Cluster Centroid has better performance than Tomek link and NCL for all datasets except the first one with imbalance rate = 1.82

From Fig. 4 we can conclude the following points for all medium IR dataset groups recall values.

- From Fig. 5 we show that Tomek link provides the worst performance for all datasets.
- NCL provides better performance than Cluster Centroid for all datasets
- RUS outperformed all other techniques for all datasets

From Fig. 5 we can concludes the following points for all high IR dataset groups recall value

- NCL provides better performance based on recall than Tomek link for all datasets.
- RUS outperformed all other techniques for all datasets except the last one with imbalance rate = 129.44.
- Tomek link provides the worst performance for all datasets

TABLE II. RECALL RESULTS FOR ALL EXAMINED DATASETS USING THE SELECTED UNDERSAMPLING TECHNIQUES

Fig. 5. Recall results for all high imbalance rate datasets.

Fig. 4. Recall results for all medium imbalance rate datasets.

B. F1-Measure

From Table III, Fig. 3, 6 to 16 we can concluded the following points

- RUS provides less performance than NCL for all low imbalance rate datasets
- NCL provides better or equal performance than Tomek link for all medium imbalance rate group datasets
- Clusters Centroid provides better or equal performance than Tomek link for all medium imbalance rate group datasets
- RUS provides better or equal performance than Clusters Centroid for all medium imbalance rate group datasets
- Clusters Centroid provides the worst performance for all high imbalance rate group datasets except for last one with imbalance rate = 129.44

C. Gmean

From Table IV we can concluded the following points:

- Tomek link provides the worst performance for all low, medium, and high imbalance rate datasets
- NCL has better performance than Cluster Centroid for all datasets in the low imbalance rate group except the first one with imbalance rate = 1.82

TABLE III. F1-MEASURE RESULTS FOR ALL EXAMINED DATASETS USING THE SELECTED UNDERSAMPLING TECHNIQUES

Fig. 11. Recall for minor class results for all low imbalance rate datasets.

D. Recall for Minor Class

From Table V we can concluded the following points:

- NCL outperformed Cluster Centroid for all datasets in the Low imbalance rate group except the first one with an imbalance rate = 1.82.
- NCL provides better or equal performance than Tomek link for all Low imbalance rate datasets.
- Clusters Centroid provides better performance than Tomek link for all Low imbalance rate datasets.
- Clusters Centroid and RUS provide recall value = 1 for the minor class for all datasets in the medium imbalance rate group.
- Tomek link provides the worst performance for all medium and high imbalance rate datasets.
- Clusters Centroid and RUS provide the same recall value for the minor class for all datasets in the high imbalance rate group.

Fig. 12. Recall for minor class results for all medium imbalance rate datasets.

E. F1 Measure for Minor Class

From Table VI we can conclude the following points:

- NCL provides better or equal performance than Tomek link and Cluster Centroid for all low imbalance rate

TABLE V. RECALL FOR MINOR CLASS

datasets except vehicle0 dataset with imbalance rate = 3.25

- RUS provides less performance than NCL for all medium imbalance rate datasets except the first one with imbalance rate = 15.47
- Cluster Centroid provides less performance than NCL and RUS for all medium imbalance rate datasets
- RUS provides better performance than Clusters Centroid for all high imbalance rate datasets except for the abalone19 dataset with imbalance rate = 129.44

V. CONCLUSION AND FUTURE WORK

Sampling techniques are one of the most effective ways of handling imbalanced data set problems in machine learning.

This paper is concerned on comparing the effects of four common under-sampling techniques including Tomek Link, NCL, RUS, and Clusters Centroid in handling imbalance datasets problems for various Imbalance ratios ranges from low, medium, and high IR. Twelve imbalanced data sets with various IR have been used for comparison. DT has been used for classification.

Fig. 15. F1-measure for minor class results for all medium imbalance rate datasets.

Results from all low IR datasets clearly show that NCL

TABLE VI. F1-MEASURE FOR MINOR CLASS

Dataset	Tomek Link	NCL	Cluster Centroids	RUS
glass1	.67	.78	.61	.64
ecoli-0_vs_1	.96	.96	.96	.74
vehicle0	.87	.83	.87	.87

abalone19	.08	.03	.04	.03

Fig. 16. F1-measure for minor class results for all high imbalance rate datasets.

outperformed both Tomek Link and RUS, while Clusters Centroid outperformed NCL based on recall. Based on minor class recall and gmean, NCL outperformed Clusters Centroid. RUS provides less performance than NCL for all low IR datasets.

For all medium IR datasets, Tomek Link provides the worst performance, while NCL and RUS outperformed other techniques in terms of recall, minor class recall, and gmean values. Based on the minor class F1 measure NCL outperformed RUS which outperformed Clusters Centroid based on the average F1 measure.

For all high IR datasets, Tomek Link provides the worst performance, while NCL and RUS outperformed other techniques based on recall, minor class recall, and gmean values. Based on the average F1 measure and minor class F1 measure, RUS provides better performance than Clusters Centroid.

Finally, the results presented in this paper were derived from the databases used here and according to the rates that were set to classify these databases for only four common under sampling techniques.

In the future, we need to compare the effect of these techniques by applying them to more databases in each IR

category. Also, we can study more under-sampling techniques, and comparing them with other oversampling techniques.

Multiclass Chest Disease Classification Using Deep CNNs with Bayesian Optimization

Maneet Kaur Bohmrah, Harjot Kaur
Department of Computer Science and Engineering
Guru Nanak Dev University
Amritsar, India, 143001

Abstract—Ever since its outbreak, numerous research studies have been initiated worldwide as an attempt for an accurate and efficient diagnosis of COVID-19. In the recent past, patients suffering from various chronic lung diseases, either passed away due to COVID-19 or Pneumonia. Both of these pulmonary diseases are strongly correlated as they share a common set of symptoms and even for medical professionals, it has been difficult to perform discerned diagnosis for both of these diseases. The dire need of the current scenario is a chest-disease diagnosis framework for accurate, precise, real-time and automatic detection of COVID-19 because of its mass fatality rate. The review of various contemporary and previous research works show that the currently available computer-aided diagnosis systems are insufficient for real-time implementation of COVID-19 prediction due to their long training time, substantial memory requirements and excessive computations. This work proposes an optimized hybrid DNN-ML framework by combining Deep Neural Networks' (DNNs) models and optimized Machine Learning (ML) classifiers along with an efficacious image preprocessing approach. For feature extraction, Deep learning (DL) models namely GoogleNet, EfficientNetB0, and ResNet50 have been deployed and extracted features have been further fed to Bayesian optimized ML classifiers. The two major contributions of this study are, Edge based Region of Interest (ROI) extraction and use of Bayesian optimization approach for configuring optimal architectures of ML classifiers. With extensive experimentation, it has been observed that the proposed optimized hybrid DNN-ML model with encapsulated image preprocessing techniques performed much better as compared to various previously existing ML-DNN models. Based on the promising results obtained from this proposed light weight hybrid framework, it has been concluded that, this model can facilitate radiologists, while functioning as an accurate disease diagnosis and support system for early detection of COVID-19 and Pneumonia.

Keywords—Deep neural networks; machine learning; Bayesian optimization; image preprocessing; COVID-19; pneumonia

I. INTRODUCTION

Recently, a new virus known as **COVID-19** emerged in China and began to spread globally as an respiratory illness. Since its outburst, COVID-19 has contributed significantly to the economic crisis of numerous nations and adversely affected human life. Due to its transmissible characteristics, it can spread vigorously with uncertain transmission methods and co-exist for a longer duration of time [1]. According to statistics received from World Health Organization (WHO) [2], approximately six million people worldwide have died till date because of COVID-19 and over forty million cases have been reported so far. People who are older or have chronic health conditions seem to be more susceptible to

contacting COVID-19 infection. Various symptoms of COVID-19 include high fever, coughing, anxiety and breathlessness. This virus spreads quickly via respiratory droplets produced by an infected person's cough or sneeze [3].

Numerous medical professionals globally, have been developing vaccines and researching on treatments to combat this virus. Moreover, many medical techniques and therapies have been developed and are currently under development for treatment and recovery of the affected individuals. Unfortunately, despite several protective measures, the available medical systems have failed to combat and control the virus, because it has been continuously undergoing several mutations [4]. This study requires advanced diagnosis and treatment methodologies to control its menace. Presently, COVID-19 has been diagnosed using time consuming primitive methods like, administering RT-PCR (Reverse Transcription - Polymerase Chain Reaction) examination. Another alternative is *Computed Tomography (CT) scan and Chest X-ray (CXR)* images, that have emerged as an robust imagery techniques for diagnosis of the same [5]

While investigating CXR and CT scan images, notable clinical findings that can be inferred are, ground glass opacities (GGO), thickening of intertubular septa and air branchogram sign, with or without increased broncho-vascular markings that lead to diagnosis of disparate lung diseases. Among these two medical imaging tools, CT scan images have been considered more reliable due to their high contrast image properties. And, they are more effective medical imaging system for diagnosis of the chest diseases. As compared, CXR images, have been widely recommended by doctors, because they are more economical as compared to CT scan image and easily accessible for patients too. For effective screening and diagnosis of COVID-19 and/or other chest infections, CXR and CT scan images have to be manually examined and then clinically correlated with patient's symptoms. Nevertheless, this manual screening is a very time consuming process and might not be feasible in emergency cases [6]. Therefore, an accurate, precise, real-time and automated COVID-19 diagnostic system is the dire need of the current scenario.

With the advent of prominent AI tools and medical imaging, researchers have started proposing novel solutions to develop automatic tools for accurate detection of COVID-19. AI based deep learning (DL) models, i.e., *Convolutional Neural Networks (CNNs)* excel in domain of image classification and provide extraordinary performance in medical image analysis. Due to their complex architecture, CNNs can be used for both feature extraction and classification tasks, which makes

them distinguishable from rest of Machine Learning (ML) algorithms [7].

In medical imaging system, accurate and precise results, are always a major concern. For image classification task, a model should be well-versed with dominant features of an image. The ultimate motivating factor for the present study is that, all the image characteristics needed for feature extraction and classification should be noise free [8]. Henceforth, this study has focused more on image preprocessing techniques (segmentation, filtration and enhancement) in order to pertain the prominent features of the image. Afterwards, resultant segmented and enhanced image has been utilized by the pretrained CNN models for feature extraction. And finally, in order to classify the features, Bayesian optimized ML classifiers have been used in this work. Various innovative and novel contributions of the present study are as follows:

- Experimentation with the new enhanced model for the diagnosis of COVID-19 for two distinct types of COVID-19 images; the Chest X-ray and CT scan image datasets.
- Proposal of Edge based Adaptive Segmentation algorithms and their integration with image filtration and enhancement techniques for the preparation of enhanced dataset.
- Utilization of pretrained models and machine learning classifiers for feature extraction and classification process, respectively.
- Implementation of Bayesian optimization technique for disparate ML classifiers.
- Performance based comparative analysis of proposed DNN-ML models trained with and without image preprocessing techniques, thereby highlighting the advantages of latter.
- Comparative analysis based on classification accuracy of Bayesian optimized ML classifiers (BO-ML) with their non-optimized ML version, thereby investigating the significance of Bayesian optimization and deducing experimental insights on CXR and CT scan datasets.
- Comparison of the experimental findings with the other existing state-of-the-art models.

The remaining part of this article has been structured as follows, Section II highlights the state-of-the-art research studies conducted for automated diagnosis of COVID-19. Section III describes the datasets, the proposed framework, and methods used. Section IV presents various experiments performed along with the findings, discussions and comparative analysis. Finally, the conclusions and future work have been discussed in Section V.

II. LITERATURE REVIEW

In recent past, numerous research studies have been performed on automatic COVID-19 detection using disparate pretrained Deep Neural Networks (DNNs) and ML algorithms from lung images, in a stand-alone and hybrid mode. Kesav et al. [9] employed GoogleNet, a pretrained neural network

for feature extraction and used different ML classifiers for performing the task of classification. On chest X-ray image dataset, Bayesian optimization has been utilized to optimize ML classifiers with accuracy score of 98.31% for binary and 98.60% for multi-class classification respectively.

Hamza et al. [10] proposed the use of Bayesian optimized neural networks and gradcam technique for visualization of chest x-rays to detect chest diseases. Arman et al. [11] designed modified Xception model based on Bayesian optimization and compared it with other DNN models such as VGG16, MobileNetV2 and InceptionV3. The proposed model achieved the highest value of classification accuracy, i.e., 99.4% to classify COVID-19, normal and pneumonia classes belonging to CXR image dataset. Canayaz et al. [12] presented a combination of ResNet50 and Bayesian optimized kNN to detect COVID-19 and this model accomplished an accuracy score of 96.42% when trained using CT scan dataset with 349 images for binary classification (COVID-19 and non COVID-19 categorization).

Awal et al. [13] experimented using various machine learning classifiers, i.e., Linear Discriminant Analysis (LDA), Quadratic Discriminant Analysis (QDA), Naive Bayes(NB), k-Nearest Neighbour (kNN), Decision Tree (DT), Random Forest (RF), extreme Gradient Boosting (XGBoost) for COVID-19 diagnosis. To optimize hyperparameters of aforementioned ML classifiers, Bayesian Optimization has been deployed and the results hence obtained showed that optimized XGBoost performed better as compared to other ML classifiers. Aslan et al. [14] utilized Artificial Neural Networks (ANN) based segmentation method for dataset enhancement and compared eight different pretrained DNNs. Further, three Bayesian optimized ML classifiers (i.e., SVM, kNN and NB) have been used in integration with these pretrained models. The results concluded that DenseNet201 and BO-SVM outperformed other competing models with 96.29% accuracy score. Nour et al. [15] proposed CNN for feature extraction and utilized Bayesian optimization based ML (SVM, kNN and DT) classifiers, achieving 98.97% accuracy.

Jaiswal et al. [16] deployed a pretrained DenseNet201 model to classify COVID-19 using CT scan images with an accuracy score of 96.25%. The combination of Bayes and SqueezeNet, has been utilized by Ucar et al [17] to detect COVID-19 using CXR images and the accuracy score accomplished was 98.30% . A Gravitational Search Algorithm (GSA) has been deployed to optimize hyperparameters of DenseNet121 (Ezzat et al.[18]) for classification of COVID-19 using CXR images and with the an accuracy value of 98.38%. Das et al. [19] presented a fully automated COVID-19 detection model. COVID-19 radiography dataset from Kaggle repository has been used that consisted of three classes: COVID-19 positive, pneumonia infection, and no infection. Two CNN models namely, VGG16 and ResNet50 have been implemented and compared in this work. With an accuracy score of 97.67%, VGG16 model provided the best performance in automated COVID-19 detection model.

According to Monshi et al. [20], the hyperparameter optimization of ML classifiers provided best results. The pretrained models have been implemented in this work to design a novel CovidXrayNet framework based on EfficientNet-B0 and Bayesian optimized ML classifiers. The testing accuracy value

of this model on data generated from two distinct databases has been revealed as 95.82%.

To detect COVID-19, Panwar et al. [21] presented a Transfer Learning (TL) based nCOVnet Deep Learning approach and obtained an accuracy score of 88.10% in training and testing of the CT scan images. Asif et al. [22] designed CNN model to diagnose COVID-19 using CXR images. Without applying any preprocessing techniques, input images have been fed into the Inception-V3 model and accomplished classification accuracy score of 96%.

COVID-19 and Pneumonia detection has been performed using 3-stage model based on CXR images (Bhattacharya et al. [23]). To start with, the affected lung region has been separated from the CXR images by deploying the Conditional Generative Adversarial Network (C-GAN). The characteristics from segmented lung pictures have been extracted in the stage two by using DNN based feature extraction model. Afterwards, different ML classifiers have been deployed to categorize the CXR images according to the extracted features. The proposed combination of VGG19 with Binary Robust Invariant Scale Key-points (BRISK) yielded the best classification accuracy score of 96.6%.

Kaur et al. [24] proposed a classifier fusion model using ResNet50 to diagnose COVID-19 using CXR images. Kumar et al. [25] designed a model with the blended features of MobileNetV2 and DarkNet19 model based on CT scan dataset. This was one of the earliest attempts of using open-source DNNs for COVID-19 detection from CXR images. An automated tool for COVID-19 diagnosis, COVID-Net (Linda Wang et al. [26]) has been proposed and testing of same along with VGG19 and ResNet50 has been performed on COVIDx (an open-access dataset formed from collection of five different datasets). This experimental setup attained 93.3% accuracy. The performance of seven deep learning models have been examined (Khalid El Asnaoui et al.[27]) in order to identify and categorize COVID-19 and Pneumonia. The process of image preprocessing has been applied on the raw CT and X-ray images to enhance their quality and an accuracy score of 92.18% has been obtained by using Inception-ResNetV2.

A transfer learning based COVID-19 detection from CXR and CT images has been proposed by Afshar Shamsi et al. [28]. To accomplish the classification objective, four different pre-trained models (namely, VGG16, ResNet50, DenseNet121 and InceptionResNet) have been used for feature extraction, and the extracted features were then fed into ML models. With an accuracy score of 87.9%, the combination of ResNet50 model and SVM classifier produced the best results. Arellano et al. [29] proposed a modified pretrained DenseNet121 model, with relearning of last layer for identification of COVID-19 from CXR images. A publicly available COVID-19 database has been used for training the model with an accuracy value of 94.7%.

Most of studies in the existing literature used raw images directly or combined with computationally intensive image preprocessing functions. The vital image features such as texture, color, shape, etc. play a significant role in the process of image classification, and it is performed by the DNN model. Henceforth, this tri-modular approach towards the proposal of optimized hybrid DNN-ML model encompasses

first module for feature processing task, which includes the use of proposed image preprocessing techniques for image enhancement. Second module uses pretrained DNN models for feature extraction from enhanced images and third uses optimized ML for classification from the extracted image features.

III. MATERIALS AND METHODS

This section provides details about various encompassing the proposed hybrid DNN-ML model. The datasets used for training of the proposed model have also been discussed in this section.

A. Description of the Dataset Used

For verification and validation of the proposed optimized hybrid DNN-ML framework, two different and original CXR (Chest X-Rays) and CT scan datasets have been utilized. The first dataset, i.e, CXR dataset, is a multiclass dataset, consists of COVID-19, viral pneumonia, and normal CXR image classes. The second dataset, comprises CT scan images, is a binary class dataset consisting of only COVID and non-COVID (COVID negative) image classes. First dataset in original form has been collected from different sources ([30], [31], [32]). The reason behind choosing these sources is as they contain original or non-processed CXR images. Because of continuous and ongoing research on COVID-19 disease, the newer version of this dataset may contain processed images which may lose their originality with the passage of time. The collected CXR image dataset is a balanced image repository containing 364 images for COVID-19 and other classes in order to avoid the problem of overfitting. Similarly, the second dataset related to lung disease patients comprises 349 CT scan images for both the classes (i.e., COVID-19 and non-COVID-19) [33].

The CXR images of patients suffering from COVID-19, Viral Pneumonia diseases, and Normal CXR images, and CT scan images of COVID-19 and COVID-19 negative patients have been presented in Fig. 1(a) and (b) respectively. CXR images of patients infected with COVID-19 show hyperlucent lung area denoting hyperinflation of lungs due to hindrance of small airways. CXR images with no abnormality detected show chest wall with normal shape and size plus trachea with normal appearance and zero opacity. CXR images of patients infected with viral pneumonia represent diffused bilateral GGO showing disperse alveolar. For training of the proposed hybrid model, enhanced version of both datasets have been prepared by using image preprocessing techniques, as presented in the next section. In order to study the effects of applied image preprocessing technique, results for the same have been verified using both original and enhanced CXR and CT scan image datasets.

B. Image Preprocessing

A variety of proficient and non-invasive medical imaging systems such as MRI, PET, Endoscopy, CT scan and X-Rays can be used to capture images internal infected parts of various organs in the human body. The two most commonly used medical imaging modalities for diagnosis of infectious lungs diseases are CT scan and CXR images. Both raw CXR and

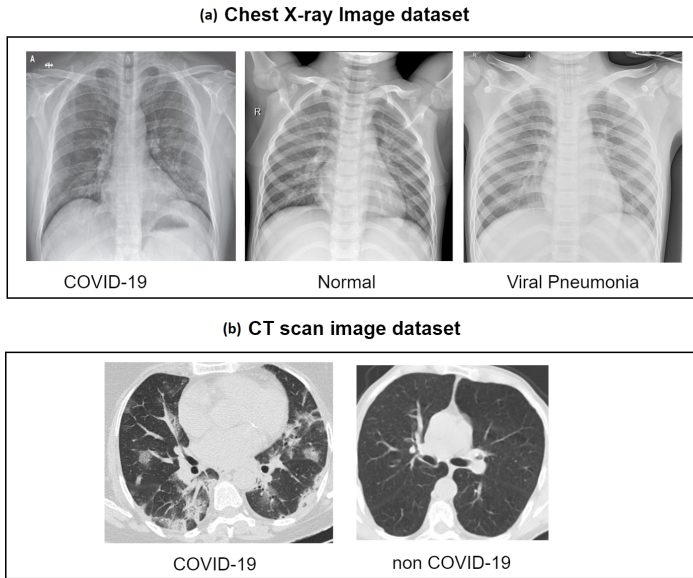

Fig. 1. Sample images from the original CXR and CT scan image datasets.

CT scan images can contain different types of noise patterns, including unrelated blobs, soft lung tissues and fine blood vessels. Henceforth, classification results can be misguided by soft lung tissues and minute blood vessels found in CXR images and CT scans. Thus, in order to improve the model accuracy, it is imperative to preprocess these medical images so that pertinent information can be extracted from the same after eliminating various types of noise patterns [34]. Also, to enhance the image quality of the raw medical data, image preprocessing can be applied to digitized images for enhancement of visual information contained in them [35].

The proposed image preprocessing approach applied to raw CXR images and CT scan images for the purpose of image enhancement comprises the following steps:

- 1) Image Segmentation (Using Edge Detection)
- 2) Image Filtration (Median filter)
- 3) Image Enhancement (Intensity improvement using CLAHE's method)

1) *Proposed Image Segmentation Technique: Image Segmentation* performs segmentation or masking of meaningful region or *Region of Interest (ROI)* area from an image so that there is no effect of noise patterns on the accuracy of image classification process [36].

For detection of COVID-19 using CXR images and CT scans, the target ROI is lungs (i.e. both left and right lung regions). The training of DNN model based on masked lung area, i.e., ROI will always provide with a more accurate disease prediction. The process of image segmentation used to perform ROI extraction from CXR and CT scan images is a very time-consuming and tedious process due to large size of COVID-19 image datasets; therefore, it can't be performed manually. It has been also shown in previous studies that, AI based U-NET model as the conditional Generative Adversial Networks (GANs) [14] [23] has been used for the extraction of ROI regions. The inclusion of DNNs for image segmentation pro-

cess in various previous studies has contributed to additional overhead in terms of overall training time and computational complexity.

Originally, both CT scan and CXR images are *grayscale* in nature. But, the available CT scan and CXR images in the used dataset may contain some blue colored biomarkers. Therefore, for generation of accurate binary mask in the image segmentation step, it is important to convert these existing original images into grayscale. This study devises an *adaptive edge based image segmentation technique* has been devised as an intermediate and transitional solution for fast and accurate ROI extraction from the original images. This proposed technique uses *Canny Edge Detection* and a set of *Morphological operations* for automatic extraction of lungs ROI. It consists of three major steps.

- 1) *Image smoothing*, which is performed in the first step by using *Gaussian filter* function $G_f(x, y)$ ¹, (equation 1);
- 2) The second step involves calculation of *gradient magnitude* $G_m(x, y)$ and *gradient direction* $\theta(x, y)$ (equations 2 and 3);
- 3) Application of *edge point detection and connection* function $E_p(x, y)$ has been performed in step 3 (equation 4).

$$G_f(x, y) = [G_x(x, y) * G_y(x, y)] * I(x, y) \quad (1)$$

$$G_m(x, y) = \sqrt{G_x^2(x, y) + G_y^2(x, y)} \quad (2)$$

$$\theta(x, y) = \arctan \left[\frac{G_y(x, y)}{G_x(x, y)} \right] \quad (3)$$

where,

- $G_x(x, y) = (-P_1 + P_2 - P_3 + P_4)/2$;
- $G_y(x, y) = (P_1 + P_2 - P_3 - P_4)/2$;
- $I(x, y)$ is an original grayscale CXR/CT scan image;
- P_1, P_2, P_3, P_4 are the pixel values of the coordinates $(x, y), (x+1, y), (x, y+1), (x+1, y+1)$, respectively of an original grayscale image;
- x and y represent the corresponding row and column of an original grayscale image.

The proposed image segmentation technique uses *canny edge detection method* combined with *Hough Transform (HT)* [37] for connection of edge points. Hough Transform method overcomes the boundary leakage problem that arises during the process of edge detection by finding all the collinear points (along the directions of an edge) by joining them as edge points, thereby producing efficient results for low intensity images as well.

¹Gaussian filter is based on Gaussian function, and it can be defined as

$$G(x, y) = \frac{1}{2\pi\sigma^2} \exp \left[-\frac{(x)^2 + (y)^2}{2\pi\sigma^2} \right]$$

$$E_p(x, y) = \begin{cases} \text{mark (x,y) as edge points in } G_f(x, y)^2 & \text{if } G_m(x, y) \geq t \\ \text{mark (x,y) as candidate edge points,} & \text{otherwise} \end{cases} \quad (4)$$

where, t is the threshold value, obtained by applying Ostu method [38]. The resultant HT Canny Edge-detected binary image $BM(x, y)$ is further preprocessed by using 3-step application of widely acceptable *dilation*, *fill* and *erosion* morphological operators. First step involves application of dilation operator (*dil*) for edge dilation to $BM(x, y)$ resulting in $BM_1(x, y)$ (Eq. 5) The second step comprises use of fill operation (*fill*) (Eq. 6) on dilated image $BM_1(x, y)$ for filling the holes based object intensity of displayed region resulting in a filled image $BM_2(x, y)$. The third and final step deploys the erosion operator (*erode*) (Eq. 7) on $BM_2(x, y)$ for removal of the connected components on the edge boundary resulting in computation of a final binary image $BM_{final}(x, y)$.

$$BM_1(x, y) = dil(G_f(x, y)); \quad (5)$$

$$BM_2(x, y) = fill(BM_1(x, y)); \quad (6)$$

$$BM_{final}(x, y) = erode(BM_2(x, y)); \quad (7)$$

$$I_s(x, y) = BM_{final}(x, y) * I(x, y) \quad (8)$$

where

- $BM_1(x, y)$ - A binary mask obtained after edge detection;
- $BM_2(x, y)$ - A binary mask obtained after edge dilation;
- $BM_{final}(x, y)$ - The final binary mask obtained after removal of connected components;
- $I_s(x, y)$ - The final segmented image.

The final segmented image $I_s(x, y)$ with the extracted ROI is procured by segmenting an original grayscale image with the computed binary image $BM_{final}(x, y)$ mask, resulting from the application of edge detection and morphological operators as a binary mask (Eq. 8).

2) *Image Filtration Methodology*: **Image filtration** is responsible for modification or enhancement of image modification by removing different types of noise³ existing in them. *Noise* can be classified as *Gaussian*, *Salt and Pepper*, *Poisson*, *impulsive and speckle noise*. The CXR and CT scan images which have been used to validate proposed model are mostly subject to Gaussian, Salt and Pepper, and Poisson noise. *Gaussian noise* can be eliminated by using a *Gaussian filter* (as described in image segmentation phase). And, for the removal of *Salt and Pepper*, and *Poisson noise* from CXR and CT images, *median filter* has been applied to segmented image that includes the extracted ROI (for lungs region).

$$I_f(x, y) = Med(I_s(x, y)) \quad (9)$$

where, Med is a median filter and $I_f(x, y)$ is a filtered and sharpened image⁴ obtained after application of median filter to segmented image $I_s(x, y)$.

The proposed image filtration technique uses a median filter to generate a low-frequency image by replacing the pixel value with a median pixel value in an image, computed over a square area of 8×8 pixels centered at the pixel locations.

3) *Proposed Image Enhancement*: **Image enhancement** enhances the contrast value of grayscale and colored images, and plays a vital role in medical imaging for improvement of visual perception quality. In case of CXR and CT scan images, the strong contrast in the white area washes out the vital information saved in white pixels of an image [8]. The proposed image enhancement methodology, applies improved version of *AHE* (*Adaptive Histogram Equalization*), termed as *CLAHE* (*Contrast Limited Adaptive Histogram Equalization*) [39] to filtered images (Eq. 10) for *intensity enhancement*, *improvement of local contrast and edge definitions*; and produces final enhanced images used for training the proposed hybrid DNN-ML framework.

$$I_e(x, y) = Clahe(I_f(x, y)) \quad (10)$$

where $I_e(x, y)$ is a final enhanced image and *CLAHE* is an image enhancement technique that enhances images by evenly spreading intensity level in small regions throughout the images and setting up the maximum contrast limit [40].

The step-wise functional implementation for preprocessing of CXR and CT scan images has been presented as Algorithm 1 and the corresponding set of transformations have been demonstrated graphically as in Fig. 2(a)-2(h) and Fig. 3(a)-3(h), respectively.

Algorithm 1 The Proposed Image Preprocessing Methodology

- 10: **end for**

³Noise refers to errors occurring at the time of image acquisition process and in case of CXR, imaging of ribs can be considered as noise

⁴The process of median filtering improves the sharpness of CXR and CT scan images by eliminating the impacts of noise and blurriness during image acquisition.

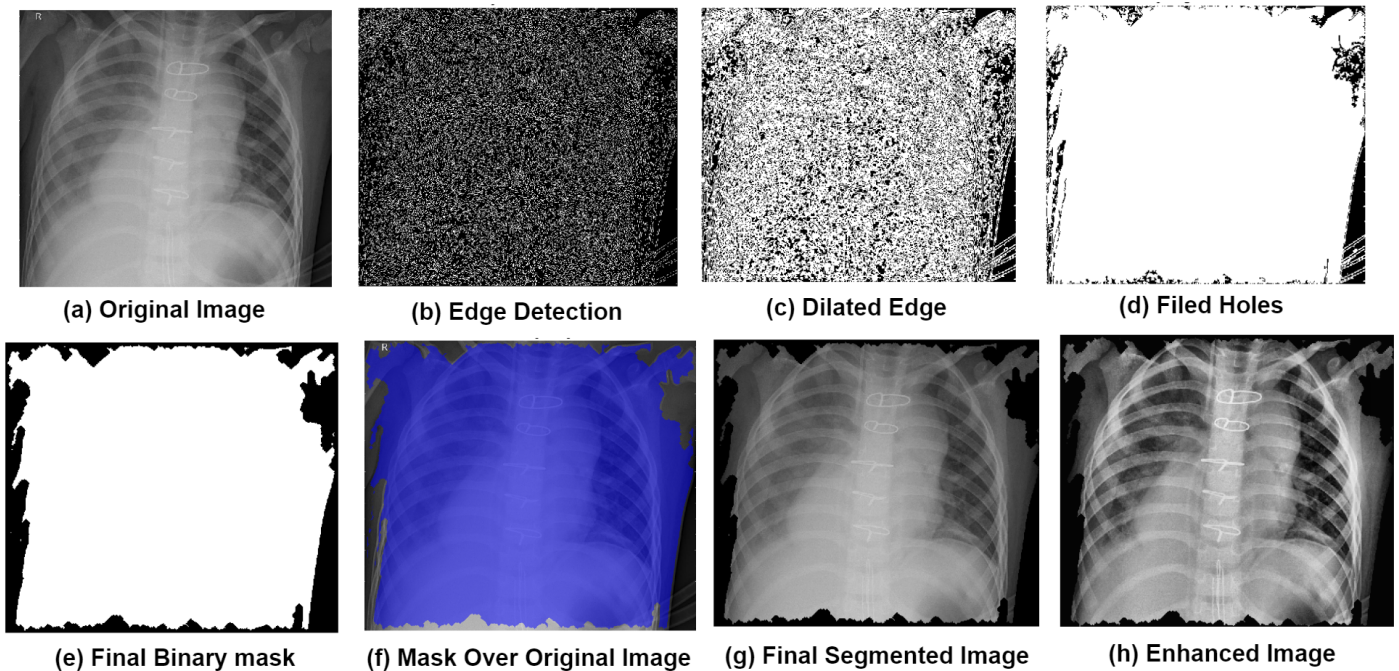

Fig. 2. Application of the proposed segmentation and image enhancement technique on Chest X-ray images.

C. Feature Extraction Process

After the feature enhancement phase (which includes image segmentation, filtration and intensification steps), **feature extraction** process is applied on the processed, enhanced and obtained segmented CXR and CT scan images, from the previous step. Feature extraction is the typical and challenging task, which involves capturing of various significant attributes of an image such as *texture, color, intensity, edge information* etc. This work uses advanced *Deep Neural Networks (DNNs)* to extract features of enhanced images.

Convolutional Neural networks (CNNs) are a sub-type of DNNs, widely used in the domain of computer vision, such as object detection and image classification etc. CNNs consist of input, convolution, max/average pooling, fully connected and classification layers. The combination of these layers with *different techniques and topologies* has resulted in various variations of CNNs such as VGG19, ResNet50, GoogleNet and many more. The layers used by the proposed model for performing the process of feature extraction can be summarized as follows. Firstly, input images are loaded into image / input layer and further fed to convolutional layers for convolution operation and for production of the final output feature map. The pooling layer also called down sampling downsizes the feature map, i.e, reduces the feature map without any significant feature loss related to input image. Lastly, a fully connected layer collects the final output comprising features extracted by CNN model and passes them to classification layer.

This work uses three pretrained DNN models namely, *GoogleNet, ResNet50 and EfficientNetB0* as a feature extractor tool to extract various significant characteristics from CXR and CT scan images. These prominent extracted features are further used by the feature classifiers in order to classify COVID-19

images. Each of these models has a different architecture and specific input/image layer size. It is important to resize the input image according to the input layer size for each model and this study uses data augmentation approach for image resizing.

1) *GoogleNet*: *GoogleNet* is a pretrained CNN consisting of 144 layers including convolution, ReLU, average and max pooling, concatenation and fully connected. Inception modules are the building blocks of *GoogleNet* which comprises convolution with filters in vary size (1×1 , 3×3 and 5×5) and *performs convolution operation in parallel*. Each inception block contains max pooling layer which reduces feature dimensions while retaining most significant features simultaneously [41]. The fully connected layer in *GoogleNet* called “loss3-classifier”, performs storage and retrieval of extracted features, and it extracted almost 1000 features in this work.

2) *EfficientNetB0*: *EfficientNetB0* is based on the principle of compound scaling which balances the network length, width and resolution to increase the feature extraction efficiency. It consists of convolution layers, 2D global average pooling layer, batch normalization, fully connected layer, and sixteen depth separable *convolutional blocks (mobile inverted bottleneck convolution)* [42]. The “dense | matmul” layer has been used in this work for performing feature extraction process, and it extracted almost 1000 significant features.

3) *ResNet50*: *ResNet50* is a variant of ResNet model also called “Residual Network” with deep 50 layers. And, the residual connection existing in this network can be termed as distinguishable feature which helps grasping residual functions and mapping the input with desired output. The two major components of ResNet50 are *convolutional and identity blocks* that further comprise several convolutional layers followed by *batch normalization and activation function (ReLU)*. These

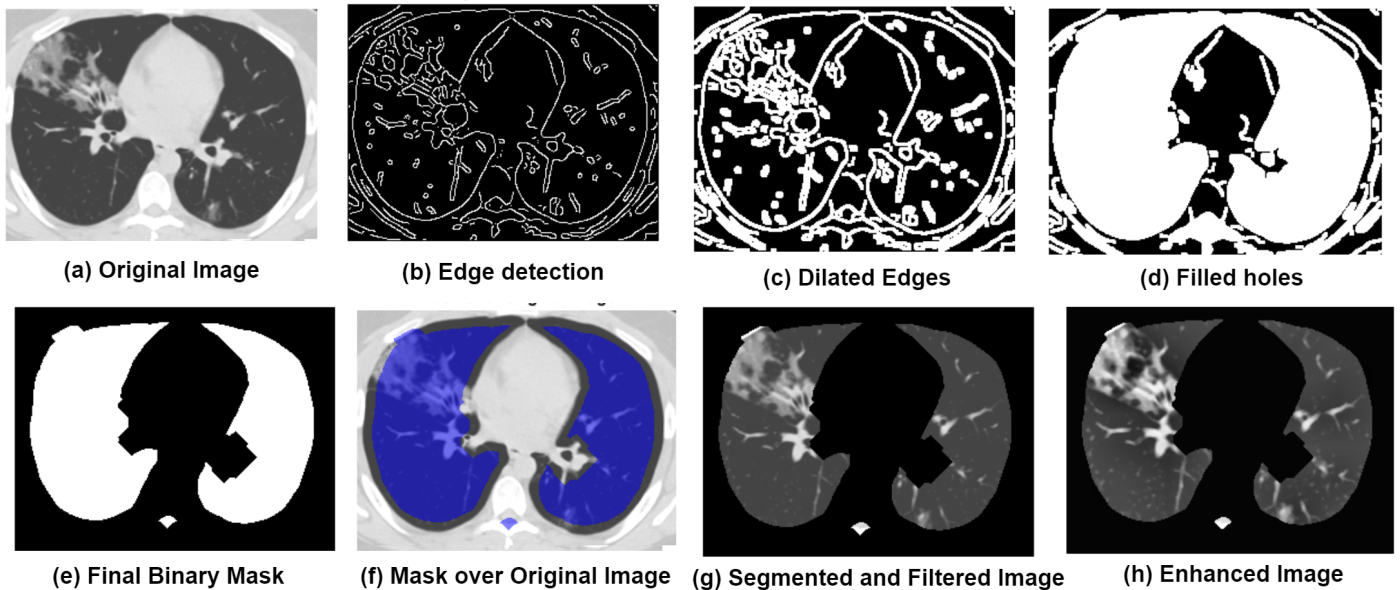

Fig. 3. Application of the proposed segmentation and image enhancement technique on CT scan images.

layers are responsible for capturing the features such as color, shape, texture and edge information [43]. This work uses ResNet50 with “fc1000” fully connected layer for extraction of 1000 features.

For the purpose of validation and benchmarking, all these three pretrained DNN architectures have been trained using enhanced CXR dataset. Each model has been initially operated for 30 epochs and each epoch further consists of 330 iterations, with batchsize of 64 and learning rate of 0.0001. For the training of aforementioned pretrained CNN models the enhanced CXR dataset has been splitted into training and testing set ratio of 70:30 respectively. It has been observed that when these three DNNs, i.e., GoogleNet, EfficientNetB0 and ResNet50 trained on enhanced CXR dataset have been compared for accuracy, they performed with 96.94%, 95.72% and 92.97% respectively. The performance metrics for all three implemented pretrained networks have been shown in Table I. *The highest accuracy has been achieved by ResNet50 (96.94%) with total training time of 514 minutes*, which outperformed the other implemented models to detect COVID-19 using enhanced CXR dataset. GoogleNet stayed close with 95.72% accuracy, but training time (612 min) taken to achieve the same has been more as compared. The training time (674 min.) taken by EfficientNetB0 and achieve accuracy (92.97%). Henceforth, for performing feature extraction in this work, ResNet50 can serve as the best choice. The sequential process of feature extraction has been mentioned in Algorithm 2.

TABLE I. RESULTS OBTAINED FOR PRETRAINED DNNs USING ENHANCED CXR DATASET

DNN model	Accuracy (%)	Recall (%)	Precision (%)	F-Score (%)	Time (min)
GoogleNet	95.72%	95.2	95.8	95.75	612
EfficientNetB0	92.97%	93.4	93.1	92.96	674
ResNet50	96.94%	96.92	96.93	96.92	514

Algorithm 2 FEATURE EXTRACTOR

- 6: $f_{ext} \leftarrow COVNET_{max}(FC_{layer})$ \triangleright Extract set of features from fully connected layer FC_{layer} of extractor

D. Feature Classification Process

The features extracted by the “fc” fully connected feature layer of ResNet50 model are fed to ML classifiers for performing **feature classification**. This study utilizes Bayesian optimized ML classifiers(i.e, *Decision Tree (DT)*, *K-Nearest Neighbor (kNN)*, *Naive Bayes (NB)*, *Discriminant Analysis (DA)* and *Support Vector Machine (SVM)*) for *feature-based image classification* from CXR and CT scan image datasets.

- *Decision Tree (DT)* classifier [44] is a tree based decision-making model for classification of image features where internal nodes and branches of a tree represent and rules, respectively. DT classifier works

on entropy and information gain parameters (Eq. 11).

$$entropy(D) = \sum_{i=1}^{|c|} P_r(C_i) \log_2 P_r(C_i), \text{ where } \sum_{i=1}^{|c|} P_r(C_i) = 1 \quad (11)$$

On the basis of these parameters, each node of DT is further splitted until the traversal of final leaf node, which represents the final output class. The vital hyperparameters that can be considered for fine tuning of DT classifier are *maximum number of splits* and *maximum depth*.

- *K-Nearest Neighbor (kNN)* [45] classifies the new data point according to similarity with its neighboring points. To find similarity, distance between the new and neighboring data points is computed using various methods (i.e., Euclidean, Manhattan, Spearman, Murkowski, etc.). This study computes *euclidean distance D* (equation 12) with k-NN for image classification.

$$D = \sqrt{(x - x_i)^2 - y - y_i)^2} \quad (12)$$

k-NN classifier can be refined by optimal values of *neighbor size (k)* and *distance method* as vital hyperparameters for accurate results.

- *Naive Bayes(NB)* [46] is a simple probabilistic algorithm based on *Bayes' theorem* (Eq. 16) and it classifies images identical to the corresponding disease type (COVID-19, Viral Pneumonia, Normal images) with the largest posterior probability. The objective function $O(x)$ of NB can be defined as (Eq. 13)

$$\hat{y} = argmax_y P(y) \pi_{i=1}^n P(x_i | y) \quad (13)$$

where, $P(x_i | y)$ is the posterior probability of x_i for given values of y .

In NB classifier, the smoothing hyperparameter (α), which is continuous in nature is the only one that needs to be fine-tuned for refinement of the former.

- *Discriminant Analysis (DA)* [47] is a statistical approach based on Bayes' theorem (16) and estimates the probability of new data point with respect to each class. And, the class having highest probability will be the class DA for a new point. The objective function $O(x)$ for DA can be defined by (Eq. 14)

$$\hat{y} = argmax_{y=1 \dots k} \sum_{k=1}^k \hat{P}(k | x) C(y | k) \quad (14)$$

- *Support vector machine (SVM)* [48], is a prominent nonlinear classifier which divides the dataset into two parts by using a hyperplane. It can efficiently handle both linear and non-linear data. Hyperplane learning is facilitated by Kernel function $f(x)$ (where type of kernel functions are Linear, Polynomial, Radial Basis Function(RBF), Sigmoid). The objective function

$O(x)$ for SVM can be defined by Eq. 15.

$$argmin\left(\frac{1}{n} \sum_{i=1}^n max(0, 1 - y_i f(x_i) + Ew^T \cdot w)\right) \quad (15)$$

where, w denotes normalization vector and E represents classification error rate. The most crucial hyperparameter which can be optimized for best results in SVM model is *kernel type*.

1) *Hyperparameter Tuning process for ML Classifiers:*

Hyperparameter Optimization (HPO) [49] process involves finding the most appropriate set of hyperparameter values before training phase of ML classifier that results in the best performance in a finite duration of time for a particular dataset. The major objective of HPO is to obtain optimal performance for ML models by finetuning their hyperparameters under time constraints. Since, *training time* is one of the crucial factors for HPO of ML models, therefore, for every new set of hyperparameter values, the entire model is retrained and performance of the latter is evaluated [50], [51]. It is important to determine the optimal values for the relevant hyperparameters in a ML classifier, in order to maximize the value of classification accuracy. Most commonly used hyperparameter tuning methods are *Grid Search (GS)*, *Random Search (RS)*, and *Bayesian optimization (BO)*.

Grid search is a time-consuming optimization technique, as it iterates for all the possible values of the selected hyperparameters and henceforth, is an infeasible approach. On the other hand, random search, randomly selects various possible values for the selected set of hyperparameters and computes the results, and may miss the best suitable combination for set of hyperparameter values, concluding it to be an inefficient approach. As compared to GS and RS, BO, is a probabilistic optimization technique that uses prior information (previous outcomes) of various experimented hyperparameter values to compute the next ones and avoids unnecessary iterations. This increases the computational power of BO, and it finds optimal hyperparameter values using fewer iterations as compared [52]. Therefore, this study has adopted BO as a hyperparameter tuning method that makes it as heart and soul of the proposed hybrid DNN-ML model for chest disease diagnosis. The implementation of BO along with its various outcomes, has been discussed in the upcoming sections.

2) *Bayesian Optimization: Bayesian optimization (BO)* [53] has been derived from Bayes' theorem. And, it states that for a given information I , the posterior probability ($P(M|I)$) of a given model M is directly proportional to the product of likelihood $P(I|M)$ and marginal or prior probability $P(M)$ defined in Equation 16.

$$P(M|I) = P(I|M) \times P(M) \quad (16)$$

Bayesian approach uses the information retrieved from data(considered as prior knowledge) along with the factors that improve existing knowledge from the derived posterior knowledge. BO based Hyperparameter optimization problem can be defined as in equation 17) and its goal is to obtain maximize or minimize the value of objective function $O(x)$.

$$x^* = argmin_{x \in X} O(x), \text{ or } argmax_{x \in X} O(x) \quad (17)$$

where,

- X denotes the search space comprising x samples, expressed as $x_1, x_2, x_3, \dots, x_n$ with size of search space $= n$.
- x^* represents hyperparameter configuration that generates the maximum/minimum value of $O(x)$.

The values of x_1, x_2, \dots, x_n can be estimated using the objective function $O(x)$. The sequential combination of these samples and their evaluations forms a set S expressed as $S = x_1, O(x_1), \dots, x_n, O(x_n)$. The set S is further used to define the surrogate model (SM) for generating the value of posterior probability.

This study uses Gaussian Process (GP) as a surrogate model because of its stochastic behavior and normal distribution property. GP is defined as the function of mean $\mu(x)$ and a covariance matrix $K(x, x')$ (Eq. 18).

$$O \sim GP(\mu(x), K(x, x')) \quad (18)$$

The optimal values for $O(x)$ can be determined using the posterior probability value, according to the acquisition function(α). The minimum value of Bayesian optimized objective function $O(x)$ can be derived by from set X selected on the basis of α .

$$x^+ = \underset{x \in X}{\operatorname{argmin}} \alpha(x | X), \text{ or } \underset{x_i \in X_{1:t}}{\operatorname{argmin}} O(x_i) \quad (19)$$

where, x^+ represent the position for which objective function $O(x)$ obtains maximum value after t sample points. Acquisition function uses Expected improvement (EI) method (equation 20), to evaluate the degree of improvement for the objective function $O(x)$.

$$EI(x) = \max\{0, O_{t+1}(x) - O(x^+)\} \quad (20)$$

The step-wise implementation of proposed Bayesian Optimization for hyperparameter optimization of ML classifiers has been shown as Algorithm 3. The set of computed hyperparameters using BO with ML classifiers, for chest disease diagnosis from CXR and CT scan image datasets are shown in Table II.

E. Evaluation Metrics

The four major performance metrics, i.e., *Accuracy*, *Precision*, *Recall* and *F-Score* have been utilized in this study to assess the effectiveness of proposed optimized hybrid DNN-ML model.

$$Accuracy = \frac{TP + TN}{TP + TN + FP + FN} \times 100\% \quad (21)$$

$$Precision = \frac{TP}{TP + FP} \times 100\% \quad (22)$$

$$Recall = \frac{TP}{TP + FN} \times 100\% \quad (23)$$

Algorithm 3 Pseudocode for applied Bayesian optimization technique

Input: $X \leftarrow$ Hyperparameter Space of size n , $O(x) \leftarrow$ Objective function

Output: $x_{optimal} \leftarrow$ optimal hyperparameter configuration, $y_{optimal} \leftarrow$ optimal objective function value

- 1: Assign initial value x_0 and calculate objective function value $y_0 = O(x_0) \triangleright$ initial hyperparameter configuration
- 2: Set $x_{optimal} = x_0$ and $y_{optimal} = y_0$ with Training set $T_0 = x_0, y_0$
- 3: **for** i in range n **do**
- 4: Obtain new values for hyperparameter configuration by optimizing acquisition function α_i
- 5: $x_i = \underset{x \in X}{\operatorname{argmin}} \alpha(x | T_{i-1})$
- 6: Calculate objective value $y_i = O(x_i)$
- 7: Update the training set $T_i = T_{i-1} \cup \{x_i, y_i\}$
- 8: Update the surrogate model
- 9: **if** $y_i < y_{optimal}$ **then**
- 10: $\{x_{optimal}, y_{optimal}\} = \{x_i, y_i\}$
- 11: **end if**
- 12: **end for**
- 13: **return** $\{x_{optimal}, y_{optimal}\} \Leftarrow$ optimal set of hyperparameter configuration and objective function value

$$F - score = \frac{2TP}{2TP + FP + FN} \times 100\% \quad (24)$$

where, TP, TN, FP, FN are values of *True Positive, True Negative, False Positive and False Negative* scores, respectively. These values can be calculated from the resultant confusion matrix.

F. Proposed Framework

This section describes the proposed framework for classification of COVID-19 images using two different datasets that

vary according to size, mode and labels. This work proposes a *three-layered optimized hybrid DNN-ML framework*. The three different layers are, feature enhancement, feature extraction and classification layer performing three distinguished tasks. The framework of proposed approach has been presented in Fig. 4. *Phase-I* (feature enhancement layer) performs the image preprocessing task for enhancing the image quality and ROI extraction with significant features of an image. This Phase comprises the proposed image segmentation, median filter and CLAHE methods for capturing image features that denote abnormal/disease region, for passing to Phase-II (feature extraction layer). *Phase-II* has deployed ResNet50 as a feature extractor tool because of its strengths such as lesser training time and higher classification accuracy. A sum total of almost 1000 distinguishable features has been extracted by the Phase-II, further dividing them into training and testing feature set in ratio 70:30. The training features have been given to *Phase-III* (Feature classification layer) as an input for training of ML classifiers. And, the test features have been employed to validate the classification accuracy of Bayesian optimized ML classifiers for CXR and CT scan image datasets. The Algorithm with all sub-procedures for the proposed hybrid BO DNN-ML model has been presented as 4.

Algorithm 4 Sequential Implementation for the proposed hybrid BO DNN-ML model

```
Input: DS ← Image repository
Output: Image classification and accuracy using proposed model
1: procedure IMAGE PREPROCESSING(DS) ▷ Apply various Image Preprocessing techniques
2:   N ← Number of images in each class

IV. EXPERIMENTAL RESULTS

In this study, three experiments have been conducted for the performance analysis of the proposed approach to detect COVID-19 on two different types of datasets: Chest Xray and CT scan image dataset. Firstly, the images have been segmented and enhanced with the proposed adaptive edge based segmentation algorithm. Afterwards, the proposed hybrid model described in Section 3 has been applied to enhance images for the next processes of feature extraction and

classification. This section presents experimental specifications and results obtained in detail.

A. Experimental Setup

The hardware and software specifications of experimental setup include a computer system with 8 GB RAM, 7th Generation Intel Core i7 processor, Windows 10 as an operating system and MATLAB R2023b installed on it. The experiments have been carried out using two different datasets (CXR & CT scan images) and preprocessing applied to them before training of the proposed model. Various Morphological operators predefined in MATLAB [54] have been used for preparation of an enhanced dataset.

B. Experiment 1: Performance Evaluation of ResNet50 using Original CXR and CT Scan Datasets

The experiment 1 investigates the impact of image preprocessing for the improvement of *classification accuracy*. Numerous research studies have shown disease detection models with high classification accuracy but all of them used computationally intensive pretrained models to perform image preprocessing. Moreover, some research studies also utilized ANN models to perform image segmentation which introduces an additional overhead in overall computational time. This experiment illustrates the use of edge detection technique for image segmentation which improves both classification accuracy and efficiency of light weight ResNet50 model. Various performance metrics used for performance evaluation and comparison of ResNet50 with both original and enhanced datasets have been mentioned in Eq. 21, 22, 23 and 24. A summary of comparative results (Table III) show that ResNet50 achieved highest accuracy values of 96.94% and 96.67% with enhanced CXR and CT scan datasets. These results depict that no matter what type of images have been used for the training of DNN model, *feature enhancement always leads to the accuracy improvement*.

TABLE III. PERFORMANCE METRICS FOR COMPARISON OF ORIGINAL AND ENHANCED IMAGE DATASETS WITH RESNET50

Dataset Modality	Dataset Type	Accuracy (%)	Class	Recall (%)	Precision (%)	F-Score (%)
CXR	Original	95.11%	COVID-19	95.4	100	95.04
			Normal	93.6	91.9

			COVID-19	96.2	97.1	

C. Experiment 2: Performance Analysis of the Proposed hybrid DNN-ML Model

Firstly, the proposed hybrid DNN-ML model has been trained and evaluated for CXR images dataset. ResNet50 has been employed as a feature extractor for the proposed model in experiment 2 and features extracted served as an input to disparate ML classifiers (viz., SVM, KNN, NB, DT, and DA). SVM classifier has been able to achieve the highest accuracy value of 97.25% with AUC value as 99.27% (Table IV). The

Fig. 4. Conceptual framework of the proposed optimized hybrid DNN-ML model.

confusion matrix obtained for various ML classifiers that have been trained using features extracted by ResNet50 has been shown in Fig. 5.

The same experiment is repeated CT scan dataset and as mentioned before, SVM outshined the rest of ML classifiers by achieving highest accuracy value 97.62% with AUC value as 99.84%. All the performance metrics and confusion matrix related to same have been presented as Table V and Fig. 6, respectively.

D. Experiment 3: Performance Analysis of BO based hybrid DNN-ML Model

This experiment involves training, validation and evaluation of the proposed Bayesian optimized hybrid DNN-ML model using enhanced CXR and CT scan datasets. The results obtained have been shown in Tables VI and VII. The maximum values of classification accuracy when the proposed Bayesian

optimized hybrid model has been trained with SVM for CXR and kNN classifier for CT scan image dataset, are 98.78% and 99.05% respectively. The confusion matrix and ROC curve after combining ResNet50 with the proposed BO-ML classifiers using CXR images have been presented in Fig. 7 and 8, respectively. Similarly, the confusion matrix and ROC curve for the proposed ResNet50 based BO-hybrid model trained on CT scan dataset have been presented in Fig. 9 and 10 respectively. The objective function presenting number of evaluations for BO-SVM validated with CXR and BO-KNN for CT scan image datasets have been presented in Fig. 8 and 10, respectively.

The performance comparison of ResNet50 model on original dataset containing raw images and enhanced dataset (using proposed image preprocessing methods) for CXR and CT scan images has been shown in Fig. 11. It can be concluded from the results, that image preprocessing techniques, i.e., primarily image segmentation and enhancement has helped in

Fig. 7. Confusion matrix obtained by using combination of ResNet50 and BO-ML classifiers for an enhanced CXR dataset.

Fig. 8. ROC and Expected Improvement function(BO-SVM) for the proposed optimized hybrid DNN-ML model for CXR images.

tremendous improvement of ResNet50 model’s performance for COVID-19 detection. And, it has considerable affect on classification accuracy score. The performance of Bayesian optimized ML classifiers combined with ResNet50 (DNN) is much better in terms of classification accuracy score as compared to non-optimized versions (Fig. 12). The final output in the form of tuple (image class, accuracy score) for CT scan images using the proposed hybrid BO DNN-ML model has been presented in Fig. 13.

E. Discussions

The work presented in this article has been compared with various contemporary and previous research studies for COVID -19 diagnosis using disparate medical imaging datasets. The comparative analysis includes parameters such as type of dataset, classification genre, applied image pre-processing, classification techniques and performance metrics (Accuracy) as discussed in Table VIII. The research studies that have specifically utilized CXR and CT scan image datasets for the validation of the proposed and deployed COVID-19 diagnosis framework, have only been considered in this comparative analysis. Arman et al. 2022 [13] had utilized a hybrid model that showed higher value of classification accuracy for CXR images but it used complex combination of Bayesian optimization and Xception model resulting in higher training time value. As compared to the proposed study, that used both CXR and CT scan datasets for training and testing of the optimized hybrid model, all the contemporary and previous studies have only focused on the use of single dataset, i.e., either CXR [9], [11], [14], [18], [23] or CT scan datasets [12], [24] for the training and testing of the applied

ML models. Moreover, none of these have used adaptive edge based segmentation and devised image preprocessing techniques for image enhancement that contributes to a more accurate and efficient feature extraction process.

V. CONCLUSIONS AND FUTURE WORK

This work has presented the utilization of image pre-processing techniques for dataset enhancement without any additional overhead in computation cost for automated chest disease diagnosis. The proposed image preprocessing technique has used HT-Canny based edge detection method with morphological operators(dilation, fill and erosion) for image segmentation and median filter with CLAHE construct for noise removal respectively. As shown in experimental results of this article, there has been significant improvement in classification accuracy because of image segmentation, filtration and enhancement of CXR(Accuracy score = 96.94%) and CT scan (Accuracy score = 96.67%) images. While comparing the performance of three DNN models, namely, ResNet50, GoogleNet and EfficientNetB0 for feature extraction using CXR dataset, ResNet50 dominated in performance as compared to the rest of models by expending least training time(514 minutes) and best accuracy score(96.94%). Furthermore, the present study combined disparate ML classifiers(namely DT, kNN, NB, DA and SVM models) with ResNet50 to formulate the proposed hybrid DNN-ML model. The proposed model showed that SVM classifier outperformed the rest of ML classifiers with an accuracy score of 97.25% and 97.62% for enhanced CXR and CT scan images respectively. Whereas, when Resnet50 was combined with Bayesian optimized ML classifiers to formulate the optimized hybrid DNN-ML model, BO-SVM(Accuracy

score = 98.78 %) and BO-kNN (Accuracy score = 99.05 %), outperformed their non-optimized versions, when trained with CXR and CT scan images respectively. It can also be noticed from the experimental results that, the proposed Bayesian optimized hybrid DNN-ML model performed much better when trained and tested on CT scan images than on the CXR dataset. As a future research direction, the use of meta-heuristic algorithms has been proposed to perform feature selection, so as size of feature dimension set can be reduced. This will help in minimizing computation time and improve accuracy score. Also, the proposed Bayesian optimized hybrid DNN-ML approach can be validated using other medical imaging datasets.

Preprocessing Techniques for Clustering Arabic Text: Challenges and Future Directions

Tahani Almutairi, Shireen Saifuddin, Reem Alotaibi, Shahendah Sarhan, Sarah Nassif
Department of Information Technology, King Abdulaziz University, Jeddah, Saudi Arabia

Abstract—Arabic is a complex language for text analysis because of its orthographic features, rich synonyms, and semantic style. Thus, Arabic text must be prepared more carefully in the preprocessing stage for the analyzer to improve the quality of the results. Moreover, many preprocessing steps have been proposed to improve the text analyzer quality by reducing high dimensionality, selecting the proper features to describe the text, and enhancing the process speed. This paper deeply investigates and summarizes the use of Arabic preprocessing techniques in Arabic text in general and focuses in-depth on clustering. Moreover, it focuses on seven preprocesses that are now used to prepare Arabic and provides the available tools for each of them; the seven preprocess are tokenization, normalization, stopword removal, stemming, vectorization, lemmatization, and feature selection. In addition, this paper investigates any work that uses synonyms and semantic techniques for preprocessing to prepare the text or reduce the dimensionality of the clustering algorithm. Therefore, this survey investigated nine techniques for Arabic text preprocessing to identify the challenges in this area. Finally, this study aims to serve as a reference for researchers interested in this area, and ends with potential future research directions.

Keywords—Arabic preprocessing; Arabic language; survey; clustering; Arabic analysis

I. INTRODUCTION

Arabic is the fourth most spoken language by native speakers, and the fifth most widely used language [1], [2], [3]. Arabic differs from other languages in that it is written and read from right to left with specific grammar, spelling, vocabulary, punctuation marks, and no case-sensitive letters. Moreover, sentences consist of verbs, subjects, and objects [4]. Arabic spoken by Arabs is known as classical Arabic (CA). Over time, CA progressed and developed into modern standard Arabic (MSA). Both versions have the same morphology and syntax but disagree grammatically and stylistically. Arabic dialects developed over time, adding to the diversity of Arabic. Dialects are informal versions of the language spoken by friends and family. Moreover, the dialects differ among Arabic countries [4], [3].

Arabic has recently attracted the attention of researchers, using various technologies and techniques. Over the past decade, Arabic and its dialects have gained attention in natural language processing (NLP) research [5], [6], which has helped the preprocessing stage in dealing with text in different applications that benefit diverse areas, especially text analysis, such as text classification, clustering, and sentiment analysis [7]. Text clustering is an unsupervised learning technique that discovers and groups text or documents into clusters. Document clustering groups similar documents without prior knowledge of their labels. Thus, every cluster formed contains

similar texts or documents. Clustering techniques identify and group texts or documents into clusters. Clustering is significant in many applications such as document retrieval, summarization, recommendation, marketing, customer analysis, document clustering, output detection, agriculture, pharmacy, and image processing [1], [8].

Many studies have used text preprocessing techniques to handle the high dimensionality of data before clustering to obtain good text clustering results [9]. Text preprocessing techniques are typically used to dramatically decrease the document size, facilitate feature selection, and enhance processing speeds. Arabic text pre-processing does not involve straightforward steps. Arabic text requires a morphological analysis that adds more challenges but is required for many reasons. The first is common orthographic variations, in which words are derived from a trilateral or quadrilateral origin system. The original system often obscures Arabic terms. Another reason for this is that Arabic synonyms within a language are extensive [1], [10], [6]. Moreover, preprocessing algorithms and techniques are limited and require further research [11].

Several Arabic preprocessing techniques, similar to other languages, have been proposed. However, some are specific and related to Arabic NLP techniques, such as tokenization, stemming, normalization, stopword removal, and lemmatization. Most Arabic preprocessing surveys focus on the classification, categorization, or specific types of Arabic fields. Only one study [12] focused on clustering to demonstrate the significant impact of term turning with stemming preprocess when vectorizing text based on TF-IDF. The authors examined and compared different text-preprocessing techniques for clustering Arabic documents. It investigated the effectiveness of techniques such as term pruning, term weighting using TF-IDF, and morphological analysis methods, including root-based stemming, light stemming, and raw text normalization. Furthermore, this study evaluates the impact of clustering algorithms, including the widely used partitioning algorithm.

In contrast, [5] comprehensively classified works on three Arabic varieties: MSA, CA, and Dialect, focusing on Arabic and Arabizi types. The authors endeavored to associate each work with publicly available resources, wherever possible, to facilitate further research and development in this field. In another study [13], the authors discussed the challenges posed by Arabic in the field of NLP and provided a brief history of Arabic NLP. The tools and resources available for Arabic NLP can be broadly classified into enabling technologies that are not user-facing, and advanced user-targeting applications.

In addition, [10] proposed the extraction of information from Arabic social media text by addressing data collection, cleaning, enrichment, and availability challenges. The

objective is to enhance information quality and reliability, contributing to a more effective and accurate analysis of Arabic social media content. Finally, according to [14], preprocessing is required to improve the accuracy and efficiency of Arabic information. Therefore, the author analyzed the existing techniques and identified the limitations and challenges of both types. They emphasized the importance of stemming and the need for further research to improve Arabic information retrieval.

This work explores and summarizes the application of Arabic preprocessing methods for clustering. Only one survey paper in the literature examines preprocessing methods for clustering Arabic text; other survey papers address different tasks or focus on one or two steps of the preprocessing process. This paper focus on tokenization, Arabic normalization, stop word removal, stemming, and lemmatization. It also discusses feature selection and vectorization as preparation steps for dimensionality reduction. In addition, it investigates Arabic synonyms and semantic solutions to determine whether any researcher used them as a preprocessing step to reduce the dimensionality of the clustered data.

In addition, this survey can also serve as a resource for scholars who are generally interested in Arabic preprocessing in general by answering the following questions: which preprocessing steps are used for clustering in particular, and to the Arabic language in general? Which tools are available for each preprocessing step's algorithms and techniques? Furthermore, can preprocessing be utilized to minimize dimensions and does it address the richness of synonyms in Arabic? And last, is one of the main features of Arabic that preprocessing addresses semantics?

To the best of our knowledge, this survey is one of the few that thoroughly examines clustering-focused Arabic preprocessing methods. The several preprocessing phases are covered in this paper, which also explores the field by offering resources for each Arabic language preprocessing step. While it primarily focuses on text clustering, it will also produce scientific information about Arabic preprocessing that can serve as a foundation for other domains.

The remainder of this paper is organized as follows. Section II presents the methodology used for this survey. Section III presents the Arabic preprocessing techniques. Recent studies on clustering preprocessing techniques are discussed in Section IV. Finally, the discussion and conclusions are presented in Sections V and VI, respectively.

II. METHODOLOGY

This survey was based on the PRISMA framework, a standard research strategy that searches online databases. PRISMA framework is used to systematically and carefully select high-quality and dependable references. The framework is shown in Fig. 1 and consists of four phases: identification of the research and search process, paper selection process, quality assessment, and extraction and synthesis phases.

In the first phase, the research process focuses on identifying and searching for high-quality resources that may be beneficial. This survey conducted an efficient search of libraries and journal databases, including IEEE Xplore, Springer, and

ScienceDirect, to find high-quality resources. Books, survey papers, and articles that contained important information for the survey were found via Google Scholar. Also, this survey looked up pertinent articles and references using a variety of keywords. Following their collection, the documents were sorted according to a set of criteria in order to identify the most pertinent and appropriate ones.

The following criteria were used to choose and assess the research publications in the paper selection process and quality assessment phases. Initially, between 2017 and 2024, possibly pertinent papers on Arabic preprocessing had to be presented at prestigious conferences or in scholarly journals. Additionally, the study needed to be relevant to the scope of this survey's Arabic preprocessing processes, with an emphasis on or discussion of the preprocessing tool that yields excellent results for Arabic language preparation. The titles and abstracts of the gathered papers were checked to make sure they fit the survey's scope. Lastly, the remaining studies were carefully reviewed. Only the most appropriate and high-quality papers valuable to this survey were used as references in the extraction and synthesis phase, resulting in 60 research papers.

III. ARABIC PREPROCESSING TECHNIQUES

This paper outlines the main Arabic preprocessing techniques shown in Fig. 2. The order of steps may vary depending on the model and research goals. The following subsection discusses these techniques and suggests helpful resources for each step.

A. Tokenization

Tokenization is an essential preprocessing step for any language because it is the first step that splits the long text into a small part called a "token," making it easy to use in text analysis algorithms [15], [16]. These words were then separated into numerous delimiters, including white spaces, tabs, and punctuation marks [15]. Although there are multiple tokenization algorithms, there is only one possible way to split a dataset into words. Moreover, a sub-word tokenizer allows splitting a dataset into units called "sub-words" [16], [12]. Therefore, depending on the depth of linguistic analysis, different Arabic tokenizer levels can be developed.

Because tokenization is essential, many research publications have discussed and used this technique. Similar to the authors in [15], the three tokenizers included stochastic, disjoint-letter, and morphological. The authors also discussed three other tokenizers: characters, words, and sentences. After evaluating these six tokenizers through applied unsupervised and supervised approaches, the authors provided the benefits and drawbacks of each Arabic tokenizer technique based on studying the effects of various tokenizers in Arabic for diverse Arabic classification techniques. Moreover, they created a tokenizer framework as an open-source library¹.

In addition, [10], [17] studied many Arabic preprocessing techniques on social media, including tokenization. The authors of [10] provided a combined solution for Arabic social media text preprocessing challenges at different stages: data collection, cleaning, enrichment, and availability. The proposed

¹<https://github.com/ARBML/tksem>

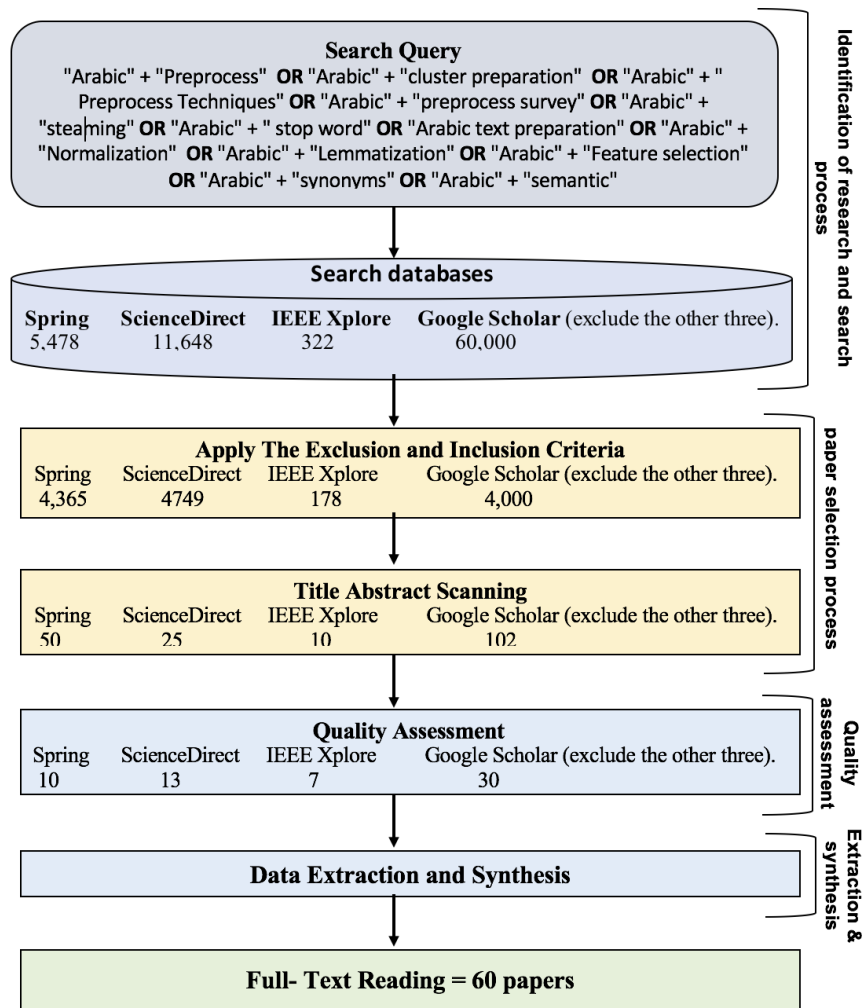

Fig. 1. The PRISMA flow diagram.

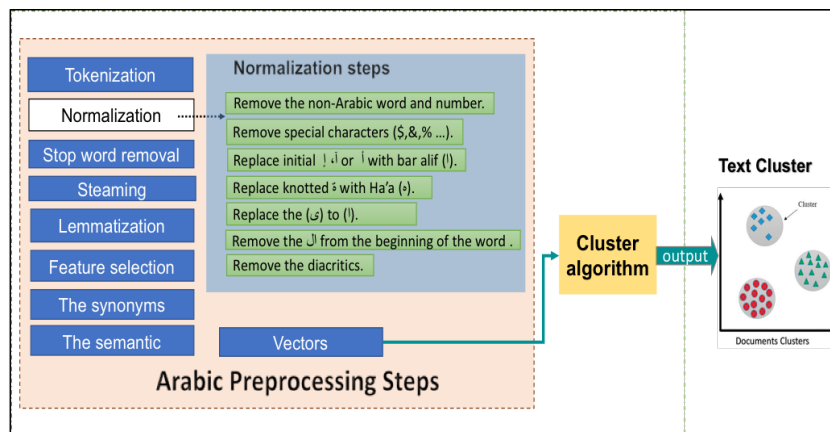

Fig. 2. Main Arabic preprocessing techniques discussed in this survey for clustering.

approach applies several NLP tools, including tokenization, stemming, and morphological analyses. The authors in [17] also investigated the impact of the 26 preprocesses applied to Arabic tweets by training a classifier to identify health-related tweets, studying the tokenization that divides the text into specific units with other preprocessing steps, where the text is divided into units in the tokenization process, and typically, those units are words.

Moreover, [12] and [18] studied Arabic document preprocessing. The authors of [12] examined and compared text preprocessing techniques in Arabic document clustering to study their effectiveness. However, they first prepared Arabic document text by tokenizing it based on words and removing stop words. In addition, [18] investigated the impact of stemming methods, an essential preprocessing step in classification. The main preprocessing steps used by the authors of [18] for Arabic include tokenization, normalization, stopword removal, feature extraction, and stemming. White space was used to tokenize the Arabic dataset.

Finally, tokenization is an essential Arabic preprocessing step because it splits long texts into small parts that are easy to use with any text analysis algorithm. However, tokenization in Arabic is not a straightforward step, according to [10]. This is complicated because of the structural sophistication of the Arabic language. Nevertheless, many tools are available for solving tokenization problems in Arabic, such as NLTK (Python) and PyArabic (Python). Finally, all reviewed resources tokenized the Arabic dataset-based words.

B. Stopword Removal

Stopword removal is essential for preprocessing all languages because it removes unimportant words and reduces the dimensionality of the texts used in the text analyzer. Stopwords include prepositions, pronouns, and articles that appear frequently and do not help distinguish documents [19]. Thus, the stopword benefits only from a syntactic procedure and does not distinguish the subject matter [20]. Furthermore, it is essential to filter out noise from vital text that is extraneous and irrelevant to the tasks [21]. Therefore, stop words are typically released with the support of a predefined list that includes common stop words.

Moreover, the most general strategy for stopword removal is based on frequency calculation and the removal of the most frequent words in all documents, which is known as dataset dependency [11], [20]. Another method to remove stop words is to use artificial patterns and perform entropy calculations. However, some general stop word lists can be used and are available online in many languages, including Arabic [20].

Stopword removal is applied to all languages as an essential step towards reducing the number of unimportant words. Many publications have discussed and provided solutions to this step in Arabic. For instance, [22] built a list containing 11,403 Arabic stop words for stop word removal. In contrast, the authors in [23] created an Arabic stopword list available online, consisting of three lists: a general list (1,377 stopwords), a corpus list that manually checked for the most repeated words appearing over 25,000 times (235 stopwords), and a combined list from the previous two. However, the authors of

[18] removed stopwords based on the prepared list, and used the same stopword list as [23].

In contrast, the authors of [21] proposed a solution to the Arabic stopword construction problem by providing a comprehensive list called the Arabic stopword list (ASL) with a stopword analyzer. The analyzer connected the ASL list with machine learning to discover the most probable stop words, divided into three classes: native particles, special nouns, and special verbs for 3,931 stop words. The authors then derived a complex stop word list containing 67,153 words by adding all possible clitics to the simple stop word list. Finally, the authors tested the proposed list against the available list through a quantitative evaluation, revealing that the ASL exceeded other lists in terms of coverage. Compared with the proposed solution, the main stopword lists are Khoja [24], El-Khair [23], and the stopword project ² and the Ranks NL³. Table I summarizes these stopword lists.

TABLE I. SUMMARY OF AVAILABLE STOPWORD LISTS

Stopword list name	Description	Limitation
Khoja	It contains 168 stopwords and was developed using statistical and rule-based techniques.	The list contains not all criticized forms of every stopword and corpus dependent.
El-Khair	It created three stopword lists: The first is a general stopwords list based on the Arabic language syntactic classes, consisting of 1,377 stopwords. The second is Corpus-based: manual checking of the words that appear more than 25,000, verifying this condition, and containing 235 words. Finally, the third list consists of 1,529 stopwords by combining the general list and the corpus-based lists	The list was not comprehensive and did not contain discretized.
Stopwords project	The Arabic list comprises 162 stopwords created under the GNU GPL v3 license.	The list corpus dependency contains some stopwords that may do not be correctly classified as stopwords, such as «مليار، قوة، اعلنت» (billion, force, announced).
Ranks NL	The Ranks NL project was search engine optimization, but the project suggests an Arabic stopword list containing 102 stopwords.	Corpus was dependent.
ASL	The general list contained 3,931 stopwords. Then, the authors added all possible clitics to get the complex list, which contained 67,153.	

The authors of [12] used a general strategy to determine a stopword list by calculating the term frequency for all terms and then removing the most frequent words after sorting the terms. Nevertheless, the authors first prepared the Arabic text through the tokenization step and removed stop words; thus, they mainly examined and documented clustering. Similarly, the authors of [17] used a general strategy to remove stopwords and compared text preprocessing techniques in Arabic based on the frequency of words in the dataset. Consequently,

²<http://code.google.com/p/stop-words>

³<http://www.ranks.nl/stopwords/arabic>

they studied stopword removal and eliminated frequently used unwanted words.

Furthermore, the authors of [22] conducted scoping reviews over the past two decades (2000–2020) for Arabic topic identification, following the PRISMA-ScR guidelines. One stage that they focused on was the preprocessing step with feature extraction, which included stopword removal, stemming lemmatization, and feature selection. The authors provide an overview of the field to make it current. Finally, they recommended future work to enhance topic identification performance by working on preprocessing phases or implementing other algorithms.

Finally, stopword removal reduces text dimensionality because it removes words that frequently appear in the text without affecting text analysis, such as prepositions and pronouns. Moreover, stop-word elimination is recommended in most cases [22]. There are two strategies for stopword removal based on the reviewed papers: a general strategy based on word frequency or building, and using a general stopword list. Many general lists can be used and are available online, such as those published in 2006 by [25] containing 1,377 words. Moreover, a recent list was published in 2019 by [21] called the ASL list, consisting of three categories: native particles, particular nouns, and special verbs. Thus, the list contains 3,931 words.

C. Normalization

Text normalization is essential for text classification and analysis. Some normalization steps were applied to all languages, such as removing numbers and special characters. However, other normalization steps are language-dependent, because there is a specific way to normalize each language. For example, one step might include normalizing uppercase letters to lowercase letters in English, as there are no lowercase or uppercase letters in Arabic. Thus, normalization in Arabic related to normalizing letters includes normalizing different forms of alif (ا, آ, إ) to (ا) and removing diacritics that are not used in English [26].

Moreover, several normalization steps are typically executed to reduce the number of extracted terms. The significant normalization applied to Arabic is presented in the following steps, based on the reviewed papers (Fig. 2).

Thus, normalization differs from stopword removal. Normalization is related to formalizing the shape and form of words and other goals, whereas stopword removal focuses on removing unimportant words from the text. Because Arabic requires a unique normalizing process, many research publications have focused on normalization steps. Table II lists the most commonly used Arabic normalizations.

Normalization is a significant and essential step in most text analysis models. For example, the authors in [17] investigated the impact of 26 preprocesses applied to Arabic social media, particularly tweets, by training a classifier to identify health tweets. Fourteen of the 26 preprocesses focused on variants to normalize the Arabic letters. The authors studied a normalization step that converts a list of words into a more uniform sequence, such as removing punctuation, diacritics, repeating, and duplicating letters, including noise removal that seeks to destroy unwanted characters from the text, such as non-Arabic

TABLE II. THE MOST ARABIC NORMALIZATION THAT USED

#	Normalization step
1	Remove non-letters and special characters, such as \$, &, and %
2	Remove non-Arabic letters
3	Replace initial (أ, إ or أ) with bar alif (أ)
4	Replace Ta'a marbota (ة) with Ha'a (ه)
5	Remove the (ال) from the beginning of the word
6	Replace the final (ى) with (أ)
7	Remove the diacritics.

letters and numbers. They also described Arabic normalization steps related to Arabic letters, and the researchers normalized many letters, including two letters, five letters, and six letters, such as “Hamza,” “alif” type, and “ta’a marbota.”

Similarly, [10] provided an integrated solution for Arabic preprocessing in social media challenges by cleaning a dataset and normalizing Arabic social media text. The cleaning step focuses on cleaning noisy text by selecting only the required text instead of many processes to remove different data noise. The algorithm transforms each letter into its standard form during cleaning. For example, “alif” “ا” has several forms, which are “أ, إ, آ”. In contrast, the normalization step changes the text into its standard form, with the algorithm changing a non-normal word into a normal word by eliminating duplicate characters and using a set of common non-normal words.

Furthermore, the authors of [18] normalized Arabic letters to help downgrade the various character shapes and produce a uniform shape representing these shapes. Therefore, the authors investigated the impact of stemming methods on feature reduction and classification accuracy.

Normalization is another essential step in preparing text for analysis. Some normalization processes are applied to all languages, whereas the other steps are language-dependent. Since Arabic has many characteristics related to letter shape, it requires normalization, including different forms of alif (ا, آ, إ) to (ا), Ta’a marbota (ة) to Ha’a (ه), and the final (ى) with (أ). Moreover, the normalization of Arabic involves removing the diacritics and the (ال) from the beginning of the word. Although several normalization steps are usually conducted to decrease the number of extracted terms, many available tools can be used for normalization problems, such as normalizing Arabic words using camel tools (Python) and PyArabic (Python).

D. Stemming

Stemming refers to the reduction of words to their stems or roots that are used to fit different word variants. Moreover, stemming is an essential preprocessing step for preparing text for the analyzer model, regardless of language type. There are three types of Arabic stemming, based on [27], [28], [6].

The first is root-based stemming, where the primary goal is to extract the roots of words using a stemmer. For example, in the Arabic language, several words can be reduced to one root, such as (التعليم، العلماء بالمعلم), which means “the education,”

“the scientists,” and “the teacher,” respectively, and are reduced to the root (علم), which means “science” [11], [28], [22].

Second, the stemmer eliminates additional suffixes and prefixes from words using light-stemming. Thus, it does not extract the original root; it only removes prefixes and suffixes from words. For example, the Arabic word (المعلم), which means “the teacher,” is reduced to (معلم), which means “teacher.” Hence, the semantics of the words are not affected by light stemming. Moreover, it normalizes words with diacritics and stretching characters (Tatweel ex: خبـــــــــــــــــر converts to خير) [11], [28], [22].

Finally, using a stem-based approach, the stemmer determines the stem that is part of the word to which grammatical prefixes and suffixes are added [28], [22]. The stem-based method does not attempt to determine the word root; it typically removes only clitics from a given word [28]. This technique preserves and represents the meaning of the text content well because it grammatically regroups inflected and related words [28], [22].

Stemming is a vital step in preparing text for analysis in most languages. Therefore, many studies have been conducted on Arabic stemming. For instance, a study [27] published in 2019 compared the stemmer ARLSTem with two versions (ARLSTem v1.0 and ARLSTem v1.1) to other light stemmers: the ISRI stemmer, Soori’s stemmer, Assem’s stemmer, and the Light10 stemmer. The authors then proposed an improved version of the ARLSTem stemmer by reordering some steps while adding others to improve performance. Next, the authors compared the improved version with the original and other stemmers, such as Light10. The results showed that the two versions of ARLSTem algorithm outperformed other algorithms based on understemming errors and overstemming indices.

Similarly, the authors in [10] provided an integrated solution for Arabic preprocessing of social media challenges by applying their new stemming algorithm to social media containing standard Arabic and dialects. The new Arabic stemmer module generates word stems, word roots, and specific word identifiers. The proposed model solved Arabic social media challenges that help understand a word’s meaning by providing its root and determining whether the word is a noun, stop word, non-standard Arabic word, dialect, error, or non-Arabic word.

In comparison, [18] investigated the impact of stemming methods, an essential preprocessing step in the classification accuracy, and the number of features used. The primary preprocesses used were tokenization, normalization, stopword removal, feature extraction, and stemming. First, the authors used the Light10 stemmer for stemming and represented documents as vectors. They then conducted experiments to test the impact of the stemming algorithms on the K-nearest neighbor, naive Bayes, and decision tree classification algorithms. The results showed the effectiveness of the stemming algorithm in reducing half of the features used while improving accuracy.

Similarly, in [28], the authors compared Arabic topic identification to investigate different stemming algorithms. The

main objective was to study the effects of stemmers: root-based, light stem, and stem-based. The authors used primary and available steaming approaches for the root-based selection of the Khoja and Tashaphyne root approaches. In contrast, light stem used Light10 and Tashaphyne light approaches, whereas for other types, they selected Farasa and Alkhalil1. The authors experimented using latent Dirichlet allocation (LDA) to identify the topics with different Arabic stemming algorithms. Hence, the authors determined which forms of words—root, stem, and light—were affected by the preprocessing step in topic identification. Indeed, Light10 identified topics better than the other stemmers.

Furthermore, [12] examined and compared text-preprocessing techniques in Arabic document clustering. The study indicated the significant impact of term pruning with stemming and term weighting as preprocessing steps in studying text preprocessing effectiveness. Notably, the authors experimented with different preprocessing techniques with term pruning combinations using the three systems. The first system combined term pruning with term weighting and light stemming (Light10). The second system combines term pruning with term weighting and normalization, whereas the last system combines term pruning with term weighting, normalization, and Khoja root-based stemming. The results were based on precision, recall, and F-measures, as the evaluation measures showed that the system using light stemming achieved better results than the others.

Similarly, [17] investigated the impact of the 26 preprocesses applied to Arabic health tweets by training four classifiers: MNB, logistic regression, linear SVC, and KNN. They discussed the steaming process and classified steaming into three types—root, light, and lemmatization—and found that stemming techniques increased the accuracy of the classifier.

Additionally, [22] investigated the effectiveness of Arabic preprocesses for text classification to demonstrate that properly selecting preprocessing techniques leads to a positive Arabic classification outcome. The preprocess techniques mentioned and discussed are stopword removal, stemming, and lemmatization. Moreover, they studied the effects of different combinations of these techniques to determine the best performance using ARLSTem v1.08. It was the best stemmer based on the surveyed papers that demonstrated positive outcomes in Arabic text classification, whereas the lemmatizer used MADAMIRA v2.1. The authors concluded that the best performance occurred when applying the three preprocess techniques were applied: stopword, stemming, and lemmatization.

Finally, the authors in [29] conducted scoping reviews over the past two decades (2000–2020) for Arabic topic identification following PRISMA-ScR guidelines, focusing on the preprocessing step. The preprocessing step and feature extraction included stopword removal, stemming lemmatization, and feature selection. Based on the authors’ reviewed papers, the best algorithms were recommended for the steaming process. Common stemmers successfully used in Arabic topic identification are ARLSTem, Tashaphyne light stemmer, Farasa, Khoja stemmer, Light10, Al Khalil Morph Sys, Assem’s stemmer, Soori’s stemmer, and the ISRI stemmer. Finally, the authors suggest future research to enhance the topic identification performance by working on the preprocessing phases and implementing other algorithms.

Thus, stemming algorithms aim to remove suffixes, infixes, and other letters to grammatically reduce the multiforms of the same word in texts while reducing features. Moreover, stemming is an essential preprocessing step, regardless of the language type. Table III summarizes the main stemming algorithms used in Arabic.

TABLE III. SUMMARY OF AVAILABLE STEMMING TOOLS

Stemming name	Stemming type	Resource
Khoja	Root-based	[30]
ISRI	Root-based	[31]
Light10 (there is the previous version of Light 1 until 9)	Light stemming	[32]
ARLSTem	Light stemming	[33], [27]
Assem's stemmer	Light stemming	[34]
Tashaphyne	Light stemming	[35]
Farasa	Stem-based	[36]

Based on the reviewed papers, two Arabic stemming types are widely used: light stemming and root-based stemming. According to [28]. Moreover, it is more efficient than topic identification. Hence, the best stemming algorithm for clustering is light stemming, whereas the two best available stemming algorithms are ARLSTem and Light10 stemming, based on reviewed papers, such as [28], [18].

Additionally, based on reviewed papers, root-based stemming has been used by some authors. The Khoja stemmer, which removes the longest suffix and prefix, is a well-known root-based stemmer. Subsequently, the root dictionary matches the remainder with verbal and noun patterns [28]. At the same time, the Tashaphyne root stemmer is another famous root-based stemmer for Arabic. This stemmer identifies the root for removing prefixes and suffixes based on a default or two customized lists of prefixes and suffixes [28]. Moreover, the Tashaphyne stemmer identifies the light stems of words.

E. Vectors

Feature extraction (vectorization) is an essential preprocessing step, and the last step is performed before the analyzer algorithm. The feature extraction process transforms the text into vectors [26]. Moreover, the two most commonly used methods for extracting features from text are term frequency-inverse document frequency (TF-IDF) and Bag of Words (BoW) [26], [37]. These methods are among the most popular for computing term weights [22], [28]. Table IV summarizes the main differences between the extraction methods.

TABLE IV. SUMMARY OF VECTOR TECHNIQUES

	BoW	TF-IDF
Focus	It constructs a collection of vectors, including the word count of occurrences in the document.	TF-IDF includes information on the more and less important words ones.
Main information	BoW vectors are straightforward to interpret.	Usually acts better in the machine learning approach.
Drawbacks	Most avoid BoW and TF-IDF techniques when understanding the context of words most involved.	
Widely used for text analysis	Used but less than TF-IDF	Yes

The TF-IDF method comprises the term frequency (TF) and inverse document frequency (IDF). The TF is related to calculating the token frequency occurrence in a document, which propagates proportionally with the document size. Therefore, tokens occur more frequently in long documents than in shorter ones. The second part, the IDF, focuses on weighing down frequent tokens while scaling up rare tokens by calculating the importance of a word in all documents [17], [29], [37].

Second, the BoW is the most straightforward representation of text in terms of numbers. This method represents a sentence as a BoW vector; therefore, the sentence is presented as words with a number to indicate the occurrence in a sentence, such as TF. For example, when applying a BoW to documents (text), the result is a matrix based on all terms as columns and appears in each document as a row. Therefore, the sparse matrix result contains many 0s because it combines all the vectors [22], [29], [37].

The main drawback of using the BoW model is that the vocabulary size increases if new sentences contain new words. Hence, the lengths of the vectors also increase. Finally, BoW does not retain information related to the grammar of a sentence or the ordering of words in the text [22], [29].

Vectorization is vital for preparing text for text analysis in most languages. Many studies on Arabic feature extraction (vectors) related to this step have been published. For example, the authors in [12] investigated and compared text preprocessing techniques in Arabic document clustering and studied the effectiveness of the following text preprocessing techniques: term pruning, steaming, and term weighting based on TF-IDF. The authors tested the preprocessing combinations using these three systems. The first system included term pruning with term weighting (TF-IDF) and light stemming. The second combines term pruning with term weighting (TF-IDF) and normalization. The last system combines term pruning with term weighting (TF-IDF), normalization, and root-based stemming. Thus, this study demonstrates the significant impact of term pruning with light stemming and TF-IDF. Furthermore, the authors in [17] investigated the impact of 26 preprocesses applied to the Arabic healthcare tweet classifier and mentioned that the most extracted feature methods used were BoW and TF-IDF. However, they applied TF-IDF as a feature-extraction preprocess to transform the text into vectors.

The authors of [22] explored the significance of Arabic preprocessing for text classification to prove that proper selection of preprocessing techniques leads to a positive Arabic classification result. Moreover, the authors investigated the consequences of different combinations of preprocessing techniques to determine the best performance. They applied feature extraction TF-IDF and, as feature selection, used chi-square, then ran the classifiers. Additionally, the authors in [18] investigated the impact of stemming methods on classification accuracy and the number of features used. Feature extraction was one of the main preprocesses used in this study. The authors represented the documents as vectors using TF-IDF.

Finally, [29] followed the PRISMA-ScR guidelines to conduct scoping reviews over the past two decades (2000–2020) of Arabic topic identification. The authors focused on the preprocessing step, and they mentioned that the most stan-

standard techniques used for feature extraction included BoW, Bag of Concepts (BoC), count vectorizer, TF-IDF vectorizer, and chi-square test (χ^2_{test}). Finally, the authors recommend future research to enhance topic identification performance by working on the preprocessing phases and implementing other algorithms.

Thus, vectorization is vital for converting textual features into numerical vectors. Vectorization is the final step in text-analysis models, and classification and clustering are essential. The TF-IDF method is the most widely used method for Arabic clustering and document analyses. Based on surveys and literature review, this method has proven to be the most effective.

F. Feature Selection

Feature selection methods have been verified as valuable for text classification and clustering. There were three feature types: irrelevant, powerfully relevant, and weakly relevant. Moreover, the clustering approach requires a suitable feature selection method that reduces the selection of irrelevant features to represent the text data [38]. The feature selection method removes irrelevant and duplicate features from datasets and retains features that include reliable and helpful information to reduce the dimensionality of the text in clustering techniques [28], [38]. Consequently, high-dimensional data affect the efficiency and performance of clustering approaches, dramatically decreasing the efficiency and increasing the execution time [38]. Feature selection algorithms can be classified into two primary categories: filtering and wrapping [9], [38].

The most well-known methods used for feature selection are chi-square and information gain (IG). The chi-square test is a filtering method for selecting features. Chi-square is a straightforward and computationally fast method. It can deal with a sizable dimensional feature and has proven its efficiency mainly when applied with the TF-IDF extracted feature technique [29], [38].

Similar to the work of [38], the researchers extracted features from the training datasets by calculating the TF-IDF score for each feature and then applied the chi-square test to select relevant features and eliminate irrelevant features. The chi-squared test was efficient. The chi-square test tests the independence between the occurrence of a specific feature and the occurrence of a specific type. The null hypothesis of the chi-square test was that no relationship existed between the two variables. Therefore, they are independent of each other.

The authors of the review paper [29] discussed the chi-square test as a feature selection method used for Arabic topic identification. The authors conducted scoping reviews for Arabic topic identification following the PRISMA-ScR guidelines over the past two decades (2000–2020), focusing on four phases of feature selection.

IG was used to discover the most relevant features in the label dataset. The IG ranks these features based on their entropy values, which reflect the impact of a unique feature on deciding the type label. The most relevant features are selected based on a predefined threshold value. As in [26], the authors first built the TF-IDF matrix by applying the feature extraction method and then used the IG method as a filtration

step to select the most relevant Arabic features based on their ranks. This filtering step is essential for reducing the spatial dimensionality of the classifier by eliminating all features with IG ranks below a given threshold value. In [39], the authors used an IG feature ranking technique to remove irrelevant features. Furthermore, IG was used to reduce the size of the features and select the top-ranked features to train the classifier.

Term pruning is a feature selection that provides a helpful step based on a survey that eliminates words with counts less or greater than a typical threshold. For example, an experimental survey [18] showed that the best practical pruning factor is a minimum of three. Thus, pruning aims to remove any word that appears fewer than three times and is considered unimportant, thereby reducing its features.

The authors of [12] examined and compared text preprocessing techniques in Arabic document clustering and demonstrated the significant impact of term pruning on different preprocessing techniques. They experimented with different combinations of preprocessing techniques with term pruning using three, five, seven, and nine terms in the three systems. The first system combined term pruning with term weighting and light stemming (Light10), whereas the second system combined term pruning with term weighting and normalization. The last system combined term pruning with term weighting, normalization, and Khoja root-based stemming. The results were based on the precision, recall, and F-measure as evaluation measures. They showed that term pruning with a minimum of three combinations of term weighting-based TF-IDF and light stemming achieved better results than the others.

G. Lemmatization

Text lemmatization seeks to regroup semantically associated words. Unfortunately, lemmatization is limited as a preprocessing task in Arabic text classification, and no study has used lemmatization for clustering based on reviewed and surveyed papers because it is a complicated level of text processing. Moreover, most Arabic lemmatizers are royal and not publicly available, unlike Arabic stemmers. Nevertheless, some studies have reported lemmatization efficiency, particularly for information retrieval, text summarization systems, and text indexation [22].

Typically, document classification is straightforward when the meaning of the content is well represented. Thus, lemmatization regroups equivalent written words semantically in various syntactic structures and relates them to their ecclesiastical base representation called a “lemma” (i.e., a dictionary reference form). Thus, applying lemmatization to text classification as a preprocessing task is particularly beneficial [22].

The authors of [29] used text lemmatization plans to regroup semantically associated words written in various syntactic forms and associate them with their lemma. Unlike stemming, lemmatization is reasonably limited to Arabic pre-process because most Arabic lemmatizers are royal and not publicly available. However, Farasa⁴ and MADAMIRA⁵ are tools available for lemmatizers.

⁴<https://alt.qcri.org/farasa/>

⁵http://innovation.columbia.edu/technologies/cu14012_arabic-language-disambiguation-for-natural-language-processing-applications?license=108

Thus, lemmatization preprocessing steps may be helpful, based on survey papers, similar to [22], [17]. For instance, the authors of [22] investigated the effectiveness of Arabic preprocesses for text classification and found that appropriate preprocessing techniques lead to an optimistic Arabic classification outcome. Hence, they studied the effects of different combinations of the following techniques to determine the best performance: stopword removal, stemming, and lemmatization. The authors used MADAMIRA v2.1 as a lemmatizer because it was the best lemmatizer based on surveyed papers that demonstrated positive outcomes in Arabic text classification. The authors identified the best performance among the three preprocess techniques together.

Similarly, [17] investigated the impact of the 26 preprocesses applied to Arabic healthcare tweets by training four classifiers: MNB, logistic regression, linear SVC, and KNN. The authors discussed the effect of preprocessing on the classifier, one of which was lemmatization. They found that the lemmatization stemming type performed well for all four classifier models.

Furthermore, the authors in [29] conducted scoping reviews for the past two decades for Arabic topic identification based on the PRISMA-ScR guidelines to provide new researchers in the field and advanced practitioners with a closer look at improvements in Arabic topic identification in the last decade, while suggesting several recommendations for better Arabic topic identification. The authors focused on several stages, one of which was preprocessing. The preprocessing step and feature extraction mentioned in [29] involve stopword removal, stemming lemmatization, and feature selection. Based on the authors and reviewed papers, a few Arabic lemmatizers are available for free. The best algorithms recommended for lemmatization by the authors are Farasa and MADAMIRA. Finally, the authors suggest future research to improve topic identification performance by performing preprocessing phases or implementing other algorithms.

Finally, some preprocessing steps may be helpful based on the survey papers, but they are not essential for preparing the Arabic text. One of these steps is lemmatization. The lemmatization step aims to regroup semantically associated words written in different syntactic forms, associate them with their lemmas in the text, and reduce their features. Unlike stopword removal and stemming, the use of lemmatization for Arabic preprocessing is reasonably limited because most Arabic lemmatizers are proprietary and not publicly available [29]. However, the lemmatization process improves performance as a preprocess but is rarely used by researchers because research in this area has not been published or is freely available online. The only two tools available in Arabic are Farasa and MADAMIRA. Thus, this area requires further research and proposed solutions public to the research community.

H. Synonyms

One Arabic language characteristic is morphological richness, wherein the same verb can have thousands (literally) of different forms [40]. Table V summarizes these methods, and the following paragraphs summarize the most widely available methods and tools for finding and creating synonyms for Arabic.

TABLE V. SUMMARY OF SYNONYM TECHNIQUES

	Sources	Techniques	Resource
WordNet [41]	The AWN was created based on Princeton WordNet (PWN) strategy and contents.	Translation and manually checked.	Open
word2Vec [42]	Twitter and Wikipedia.	CBoW and Skip-Gram have different n-gram and unigram features.	Open
FastText [43]	Common Crawl and Wikipedia.	CBoW with sub-wording techniques.	Open

The first method to find and create synonyms for Arabic is Word2Vec, an efficient solution to synonym problems that leverages the context of the target words proposed by Google. There are two types of Word2Vec: skip-gram and a Continuous Bag of Words (CBoW) [40], [41], [44]. The following paragraphs briefly describe these two methods.

In skip-grams, the input is the center word (target), whereas the outputs are the words surrounding the target words. For example, in the sentence “I have a pretty cat,” assuming the window size is 5, the input for the neural network would be “a” whereas the output would be “I,” “have,” “pretty,” and “cat.” The network contained one hidden layer with dimensions equal to the embedding size, which was smaller than the input/output vector dimension. The output layer is a softmax activation function so that each part of the output vector represents how a specific word will probably occur in the context. Word embedding for the center words can be obtained by extracting the hidden layers after providing a one-hot expression of that word into the network [40], [42], [45].

Furthermore, the vectors are more “significant” in describing word relationships. For example, vectors obtained by removing two related words sometimes represent meaningful concepts such as gender or verb tense. Finally, for all input and output data, most studies used exact dimensions and one-hot encoding [40], [42], [45].

While CBoW is similar to skip-gram, the inputs are the words surrounding the center words, whereas the output is the center word (target). The idea is that given a context, they like to know which word is most likely to occur. Thus, it aims to discover embeddings by indicating the center word in a context that provides other words in the context without respect to their order in the sentence [40], [42], [45].

The most significant distinction between skip grams and CBoW is the manner in which word vectors are generated. The CBoW model involves all samples with the target word in the neural network, and then takes the average of the extracted hidden layer. For example, assume only two sentences in a dataset: “He is a friendly man” and “She is a smart princess.” To compute the word representation for the word “a,” two examples are needed: “He is a friendly man” and “She is a smart princess.” These are placed in a neural network that takes the average value of the hidden layer [40], [42], [45].

The second method for determining synonyms is FastText, an extension of Word2Vec, as suggested by Facebook in 2016. FastText breaks words into several n-grams (subwords) instead of providing one word to the neural network. Infrequent words are then adequately represented, because it is highly likely that some of their n-grams will also appear. For instance, the

tri-grams for the word fruit are “fru,” “ru,” and “uit.” The word-embedding vector for the fruit was the sum of these n-grams. After training the neural network, the results are word embeddings for all n-grams in the training dataset [40], [46], [43].

Finally, WordNet is used for constructing lexical resources for SA. The Arabic WordNet (AWN) is based on the universally accepted Princeton WordNet (PWN) strategy and content. It enables translation into English and dozens of other languages at the lexical level. In addition, it encodes language-specific concepts and links as required or preferred. The results are called core word nets for Arabic with the essential system embedded in a solid semantic framework [41].

Moreover, the enrichment of AWN was published by [47], and the latest version was constructed by semi-automatically expanding its content, adapting and using existing approaches and resources generated for other languages to expand AWN [32]. Thus, AWN is a lexical dictionary or database utilized to discover synonyms and determine different relations among Arabic words containing several elements, including nouns, verbs, adjectives, and adverbs, which vary into sets of cognitive concepts (i.e., synsets) [48].

Because Arabic is rich in synonyms, a possible way to improve clustering performance is to reduce synonym words to a single word. Thus, one of the main goals of this survey is to determine whether anyone has used the synonym method as a preprocessing step to reduce the number of synonyms to help reduce the features. Based on the reviewed papers, this study found that none of these methods were used as preprocessing steps. Nevertheless, synonym methods and techniques have been used to build lexical or corpora [49], which are used to build medical datasets, or to build a corpus for some approaches such as sentiment analysis, similar to the authors in [17]. This idea may need more research in the future to satisfy and clarify whether synonym methods can be used to reduce the features by replacing the synonym with one word, thereby demonstrating that this technique reduces the feature’s dimensionality and improves clustering quality.

I. Semantics

In this study, Arabic semantics are related to Arabic semantic ambiguity, mainly Arabic word sense disambiguation (WSD), a task that seeks to determine the meaning of a word given its context [50]. Arabic semantic obscurity depends on the meaning of a word or many words that can be misconstrued. Obscurity can come from the order of words or word types as verbs or nouns [51]. Moreover, Arabic, which uses diacritics, such as the Arabic read word (علم), can take many meanings based on how diacritic (علم: understood), (علم: flag), (علم: teach), and (علم: science).

Semantics and meaning can be classified as branches of linguistics. Semantics and meaning are associated; some use semantics to serve meaning, whereas others use meaning to serve semantics. The first states that science investigates the requirements provided by linguistic symbols to carry out meaning. In contrast, the second emphasizes the importance of overt semantics in hidden meanings. However, another

definition of semantics is the branch of linguistics that attempts to investigate changes in meaning via the analysis of linguistic structure phonetically, morphologically, lexically, and syntactically, while considering changes in usage over time [51].

Many studies have investigated this issue. For example, [50] published a 2019 review paper discussing Arabic word meaning disambiguation to inspire readers to solve Arabic words with morphological and semantic ambiguities. The morphological challenge of the Arabic language is still lacking since more than ten variations can be assigned to a non-vocalized Arabic word, for example, the words (شعر) (hair) or (شعر) (poetry). Moreover, the authors investigated numerous studies in this field by analyzing their assessment methods and linguistic resources (e.g., corpora and lexicons), recommending solutions to current semantic problems, and suggesting future directions to improve research in this area.

Thus, the Arabic language has a problem related to semantic obscurity because semantic ambiguity is associated with the meaning of a word, which can be misunderstood. Obscurity can be reached from the order of words or word types as verbs or nouns [42]. Therefore, one way to improve the clustering quality and performance is to use semantic solutions as a helpful method to solve ambiguous words when the word has the same form but different meanings based on sentences and semantics. Similar to [52], the CBOW model was used to capture the semantic relationship between the terms (word tokens), followed by using K-means to identify essential documents for Arabic summarization.

This is similar to the results of [53], who proposed a solution for Arabic Word Sense Induction (WSI) in NLP, mainly when applied to sentiment analysis. It presents a two-stage approach; the first stage uses a Transformer-based encoder like BERT or DistilBERT to encode the input sentence into context representations. In the second stage, k-means clustering and agglomerative hierarchical clustering (HAC) were applied to the embedded corpus obtained in the first stage. The proposed approach improves existing methods and revolutionizes WSI research.

Hence, one of the main goals of this survey was to determine whether anyone had used the semantic method as a preprocessing step to reduce word ambiguity and improve clustering quality. However, based on the reviewed papers, no study has used this feature as a preprocessing step. Moreover, semantic methods have been used in separate research fields using a domain-based approach. Semantic ambiguity in Arabic has recently become an active research topic. However, perhaps using the semantic ambiguity solution to improve Arabic clustering quality requires more research to satisfy and clarify whether a semantic method and word ambiguity list can improve clustering quality.

IV. RECENT ARABIC CLUSTERING PUBLICATION

This section reviews the recent Arabic clustering research papers and articles published between 2019 and 2024. It summarizes the preprocessing steps used by the authors to prepare the Arabic text, as seen in Table VI. The following section discusses the main points extracted from Table VI below.

All reviewed papers used the stemming and converting the results into TF-IDF vectors. Most of the reviewed documents (91%), used the word tokenization step and removal of stopwords, while (66%) used Arabic normalization. All reviewed papers used TF-IDF as a feature representation for clustering Arabic documents. Only two reviewed papers used bigram to combine two terms as a collocation technique to better understand semantic and meaning problem—only one reviewed paper used term pruning to eliminate low-frequency words.

Regarding the feature selection method, only two studies used IG; however, they focused on the Arabic classification-based bio-inspired method. In addition, based on the reviewed papers, only one study used dimension-reduction methods as a preparation step for Arabic clustering. None of the reviewed documents applied semantic methods for Arabic clustering, or even importing, to overcome contextual meaning. None of the reviewed studies applied synonymous methods to Arabic clustering.

Fig. 3 summarizes the percentages of used main preprocess steps related for the Arabic normalization, stemming, and feature selection extracted from Table VI. Fig. 3(A) shows that more than half of the reviewed Arabic research papers 67% applied normalization preprocess for Arabic text before applying a text analyzer. In addition, Fig. 3(B) shows that all of the reviewed Arabic research papers applied the stemming method to prepare Arabic texts. Most stemming methods used root stemming (54%), whereas 46% used light stemming. Also, one research paper applied both types of stemming. Finally, Fig. 3(C) shows that 17% of the review papers applied feature selection methods exactly applied IG. In contrast, the remaining 83% did not apply feature selection methods to prepare the Arabic texts.

V. DISCUSSION

This survey intensively investigated and focused on many Arabic preprocessing steps as references for researchers engaged in Arabic preprocessing for clustering. The survey was concluded by answering the questions raised at the beginning of this paper based on the results obtained. What preprocessing steps are used for the Arabic language in general and the cluster, especially? Preprocessing researchers have used tokenization, normalization, stopword removal, stemming, and vectorization. Some researchers have used feature selection to prepare text for a cluster to reduce the number of dimensions. In contrast, lemmatization, synonyms, and semantics were not used as preprocessing for clustering.

The second question, What tools are available for the algorithms and techniques for each preprocessing step? Many resources have been proposed for each preprocessing step; however, some preprocesses, such as lemmatization, require more investment and improvement. In addition, as a future recommendation, you can propose a stopword removal list for many fields because each domain has its own list.

In addition, the last two questions, Does preprocessing address the richness of synonyms in Arabic and can it be used to reduce dimensions? Does preprocessing address semantics as a primary characteristic of Arabic? This survey found that no one had used the synonym method as a preprocessing

step to reduce features. In addition, no one has used the semantic method as a preprocessing step to reduce word ambiguity and improve clustering quality. Additionally, this survey suggests conducting further research to address the richness of synonyms in Arabic to reduce the dimensions by combining many synonyms with the same meaning. In addition, the researcher may deal with semantics to improve clustering quality as a preprocessing process to improve step. Therefore, future research should investigate the effectiveness of using synonymous techniques and semantic solutions to reduce the dimensions of complexity or improve the quality of cluster results.

Therefore, this study concludes that preprocessing steps are preferable because they provide benefits and improve the quality of an analysis model based on the surveyed papers. Based on the reviewed research papers, Arabic preprocessing is an active research area. Nevertheless, this field requires further research, especially clustering, to provide more solutions and publicly available tools to benefit the Arabic research community.

VI. CONCLUSION

Arabic is a complex language because of its unique orthography, grammar, and punctuation. A sentence contains a verb, a subject, or an object. Words are derived from trilateral or quadrilateral systems, making them challenging for algorithms and computational systems to understand. Moreover, Arabic has extensive synonyms and the meanings of Arabic words depend on the semantics of the sentences. For all these reasons, the analysis algorithms require specific Arabic preprocessing techniques.

Arabic text preprocessing methods are used in clustering to reduce the size of documents, simplify feature selection, and enhance processing speed. Hence, the primary purpose of a text preprocessing task in clustering is to address the considerable dimensionality problems. Therefore, several preprocessing techniques have been proposed.

This survey intensively investigated and focused on many Arabic preprocessing steps as a reference for researchers engaging in Arabic preprocessing for clustering. These preprocesses include tokenization, normalization, stopword removal, stemming, vectorization, lemmatization, feature selection, synonyms, and semantics. Moreover, this survey classified these preprocesses as essential or preferable steps.

Therefore, this paper concludes that preprocessing steps are preferable since they may benefit some models and improve the quality based on the surveyed papers. Additionally, this survey suggests conducting further research to deal with a richness of synonyms for Arabic to reduce the dimension and deal with semantics to improve the clustering quality as a preprocessing process. Indeed, based on the surveyed papers, no one to date has dealt with these characteristics to improve clustering quality.

The Arabic preprocessing step is an active research area based on the reviewed research papers. Nevertheless, this field needs more research, especially for clustering, to provide more solutions and publicly available tools to benefit the Arabic research community.

TABLE VI. SUMMARY OF ARABIC CLUSTERING RESEARCH PAPERS.

Ref	Year	Tokenization	Stopword removal	Normalization	Stemming	Feature selection	Synonyms	Collection: Bigram, trigram	Vectors	Final output	Addition step
[54]	2019	Yes (word)	Yes	No	ISRI (Root)	No	No	Sentence level	TF-IDF	vectors	Sentence segmentation.
[9]	2019	Yes (word)	Yes	No	Yes (Light Stemming)	No	No	No	TF-IDF	VSM	Segmentation

Abstract—The complex challenge of detecting sarcasm in Arabic speech on social media is exacerbated by the language’s diversity and the nature of sarcastic expressions. There is a significant gap in the capability of existing models to effectively interpret sarcasm in Arabic, necessitating more sophisticated and precise detection methods. In this paper, we investigate the impact of a fundamental preprocessing component on sarcasm detection. While emojis play a crucial role in mitigating the absence of body language and facial expressions in modern communication, their impact on automated text analysis, particularly in sarcasm detection, remains underexplored. We examine the effect of excluding emojis from datasets on the performance of sarcasm detection models in social media content for Arabic, a language with a super-rich vocabulary. This investigation includes the adaptation and enhancement of AraBERT pre-training models by specifically excluding emojis to improve sarcasm detection capabilities. We use AraBERT pre-training to refine the specified models, demonstrating that the removal of emojis can significantly boost the accuracy of sarcasm detection. This approach facilitates a more refined interpretation of language, eliminating the potential confusion introduced by non-textual elements. The evaluated AraBERT models, through the focused strategy of emojis removal, adeptly navigate the complexities of Arabic sarcasm. This study establishes new benchmarks in Arabic natural language processing and offers valuable insights for social media platforms.

Keywords—Arabic language; AraBERT; sarcasm detecting; data preprocessing; emojis impact; social media content

I. INTRODUCTION

The evolution of social media platforms has transformed them into spaces for free speech, allowing users to express their ideas and opinions openly. While this open environment encourages meaningful discussions, it can also lead to problems when individuals use expressions or statements that may offend others due to differences in beliefs, backgrounds, gender, or race. Although such speech is protected under the latest version of the Communications Decency Act (CDA 230) [1], many social media platforms are actively working to enhance user protection against hateful and offensive content. A significant challenge, however, arises from their reliance on human monitoring and user reports [2], [3].

In recent years, there has been a significant increase in the prevalence of sarcastic speech on social media, giving rise to serious social problems, including social conflicts,

racist crimes, and the spread of negative social influence. To mitigate this issue, many social media platforms have implemented word filters based on NLP techniques. Sarcastic speech includes exchanges of sarcastic or offensive remarks between individuals and extends beyond text comments to include multimedia content such as videos and audio [4]. Existing research efforts have primarily focused on proposing models for the automatic detection of sarcastic speech within text comments on platforms like Twitter or YouTube [5], [6]. These models typically involve several stages, including data processing, representation, and classification. However, these stages present several challenges, particularly concerning the Arabic language [7], [8]:

- 1) Its rich vocabulary, and dialectical variations.
- 2) Arabic sarcasm often relies heavily on contextual indications and cultural references.
- 3) Collecting and annotating a large dataset for Arabic sarcasm detection produces unique difficulties.
- 4) Time-consuming and requires extensive data learning.
- 5) The multimodal nature of social media content is integrating information from various sources such as text, images, videos, and emojis.

Generally, sarcasm detection heavily relies on textual data classification. However, textual data lacks crucial expressive features such as facial expressions, body language, and tone variations. To address this limitation, social media communities have introduced emojis as non-traditional vocabulary to compensate for this deficiency in information. Emojis have demonstrated their effectiveness in partially bridging the gap between textual and vocal/visual communication [9].

Nevertheless, rich languages like Arabic possess their own tools that can better address this gap than emojis, including a vast and diverse lexicon. Table I provides a comparison of the number of roots between Arabic and other languages. Additionally, Arabic speakers use numerous dialects with significant dialectical variations. Moreover, sarcasm in Arabic heavily relies on contextual cues, puns, and euphemisms. This results in an extensive textual information space generated solely using textual vocabulary, decreasing the contribution of the limited emojis dictionary.

These factors raise questions regarding the added value of emojis to classifier performance. While it is intuitive that

TABLE I. COMPARISON BETWEEN ARABIC AND SOME OTHER LANGUAGES IN TERMS OF THE NUMBER OF ROOTS

Language	Approximate Number of Roots	Notes
Arabic	23090 [11]	Roots of 3 letters By applying 73 trilateral patterns and 18 affixes produced around 27.6M words.
English	8,400 [12]	This study highlights the significant growth in root word vocabulary during the primary school years.
Russian	450 [13]	The study highlights the significance of understanding root words for mastering Russian vocabulary.

adding redundant data should not degrade performance, excess data has been shown to harm classifiers' performance in certain instances [10]. Hence, we hypothesize that using emojis for sarcasm detection in rich languages like Arabic may either reduce accuracy or offer no improvement. The rationale behind this approach is that focusing purely on the textual elements allows the models to concentrate on linguistic and semantic analysis without the potential confounds introduced by emojis.

The successful development of an Arabic sarcasm detection model, enhanced by transfer learning methods and refined by the strategic removal of emojis from the dataset, will have a significant social impact. This approach will enable social media platforms to more effectively detect and moderate sarcastic speech, thereby mitigating its potentially harmful effects and fostering a more positive and respectful online discourse. By focusing on the textual content and reducing noise in the data, the model's precision in identifying sarcasm will be improved, making the moderation process more efficient and reliable. Additionally, this research will lay the groundwork for further advancements in the creation of language-specific models for sarcasm detection, equipping diverse language communities with the tools needed to address such speech more effectively.

In this work, we investigate the following research questions: 1.

- 1) Does including emojis in the data improve pre-trained models' ability to detect sarcasm in the Arabic language?
- 2) How can the performance of the AraBERT pre-trained models for sarcasm detection in the Arabic language on social media platforms be improved by removing emojis from the data?
- 3) How accurately can it identify and classify sarcasm in Arabic speech on social media?

In the next section, we discuss related work on detecting textual aggressions on social media. In Section III, we describe the methodology used in this study. Section IV presents the experiments and analysis of the results. Finally, Section V concludes the study and discusses the future direction of sarcasm speech in the Arabic language.

II. RELATED WORK

User-generated content online, especially on social media platforms, can sometimes contain harmful language and hate speech, which can have detrimental effects on the online community and potentially lead to hate crimes. Recently, there has been a marked interest in smart algorithms designed to

automatically identify and flag such offensive language and hate speech. Nonetheless, NLP research concerning the Arabic language is typically limited [14], as is the investigation into sarcasm detection. In this section, we aim to highlight previous efforts focused on detecting Arabic sarcasm on social media.

In the field of NLP, large-scale pre-trained models have become the standard approach for a wide range of tasks. Models like Bidirectional Encoder Representations from Transformers (BERT) are trained on massive datasets, allowing them to generalize effectively to various downstream tasks [6]. The BERT model has been employed for extensive Arabic datasets, resulting in the creation of AraBERT [15]. In [16], an automated approach to detect offensive language and detailed hate speech in Arabic tweets is proposed. The BERT model is utilized alongside two traditional machine learning methods: (i) Support Vector Machine (SVM) and (ii) Logistic Regression (LR). Additionally, the authors explore the integration of sentiment analysis and emojis descriptions as supplementary features to the textual content of tweets. Experimental results indicate that the BERT-based model outperforms existing benchmark systems in three key areas: (a) detecting offensive language with an F1-score of 84.3%, (b) identifying hate speech with an 81.8% F1-score, and (c) discerning detailed categories of hate speech (such as race, religion, social class, etc.) with a 45.1% F1-score. While sentiment analysis marginally boosts the model's efficiency in detecting offensive language and hate speech, it does not enhance the model's capability in classifying specific hate speech types.

Moreover, a universal language-agnostic approach is proposed in [17] to gather a substantial proportion of tweets with offensive and hate content, regardless of their subjects or styles. The authors gathered a significant collection of offensive tweets by leveraging the non-verbal cues in emojis. They then applied the proposed methodology to Arabic tweets and compared the results with English tweets, highlighting notable cultural variances. A consistent pattern emerged with these emojis signifying offensive content over various periods on Twitter. They hand-labeled and made publicly available the most extensive Arabic dataset encompassing offensive language, detailed hate speech, profanity, and violent content. As a result, the authors found that even advanced transformer models can overlook cultural contexts, backgrounds, or the precision inherent in authentic data, such as sarcasm.

As highlighted by [18], identifying offensive language within Arabic content is intricate. Several challenges arise, such as: (i) The colloquial language frequently used on social media platforms. These posts often contain abbreviations and slang, making it challenging for classifiers to understand and process them semantically. (ii) The diverse dialects and versions of the Arabic language add another layer of complexity to discerning offensive content. The text may require extensive preprocessing before being fed into a classification model. To combat the issue of colloquialism, the researchers processed each tweet by translating emoticons and emojis into their Arabic textual equivalents and breaking down hashtags into individual words separated by spaces. To address the issue of dialect variation, the texts were transformed from regional dialects to Modern Standard Arabic (MSA). The study tested various classifiers, including traditional machine learning models such as SVM, LR, Decision Tree (DT),

Bagging, AdaBoost, and Random Forest (RF). The results show that, among traditional machine learning models, SVM topped the list with an F1-score of 82%, followed by LR at 81% and DT at 69%. For ensemble models, Bagging led with an F1-score of 88%, followed by RF at 87%, and AdaBoost at 86%.

In the study [19], features were derived from textual descriptions of emojis. Depending on the class size and the specific emojis, these features either enhanced or hindered the model's performance. The authors introduced a transformer-based technique to tackle the problem of detecting offensive language. Their approach utilized variations of the CAMEL-BERT model and was tested using a combination of four benchmark Arabic Twitter datasets, all annotated for hate speech detection, including the dataset from the OSACT5 2022 workshop shared task. The model demonstrated proficiency in identifying offensive content in Arabic tweets, achieving an accuracy of 87.15% and an F1-score of 83.6%.

In [20], the word embedding (word2vec) feature was applied in tandem with part-of-speech and/or emojis to detect such language in Indonesian tweets on Twitter. They also experimented with combining unigrams with part-of-speech and/or emojis. Classification for this study was performed using a Support Vector Machine, Random Forest Decision Tree, and Logistic Regression methods. The highest accuracy attained was 79.85%, with an F-Measure of 87.51%, using the fusion of unigram features, part-of-speech, and emojis. Furthermore, the work in [21] investigates the impact of combining emojis-based elements, which are increasingly common on social media, with multiple textual factors for the sentiment analysis of casual Arabic tweets. The authors employed four methods to extract textual features: Bag-of-Words (BoW), Latent Semantic Analysis, and two Word Embedding variants. The study evaluates the impact of merging emojis with these textual elements using the SVM classifier, considering both scenarios: with and without feature selection. Results indicate that models incorporating emojis with word embedding and optimal feature selection produce better outcomes. The implications of amalgamating emojis-based aspects from Arabic tweets with diverse textual elements are explored.

In this study, we hypothesize that removing emojis from the training dataset will enhance the ability of AraBERT pre-trained models to discern the subtleties of sarcastic language in Arabic text, as it will encourage the model to focus more on context.

III. PROPOSED WORK

We use transfer learning with three pre-trained models: AraBERT-v2, AraBERTv02-twitter, and Multi-dialect-BERT-base-Arabic. The models are evaluated using datasets from three different sources: SemEval 2020, YouTube, and L-HSAB, preprocessing. The evaluation of the models is performed with and without emojis. This suggests that the role of emojis in understanding the text is considered a variable in the model's performance. Finally, the performance of these models is evaluated using standard performance metrics: accuracy, precision, recall, and F1-score.

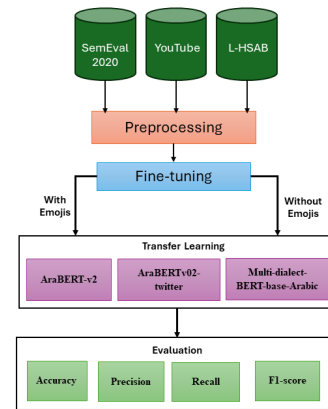

Fig. 1. Workflow of the methodology.

A. Classification Model

The core of this study revolves around the selection and application of advanced machine learning models, specifically tailored for processing Arabic text, the workflow of this study is presented in Fig. 1.

These models are critical in accurately detecting sarcasm in Arabic social media content. The selected models are:

1) *AraBERT_v2*: This model is a BERT-based framework specifically adapted for Arabic text. AraBERT's architecture allows it to understand the contextual nuances of the Arabic language, making it an ideal choice for tasks like sarcasm detection where context plays a crucial role. Moreover, it comprises 12 transformer layers and 768 hidden units in each layer [22].

2) *AraBERTv02-twitter*: Building upon the foundation laid by AraBERT, Arabert_v2 is an advanced version that offers improved capabilities. Its enhanced features include a better understanding of dialectal variations and more refined contextual analysis. This version is particularly effective in handling the intricate aspects of sarcasm in various forms of Arabic language and dialects, maintaining the same architecture layer of Arabert_v2 [23].

3) *Multidialect Bert base AraBERT*: Recognizing the diversity of the Arabic language, this model is designed to handle multiple dialects. Its architecture is tailored to adapt to the linguistic variations found across different Arabic-speaking regions and the model is trained on the entire Wikipedia for each language, which is crucial for a comprehensive sarcasm detection tool that can operate effectively across diverse social media platforms and content. The architecture is composed of 12 encoder blocks, each equipped with 12 self-attention heads, and is followed by hidden layers that have a size of 768 [24], [23].

Table II presents the key hyperparameters for the three models, which have been determined based on empirical.

B. Datasets

The success of transfer learning models in NLP tasks heavily relies on the quality and relevance of the datasets used

TABLE II. MAIN HYPERPARAMETERS FOR FINE-TUNING THE THREE MODELS

Parameter	Value
Adam optimizer	1e-8
Learning Rate	5e-5
Batch Size	16
Maximum Sequence Length	256
Epochs	15

Fig. 2. Snapshot of SemEval dataset.

for training and testing. In this study, three distinct datasets have been carefully selected to ensure comprehensive coverage of the various facets of Arabic sarcasm and related nuances in social media contexts. These datasets are:

1) *SemEval 2020 task 12 dataset*: This dataset is specifically designed for sarcasm detection, making it highly relevant for this research. Fig. 2 shows a sample of the SemEval dataset. It comprises a collection of social media posts annotated for sarcasm, providing a foundational basis for training and testing the models. Including this dataset is crucial as it offers direct insights into the textual characteristics and markers indicative of sarcasm in social media content [25].

2) *YouTube dataset for anti-social behavior detection*: Recognizing the importance of context in sarcasm detection, this dataset from YouTube, comprising comments and posts in Arabic, is employed to understand and identify patterns of anti-social behavior, as shown in Fig. 3 [26]. This dataset provides a broader perspective on how sarcasm might be intertwined with or differentiated from other forms of communication, particularly those that are anti-social or negative.

3) *L-HSAB (Levantine hate speech and abusive language) dataset*: The L-HSAB dataset is instrumental in understanding the landscape of hate speech and abusive language in Arabic,

Fig. 3. Snapshot of YouTube dataset.

Fig. 4. Snapshot of L-HSAB dataset.

particularly in the Levantine dialect. Fig. 4 shows a snapshot of the L-HSAB dataset. Its inclusion aids in refining the detection algorithms to discern sarcasm from potentially similar but contextually different expressions like hate speech or abusive remarks.

C. Preprocessing

Preprocessing plays a crucial role in the machine learning workflow for classification tasks. This phase requires the modification and improvement of input data to make it suitable and beneficial for use with transfer learning models. The study implemented the following steps:

- 1) Data cleaning is a pivotal step in data analysis, emphasizing the importance of removing noise and irrelevant information to enhance data quality. Data cleaning is a pivotal step in data analysis, emphasizing the importance of removing noise and irrelevant information to enhance data quality [27]. This step was applied to the three datasets by removing unnecessary columns, handling missing values, and text data normalization
- 2) Text data preprocessing is a fundamental step in NLP, enabling the transformation of raw text into a clean, organized format suitable for analysis. This process involves: (i) using regular expressions to identify and remove unwanted characters, spaces, or patterns within text data, (ii) tokenization is the process of breaking down the text into smaller units, such as words or phrases, (iii) removal of stop words, and (iv) performing Stemming which is reducing words to their root form.
- 3) Splitting the dataset into training, validation, and test sets in two distinct versions: one version includes emojis in the text data, and the other version with emojis excluded.

D. Performance Metrics

The evaluation of the model is conducted using a set of standard performance metrics in transfer learning:

1) *Accuracy*: this metric measures the proportion of correctly identified instances (both sarcastic and non-sarcastic) among the total instances. It provides an overall effectiveness of the model.

$$Accuracy = \frac{\text{Number of Correct Predictions}}{\text{Total Number of Predictions}} \quad (1)$$

2) *Precision and recall*: these metrics evaluate the accuracy of the model in identifying sarcasm. Precision measures the proportion of correctly identified sarcastic instances among all instances identified as sarcastic, while recall measures the proportion of correctly identified sarcastic instances among all actual sarcastic instances.

$$Precision = \frac{\text{True Positives}}{\text{True Positives} + \text{False Positives}} \quad (2)$$

$$Recall = \frac{\text{True Positives}}{\text{True Positives} + \text{False Negatives}} \quad (3)$$

3) *F1 score*: it is the harmonic mean of precision and recall, providing a single metric that balances both. It is particularly useful when the class distribution is imbalanced.

$$F1 = 2 \times \frac{\text{Precision} \times \text{Recall}}{\text{Precision} + \text{Recall}} \quad (4)$$

IV. RESULTS AND ANALYSIS

In this work, the investigation primarily focuses on the influence of emojis in classifying offensive language in Arabic. Additionally, it presents a comprehensive evaluation and interpretation of the outcomes, highlighting which machine learning model is most effective in accurately identifying offensive speech with or without emojis. The results are critical for understanding the nuances and accuracy of language processing techniques in a linguistically diverse and complex region like the Arab world.

The comparative analysis, which is presented in Fig. 5v to 7, assesses the influence of emojis on the performance of Arabic language models in classifying offensive content within the SemEval, YouTube, L-HSAB datasets, respectively. This evaluation is segmented into four distinct metrics: accuracy, recall, precision, and F1-score. The performance of the three considered, AraBERT_v2 (v2), AraBERT_v2_Twitter (TW), and multi_dialect_bert_base_arabert (MD) models are investigated for all of these datasets.

A. Accuracy

In Fig. 5(a), 6(a), and 7(a), the accuracy metrics are evaluated across multiple models, including AraBERT_v2 (v2), AraBERT_v2_Twitter (TW), and multi_dialect_bert_base_arabert (MD). Across these figures, the accuracy rates for each model are displayed both with and without the inclusion of emojis in the dataset. In all cases, except for L-HSAB with the TW model, the accuracy tends to be higher when emojis are excluded. This trend suggests that emojis may introduce ambiguity or noise that degrades the models' ability to accurately classify text.

B. Recall

The recall results across the three models: V2, TW, and MD, are examined through Fig. 5(b), 6(b), and 7(b), respectively. For all the datasets, it observed that excluding emojis leads to an increase in recall for TW and MD, while in the V2 models with the YouTube and SemEval dataset, recall shows a slight improvement when emojis are included. This suggests

that emojis may enhance detection for some models but could potentially disrupt others, resulting in missed detection. The V2 model, however, exhibits negligible differences in both cases.

C. Precision

Analyzing precision across different models in Fig. 5(c), 6(c), and 7(c) yields the following observations. In Fig. 5(c), the precision is higher when emojis are excluded for all three models. Particularly, there is a significant increase in precision observed for the V2 and TW models when emojis are excluded, suggesting that emojis may have a notable impact on lowering precision, especially for these models. For Fig. 6(c), the precision outcomes show improvements for all models when emojis are removed. The V2 and MD models demonstrate significant enhancement in precision without emoji, indicating a reduction in false positives. The TW model shows no significant difference in both cases. In Fig. 7(c), the MD model shows improvement in precision without emoji, indicating potential complications that emojis introduce in precision tasks across different models. However, the V2 and TW models show a minor increase in precision with emoji, suggesting a better ability to identify positive instances when emojis are present.

D. F1-score

In Fig. 5(d) and 6(d), a consistent trend is observed where excluding emojis benefits the F1-score across all models. This indicates that emojis do not significantly contribute to the classification process and could potentially even restrict it. The same thing almost exists in Fig. 7(d). For V2, the F1-score slightly drops when emojis are excluded. The difference in the MD case is almost negligible. These findings imply that emojis exclusion mitigates the trade-off between precision and recall for this particular model.

Based on these results, the proposed framework concludes that excluding emojis consistently improves accuracy, recall, precision, and F1-score across various models, indicating its beneficial impact on sarcasm speech classification. Emojis introduce ambiguity or noise that degrades classification accuracy, while their exclusion leads to increased recall, particularly for the TW and MD models. Precision notably increases, especially for the V2 and MD models, when emojis are removed, reducing false positives. Similarly, the F1-score improves across all models when emojis are excluded, except for a slight drop in V2's case, implying a better balance between precision and recall. Therefore, these results support our main hypothesis (RQ1, RQ2, and RQ3) that removing emojis during the preprocessing stage has a positive, or at least non-negative, impact on improving sarcasm speech classification performance.

Reflecting these findings, we believe that excluding emojis in sarcasm detection increases focus on an important aspect of NLP. Although emojis are commonly used in digital communication, their influence on language processing can vary significantly depending on the linguistic context. In the case of Arabic, a language rich in vocabulary and dialects, emojis may introduce more noise than benefit, as demonstrated by the performance improvements observed in our models when these non-textual elements were omitted.

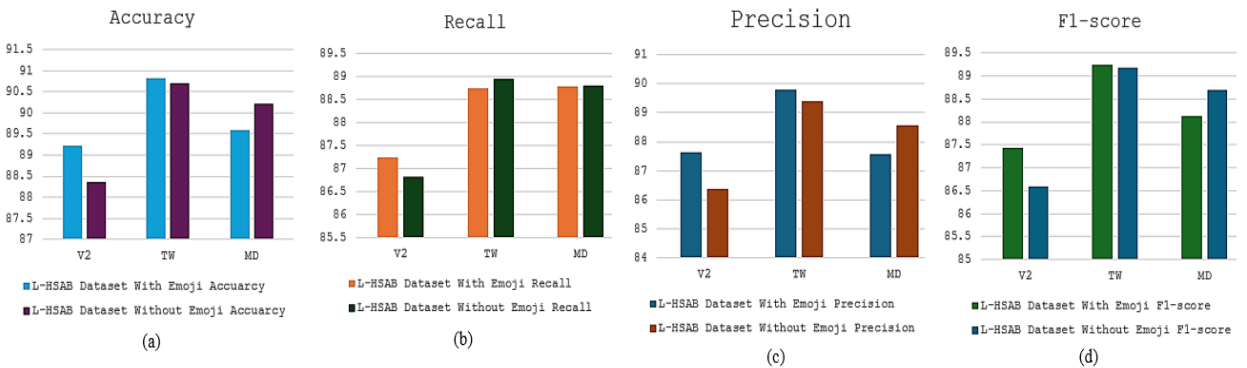

Fig. 7. Comparison results of classification with and without emojis on the L-HSAB dataset.

V. CONCLUSIONS AND FUTURE WORK

In this paper, we investigated the impact of excluding emojis during the preprocessing stage on the performance of Arabic sarcasm detection models. Detecting sarcasm in Arabic social media speech presents a multifaceted challenge due to linguistic diversity and the intricacies of sarcastic expressions. By evaluating the accuracy, recall, precision, and F1-score metrics across various models and datasets, we demonstrated that emojis exclusion enhances sarcasm detection accuracy. This research provides a more precise interpretation of lan-

guage by eliminating potential confusion introduced by non-textual elements, ultimately contributing to the advancement of language processing techniques in linguistically diverse regions. Moreover, our findings offer valuable insights for social media platforms and natural language processing research. By highlighting the positive impact of emojis exclusion on sarcasm detection model performance, new benchmarks are established in Arabic natural language processing.

Nevertheless, there are some limitations to this study, which need to be mentioned. First, such research specifies the

focus of sarcasm detection on textual information rather than considering that social media content often contains data in the form of images, videos, and so on in addition to text data. Second, although the given datasets offered a wide variety of texts, it should be noted that they might not include all the different types, styles, and details of the Arabic language used across Arabic-speaking countries. This limitation implies that when generalizing the findings of this study, the conclusions may be restricted to the contexts captured by the datasets.

Future research could focus on developing advanced machine-learning tools that interpret emojis alongside the text, reducing confusion from emojis misuse or overuse. This study provides the way for further advancements, particularly in enhancing the robustness and applicability of sarcasm detection models for Arabic and other languages, as follows:

- Integrating text with other data types like images, videos, and audio could enhance the accuracy of sarcasm detection. For instance, facial expressions in images accompanying sarcastic text might provide additional context that is not captured by textual analysis alone. The ability to process multiple data formats in real time could significantly improve the performance of the model.
- Real-time monitoring tools on social media platforms could be significantly enhanced to detect and report sarcasm in live conversations, which can help prevent the propagation of harmful comments and improve automated customer service responses. Integrating these models into platforms like Twitter and Facebook could also offer deeper insights into public opinion trends.
- A key challenge in Arabic sarcasm detection is the availability of datasets where the sarcasm is annotated. Future efforts could enhance this by using more effective schemes of data annotation like crowdsourcing or semi-supervised learning, as well as in collecting datasets that include various dialects and cultural settings to improve the model's transferability and reliability.

A Configurable Framework for High-Performance Graph Storage and Mutation

Soukaina Firmlı, Dalila Chiadmi, Kawtar Younsi Dahbi
SIP Research Team-Rabat IT Center-EMI, Mohammed V University in Rabat, Morocco

Abstract—In the realm of graph processing, efficient storage and update mechanisms are crucial due to the large volume of graphs and their dynamic nature. Traditional data structures such as adjacency lists and matrices, while effective in certain scenarios, often suffer from performance trade-offs such as high memory consumption or slow update capabilities. To address these challenges, we introduce CoreGraph, an advanced graph framework designed to optimize both read and update performance. CoreGraph leverages a novel segmentation method and in-place update techniques, along with configurable memory allocators and synchronization mechanisms, to enhance parallel processing and reduce memory consumption. CoreGraph’s update throughput (with up to 20x) and analytics performance exceed those of several state-of-the-art graph structures such as Teseo, GraphOne and LLAMA, while maintaining low memory consumption when the workload includes updates. This paper details the architecture and benefits of CoreGraph, highlighting its practical application in traffic data management where it seamlessly integrates with existing systems providing a scalable and efficient solution for real-world graph data management challenges.

Keywords—Data structures; concurrency; graph processing; graph mutations; high-performance computing; traffic management

I. INTRODUCTION

Research in graph processing technology continues to evolve and prosper due to the unique ability of graphs to represent complex relationships and inter-dependencies within data, making them suitable for many modern applications. Graph applications include Knowledge Graphs (KG) [1] used in search engines, personal assistants, and recommendation systems; Graph Neural Networks (GNNs) [2] for AI tasks like node classification, link prediction, and graph classification; and real-time graph analysis for streaming data from sources like Twitter and financial transactions.

As a result of the widespread use of graphs, there is a growing need to efficiently manage and analyze them. This has led to the development of graph processing systems and graph databases like Neo4j [3], which are well-suited for storing, analyzing, and streaming large graph data due to their scalability, real-time processing capabilities, and ability to handle complex relationships. However, these systems face multiple challenges inherent to graph processing and streaming that limit the effective use of graphs in the real world due to varying graph characteristics, memory-intensive algorithms, and access patterns that cause latency, as well as the continuous evolution of graph topology and properties [4].

To understand and address these challenges, it is important to recognize that at the heart of each graph system

lies the graph data structure, which stores the vertices and their edges, and whose performance largely contributes to the overall performance of the system. However, classic graph data structures typically trade some characteristics for others [5]. For instance, Compressed Sparse Row (CSR) representations are memory efficient with good read-only performance but have poor update performance. The challenge, therefore, is to design graph data structures that ideally offer excellent read-only performance, fast mutations (i.e., vertex or edge insertions and deletions), and low memory consumption with or without mutations.

To address these problems with classical data structures, efforts have been made to improve the updated friendliness of CSR. These include in-place update techniques [6], [7], batching techniques [8], [9], changeset-based updates with delta maps [10], and multi-versioning [11]. However, systems still struggle to offer the best tradeoff between read and, update performance and memory consumption.

To this aim, we present in this paper CoreGraph, a highly configurable end-to-end graph framework designed to address these challenges. CoreGraph builds on our previous work CSR++ [12], to offer a high-performance concurrent data structure for graph topology and properties storage. The framework is designed for in-place graph mutations, achieving superior analytics and update performance with significantly lower memory requirements compared to state of art solutions like LLAMA [11].

The main contributions of our framework can be summarized as follows:

1) *Efficient in memory architecture*: CoreGraph implements an in-memory architecture that allows for efficient graph loading, mutation, and analysis, making it suitable for a wide range of applications.

2) *Optimized storage and update protocol*: CoreGraph offers a storage and update protocol based on a novel segmentation method that optimizes graph storage for both read and write operations while minimizing memory space.

3) *High configurability*: CoreGraph is highly configurable by integrating advanced synchronization mechanisms, including Hardware Transactional Memory (HTM) and adaptable locking strategies, to enhance parallel performance while minimizing contention. Furthermore, the framework supports configurable memory allocators to optimize resource utilization and performance based on specific application needs.

We also demonstrate the practical applicability and portability of CoreGraph as a lightweight graph storage and mutation framework through a case study on traffic data manage-

ment, a domain characterized by high-frequency updates and large data volumes. CoreGraph not only improved the performance of graph mutations and analytics but also seamlessly integrated with an existing framework for traffic data management. This integration highlights CoreGraph's potential as a vital component in real-world data discovery and exploitation chains.

The rest of this paper is organized as follows: Section II presents related works, Section III gives an overview of the proposed approach for graph storage and mutation, and Section V presents the use case related to the traffic data management domain, which aims to integrate CoreGraph with an existing framework for graph analysis and updates. The study concludes in Section VI.

II. RELATED WORK

In this section, we present some notable state-of-the-art research work that proposes optimization to classic data structures for graph storage and mutation for graph processing and streaming. We give a brief overview of each work in terms of i) graph storage and ii) graph updates, and then draw their main limitations.

A. Graph Storage

First, there exist different techniques available for researchers to optimize data structures, among which we found: optimizing the memory layout of the data structures [27] [9] [25], using compression algorithms [26] [24] and using special memory allocator [19] [18].

SSTGraph [26] use a compression algorithm based on the tinyset parallel dynamic set data structure, which implements set membership using sorted packed memory arrays. This allows for logarithmic time access and updates, as well as optimal linear time scanning, by minimizing serialization overhead.

To improve the cache performance of dynamic graph data structures, many researchers [18] [19][20] use bucketing technique where buckets are used to group edges from the same source vertex together, or using linked lists to group edges from different source vertices together. As we note from the evaluation results of works in the literature, there are only a few works that provide a thorough sensitivity analysis of different variations of their solutions like [25].

Another approach used by systems [19] [9] [18] in literature is using a special memory allocator, either internal to their system or external, to minimize the memory fragmentation caused by frequent reallocations on dynamic data structures. For instance, to efficiently perform memory reclamation and manage space, Hornet's [19] internal memory management uses a B+ tree for insertions and deletions to keep track of the available blocks of edges. However, when deletions are not frequent, which is the case in most real-world scenarios, the overhead of the memory reclamation makes the update performance slower.

B. Update Protocols

The ingestion and storage of the new updates play a crucial role in the overall performance of the systems. The methods

used to implement them, that we refer to as update protocols, vary in the literature, therefore, we propose our classification for these protocols. First, update storage can be either in-place or using deltas, while update ingestion can be in bulk or concurrently with analytic workloads.

1) *Update storage*: Techniques that use in-place updates employ the static data structures in a way that allows for in-place digestion of sets with insertions and deletions of vertices and edges, without requiring the expensive rebuilding of the data structure. Systems [28] [20] [25], develop a variant of CSR based on Packed Memory Arrays (PMAs), that provides efficient in-place updates by leaving space at the end of each adjacency list. Moreover, when the number of gaps is too small or too large, systems are required to perform a re-balancing of the tree to rearrange the gaps in the array. This may slowdown the update performance and delay the analytic workloads.

Dynamic Arrays are used by systems like NetworKit [6] to perform in-place edge insertions by directly storing the new edges in dynamic growable edge arrays and reallocating twice the initial array size if there is no memory space for the new edge. The same method is employed by the Madduri et al. [9]. The author in [11] with the exception that the size of the new edge array is defined in terms of a customizable factor rather than a fixed factor of two. Subsequently, when employing dynamic arrays, the amortized cost for updates is $O(1)$ for insertions and $O(\deg V)$ for deletions. However, the memory footprint can be quite substantial as the reallocations leave unused space, when there are no updates.

On the other hand, systems [10] [29] [23] [30] employ additional data structures to store the new updates referred to as *deltas*. GraphOne [23] implements a hybrid store for deltas using adjacency lists (AL) store and an edge list (EL). The AL keeps track of a linked list of vertex degrees at various points in time using timestamps. However, the performance of GraphOne suffers because of the indirection layer and the multiple levels of data in the adjacency list as [12] points out, making it not reliable for read-intensive workloads.

2) *Update ingestion*: The ingestion of updates can be performed in bulk, with alternating phases: pending updates wait for currently executing queries to finish before they start executing, and pending queries wait for currently executing updates to finish before they start executing. Update ingestion can also be concurrent with query execution, but in that case, the system needs to guarantee consistency on the data and at user level [11].

Moreover, the updates can be ingested as single operations or in batches. First, supporting single updates can be challenging. In fact, depending on the availability of memory, systems need to allocate new blocks to store the new edges [18]. Consequently, the frequent checks for memory availability and reallocations cause a large overhead, making the single updates very slow. To remediate the slow single update performance, systems [25] [11] [23], opt for batch updates where the batch of edge updates is pre-processed to allow for parallel updates, and to reduce the system calls for frequent allocations.

C. Discussion

The related works provide a background for optimizing graph representations for graph storage and updates. Table I

presents a summary of our related work and their limitations, which we discuss below.

1) *Achieving optimal performance trade-off*: As discussed and highlighted in Table I, most systems tend to improve on an aspect of performance, either read performance, updates throughput or memory consumption, and to barely achieve the best trade-off between all three of these aspects. For instance, the majority of the systems struggle to support several versions of the graph when storing updates in deltas, because of high memory cost, and graph compaction [11] is necessary to reduce the amount of space needed for changes. However, the performing frequent compaction requires expensive computation and slows down the performance of the system.

2) *Lack of configuration and hybrid representation*: systems still exhibit limited configurability in their data structures. This limitation underscores the need for more adaptable data structures to accommodate diverse workload requirements, especially by considering different sizing of buckets within structures facilitating in-place updates. A noticeable absence of configurability in current literature highlights the need for refining existing designs to better suit diverse workloads tailored to specific application requirements.

3) *Lack of comprehensive experimental study*: There is a notable emphasis on protocols for updating graph topology. However, it is infrequent to find comprehensive implementations and evaluations of performance when considering other graph data elements, such as graph properties, reverse edges, or intermediary results in graph algorithms, and a data storage-focused approach is vital for achieving high performance in real-world applications. We also highlight the lack of validation of these graph processing systems in real-world scenarios, as most are only evaluated against generic data sets or synthetic data data sets that are not diversified.

Moreover, The performance of graph systems is significantly influenced by the dynamic memory allocator employed. To our knowledge, there are only few studies [31] that provide experimental analysis on how memory allocation impacts high-performance query engines, but not for graph storage and

mutation systems.

Therefore, in this work, we aim to address these challenges by proposing a generic and domain-independent system for graph storage and mutation.

III. PROPOSED FRAMEWORK

In this section, we present our highly configurable end-to-end graph framework CoreGraph that allows the loading, storage and mutation of graphs, as well as their analysis, while providing high performance, low memory consumption and high update throughput. The architecture of CoreGraph is shown in Fig. 1.

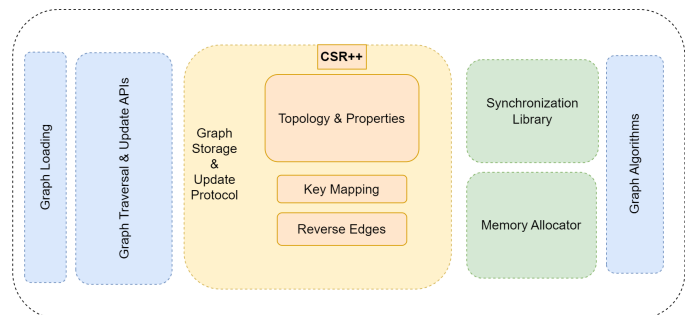

Fig. 1. CoreGraph framework.

CoreGraph enables fast concurrent accesses to the main graph data (vertex and edge tables) and stores additional graph data, such as reverse edges, user-defined keys, and vertex and edge properties. Additionally, it supports graph analytics kernels based on Green-Marl implementation [32], which are optimized to run in parallel (Section III-A).

Moreover, CoreGraph offers the main capabilities to load graphs in-memory using smart allocation and mutate graphs by exposing storage and update APIs, as well as a high performance and low memory footprint storage (Section III-B),

Finally, CoreGraph offers high configurability based on specific requirements and workloads by providing i) a configurable reallocation size for edge arrays to reduce the memory footprint when there are less frequent edge insertions (Section III-B), ii) configurable synchronization mechanism to enhance parallelism and reduce the overhead of contention (Section III-C), and iii) configurable memory allocators to optimize performance and resource utilization (Section III-D).

The main elements of our framework are represented in Fig. 1, and a detailed description will be presented below.

A. Graph Storage

The storage component of CoreGraph is a concurrent multimap that maintains the graph's topology and properties, based on the segmentation method where a fixed number of keys are grouped in an array referred to as segment. The segmentation method enables a less bulky, cache-friendly layout. Additionally, CoreGraph maintains additional graph data in addition to the basic graph data (vertex and edge tables), allowing for rapid algorithms. By storing extra graph data like reverse edges and user-defined keys, it can handle directed graphs and external IDs.

1) *Topology*: We store vertices in *segments* and the number of vertices stored in each segment of a graph is determined by the global configuration NUM_V_SEG. When there are N vertices in a graph, the number of segments is: $\text{num_segment} = N / \text{NUM_V_SEG} + 1$, as shown in Fig. 2(A). As for the structure of vertices, CoreGraph stores i) the degree ii) a pointer to their neighbor list if the degree is more than 1 and iii) optionally a pointer to the edge properties as shown in Fig. 2(B). This structure is similar to a combination of CSR and adjacency lists; However, CoreGraph's storage performance is superior to other adjacency-inspired approaches for skewed graphs due to the *inlining* of the single edges in the vertex structure, meaning if a vertex has only one neighbor, then the edge corresponding to said neighbor is stored within the structure of the vertex instead of a pointer, which minimizes the memory consumption and the cache misses when accessing the edge. Finally, if a vertex has more than one neighbor, then it's adjacency is stored as an array of edges; each edge contains the vertex ID corresponding to the index of the neighbour in the segment, and segment ID of its corresponding neighbor.

A complete sensitivity analysis [12] of the segment size shows that setting the value depends on the workload, since 1) for read intensive workloads, cache performance decreases if the size of segments is small, and the frequently allocated segments are not necessarily be allocated contiguously in memory. However, for update intensive workloads, contention between threads updating vertices in the same segment may increase, if the NUM_V_SEG is set to a big value, causing a decrease in the update throughput. Therefore we expose this option in the configuration of CoreGraph for users to set the The NUM_V_SEG so that they get the best performance depending on their workload. when configuring the segment layout. CoreGraph sets the default segment size to a value that is a multiple of 4 to enable cache alignment [4].

2) *Properties*: CoreGraph allows the user to configure the storage to store extra pointers for the vertex and edge properties. If the to-be-loaded graph data set does not include

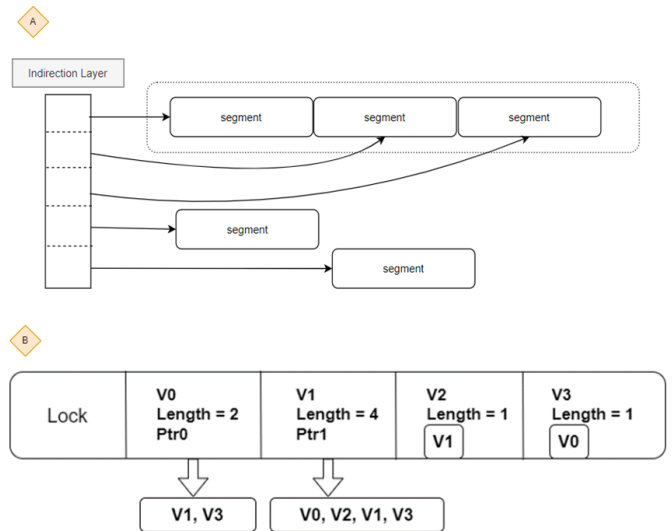

Fig. 2. Representation of Topology in CoreGraph. A) An indirection layer stores pointers to the segments to allow adding new ones and the segments are initially stored contiguously upon the loading of the graph to enhance the read performance. B) The segment structure stores a fixed number of vertices which in turn store information about their adjacencies.

vertex/edge properties, then property support can be disabled to save memory. If activated, CoreGraph keeps a vector of pointers to vertex-property arrays which are parallel to the vertex array. Similarly, if edge properties are activated, CoreGraph stores a pointer to an array of edge-property values within each vertex structure and we use the same segmentation approach as for edges. In case of multiple properties, we allocate an array that stores the values for different edge properties in a cache-aligned manner. The edge properties are stored separately from the edge arrays to enable copy-on-write functionality for the edge-property arrays of only the updated vertices, unlike CSR which requires rebuilding the edge properties for the entire graph. This approach also makes it easier to maintain the property values in the same order as the edges if sorting is needed after an update. While this design incurs a moderate memory overhead, it offers significant benefits for performance, as the performance of the insertion of new edges with an edge properties of CoreGraph is an order of magnitude faster than other state-of-the-art in-place update systems, namely, Teseo [25] and STINGER [18].

B. Update Protocols

For fast, low-memory-usage graph mutation, CoreGraph offers update APIs as abstractions for an update protocol. The update protocol includes creating new vertices and edges, removing existing ones, and modifying the vertex and edge properties. When compared to CSR, which must reallocate and copy edge and vertex arrays whenever the graph's topology is changed, our segmented approach offers significantly higher update throughput due to the fact that each vertex and edge can be updated independently during graph mutation. Vertices in CoreGraph are kept in indexed arrays (see Fig. 3). If there is free space in a segment, adding a new vertex costs $O(1)$, otherwise CoreGraph creates a new segment if necessary. However, in CoreGraph, adding a new vertex is faster reaching an update throughput of 9M vertices/s due to the segmented

nature of the vertex array; that is, we do not need to replicate the entire vertex array when adding or removing entries.

Fig. 3. Update Protocol for vertex insertions. If there is space in the segment, CoreGraph sets the length value of the first non-valid vertex from -1 to the degree of the new vertex (left), otherwise, it allocates a new segment and sets the new vertex (right).

Moreover, adding a new edge only necessitates reallocating the edge array of the source vertex because edges are stored in an array per vertex as shown in Fig. 4. When employing dynamic arrays, the amortized cost for updates is $O(1)$ for insertions and $O(\deg V)$ for deletions. However, the memory footprint can be quite substantial as the reallocations leave unused space, when there are no updates. CoreGraph addresses this problem in two ways.

First, we use a smart memory manager can help keep track of unused space and perform a better strategy for pre-allocation while maintaining a memory footprint comparable to static graph data structures.

Second, CoreGraph exposes the reallocation factor as a configuration option for users to set it at compile time. The reason for this is that most system only test on specific use cases such as the SNAP [9] data sets and assuming they're analyzing power-law graphs, thus they set the reallocation factor to double the size by default. However, today users can take advantage of the power of machine learning [33] to estimate the factor by which we can grow our dynamic arrays, using statistical variables in a stream for specific types of graphs. For instance, we can learn the patterns of the creation of new relationships in social networks, e.g., a post that goes viral on social media might bring many followers in a short amount of time This means that for a celebrity account, there are higher chances of gaining more followers than a normal account, therefore we can choose a higher factor (x4, x5) to pre-allocate the edge lists while keeping an x2 factor for normal accounts to maintain a low memory footprint of our dynamic graph. Therefore, by allowing the configuration of the reallocation factor of edge arrays, CoreGraph adapts to different types of graphs and workloads, and minimizes the overall memory consumption of its dynamic graph data structure.

With respect to deletions, CoreGraph includes a mechanism for removing entities (both physically and virtually). The system reallocates the edge array by shifting the other edges to the left to physically delete an edge. In case of virtual deletion, where an edge or vertex is logically deleted from the CoreGraph, the deleted flag is set to indicate this.

Fig. 4. Update protocol for edge insertion.

Algorithm 1 Batch Update Protocol in CoreGraph for Vertex and Edge Insertions

- 1: **Input:** Set of new edges E_{new}
- 2: **Output:** Updated CoreGraph with new edges
- 3: **//Step 1: Grouping and Conversion**
- 4: **for all** edge $e \in E_{new}$ **do**
- 5: Group e by its source vertex $src(e)$
- 6: Convert source and destination user keys to internal keys
- 7: **end for**
- 8: Insert new vertices in CoreGraph and assign new internal IDs (Sequential)
- 9: **//Step 2: Sorting and Insertion**
- 10: **for all** source vertex v in parallel **do**
- 11: Sort new edges originating from v
- 12: Insert sorted edges into direct and reverse maps
- 13: **end for**
- 14: **//Step 3: Final Sorting and Reallocation**
- 15: **for all** modified segment s in parallel **do**
- 16: Merge old edges and new edges for each source vertex in s
- 17: Sort the final edge arrays
- 18: Reallocate edge properties according to the new order of edges
- 19: **end for**

Last but not least, CoreGraph uses a batch insertion protocol to insert vertices and edges in parallel, greatly enhancing the update's performance over a singular update. CoreGraph uses a bulk update mode, wherein updates and analytical procedures are executed sequentially rather than simultaneously. Using a fast in-place update protocol, CoreGraph is resilient enough to handle frequent small updates. Algorithm 1 shows the steps to achieve the batch insertions of vertices and edges in CoreGraph.

C. Synchronization Library

CoreGraph as a customizable graph storage and mutation framework, offers different configurations for synchronization to ensure consistency when running parallel graph analytics or parallel graph mutations. CoreGraph allows the user to configure the synchronization mechanism by offering different synchronization primitives to cater for different types of workloads and graph characteristics. CoreGraph allows locking at the segment level, however this may lead to high contention

when updates are targeting the same segment can cause a slowdown, such as multiple threads inserting edges to the same vertex in high skew graphs.

To remediate to this problem, CoreGraph allows two main configurations for low and high contention workloads. This is done by 1) using adaptable locking mechanism to switch to different lock algorithm depending on the contention level and 2) using HTM for high contention workloads to speed up the parallel execution without incurring extra memory overhead.

First, CoreGraph integrates the library GLS [34] for two reasons. It offers adaptiveness, which is designed to switch the synchronization depending on the workload, allowing it to adapt to different types of workloads and therefore give the best performance in most cases. Moreover, in debug mode it gives us information about the level of contention thanks to its built-in profiler lock (as shown in Fig. 5) which allows us to switch to different synchronization mechanism.

```

Profiler Lock + RTM
Threads | Stats
1 | [lock stats] avg spin: 0 | avg queue: 0.00 | avg lat: 24 | n_acq: 5649 @ (0x2aaaacc81298)m
2 | [lock stats] avg spin: 16 | avg queue: 0.04 | avg lat: 72 | n_acq: 137324 @ (0x2aaaacc81298)m
4 | [lock stats] avg spin: 47 | avg queue: 0.22 | avg lat: 560 | n_acq: 67171 @ (0x2aaaacc82998)m
6 | [lock stats] avg spin: 94 | avg queue: 0.92 | avg lat: 1650 | n_acq: 1483192 @ (0x2aaaacc83298)m
8 | [lock stats] avg spin: 227 | avg queue: 2.85 | avg lat: 4887 | n_acq: 1935847 @ (0x2aaaacc83298)m
12 | [lock stats] avg spin: 787 | avg queue: 7.86 | avg lat: 15899 | n_acq: 2802555 @ (0x2aaaacc84298)m
24 | [lock stats] avg spin: 2822 | avg queue: 26.42 | avg lat: 48325 | n_acq: 2803888 @ (0x2aaaacc8f298)m
    
```

Fig. 5. Real-time monitoring of contention using profiler lock in GLS and HTM. The average queue allows to quantify the contention level.

CoreGraph also allows swapping synchronization primitives automatically depending on the level of conflict: it prioritizes queue-based locks for high contention workloads such as edge insertions on vertices in the same segment and spinlocks like ticket locks for low contention workloads.

Furthermore, CoreGraph offers high parallel performance through the use of Hardware Transactional Memory (HTM) in Intel Restricted Transactional Memory (RTM) as a synchronization mechanism to simulate fine-grain locking at the vertex level without incurring extra memory cost. Each segment uses a single lock as a backup locking mechanism in case of aborts, i.e., lock elision.

We run an experiment to compare the performance of CoreGraph with HTM compared to fine-grained synchronization. We implemented a variant of CoreGraph with fine-grained synchronization where instead of storing one lock for individual segments, we store one lock per individual vertex. Update times for several segments and multithreaded scalability are shown in Fig. 6. The NUM_V_SEGMENT is modified to store the graph in different number of segments, and we insert 100K edges using a random uniform distributions on the final segments.

Fig. 6 demonstrates that even with 24 threads, the quickest solution is fine-grain locking, made possible by OpenMP scheduling. When utilizing several threads, CoreGraph with coarse locks stops scaling, and performance degrades as segment sizes increase. This is due to the significant conflict among threads updating adjacent segment vertices. On the other hand, HTM performs much better when there are many conflicts created as we use only two segments to store a whole graph.

Finally, the memory requirements of several locking mechanisms are shown in Table II. The cost of implementing HTM

Fig. 6. Update times for several segments and multithreaded scalability. X-axis: number of threads, Y-axis: time (ms).

is comparable to that of a coarse lock since it does not need additional memory. However, fine-grained locking requires much more storage space since it adds $S = \text{sizeof(lock)} * \text{num_of_vertices}$, to the overall size of the structure.

Users may opt for HTM for suitable cases such to take most advantage of its performance, namely in cases where there are many conflicts. Moreover, it does not cause an increase in memory consumption.

D. Memory Allocation

Rather than using standard memory allocation functions for storing and updating large skewed graphs in-memory, which would be highly inefficient, CoreGraph optimizes this process with two main components: 1) an internal memory pool that pre-allocates the memory for loading the adjacency lists in a contiguous space and 2) a configurable allocation strategy using three state-of-the-art dynamic memory allocators, namely Glibc, Jemalloc [35] and TCMalloc [36]

First, we implement a smart loading procedure to optimize the physical memory layout of CoreGraph and therefore CoreGraph's analytic performance. Here, we describe the loading protocol using the memory manager in CoreGraph.

At the start of a graph loading process, memory of size $S = \text{sizeof(edge)} * \text{number_of_edges}$, is allocated. Then, we utilize that area to store the entire graph's edges in a contiguous space within the same primary block. While we still keep track of pointers to edge lists for each vertex, the smart loader ensures that the edges are first stored in contiguous space. The memory compression made possible by this optimization brings us very near within 10% to the CSR in terms of read performance.

TABLE II. CONFIGURATIONS PROVIDED IN COREGRAPH

Configuration	Implementation	Impact
Reallocation Factor	Resizing the edge array when inserting new edges based on factor in config.	Low memory footprint, less memory allocations
Enabling Vertex/Edge Properties	Enabling storage for extra pointers for vertex/edge properties	Lower memory footprint, high cache performance
Synchronization Mechanism	Spinlock, Ticket/Profiler Lock, Intel HTM	Less contentions, high parallel performance
Memory Allocation	Glibc, Jemalloc, TCMalloc	Less fragmentation, high parallel performance

Secondly, CoreGraph employs efficient dynamic memory allocators, which allow to reduce memory fragmentation that occurs when memory is constantly being reallocated and so has chunks of unused space, or fragments, left over. In fact, in addition to the standard Glibc memory allocator, users can configure CoreGraph to use two state-of-the-art libraries for dynamic memory allocation: Jemalloc and TcMalloc. To demonstrate the performance gain from using these libraries, we performed a sensitivity analysis on CoreGraph with the three libraries for memory allocation [12] by running the same workload on three different allocator configurations of CoreGraph. As expected, Jemalloc and TCMalloc allow for a better performance than Glibc's performance for edge insertions. This is due to the parallel and thread-safe malloc implementation in both Jemalloc and TCMalloc, which gives better scalability when using multiple threads as shown in the plots.

IV. EVALUATION

We evaluated our framework on popular reference benchmarks [12] using readily available real-world and synthetic data sets that are popular in the graph research community, using two internal and external benchmark suites, Green-Marl [32] and GFE [37]. We evaluate the performance using real-world graph data sets [38], namely Twitter (1.4 billion edges), LiveJournal (68 million edges), and synthetic dataset [39] such as Uniform-24 (260 million edges), and Graph500-22 (69 million edges). We ran the experiments on a two-socket, 36-core machine with 384 GB of RAM. Its two 2.30 Ghz Intel Xeon E5-2699 v3 CPUs have 18 cores (36 hardware threads) and 32 KB, 256 KB and 46 MB L1, L2, and LLC caches, respectively.

CoreGraph outperforms the state of the art systems, reaching an update throughput of up to 24 Meps (million edges per second) compared to STINGER [18] (10 Meps), Teseo [25] (2.5 Meps) and GraphOne [23] (2 Meps). It also performs within 10% of CSR in graph analytics, while having a moderate memory overhead of 33% compared with CSR.

We highlighted the performance gains from using our framework in terms of high read performance, high update throughput while still maintaining a low memory footprint.

We demonstrated that CoreGraph offers high degree of configurability and we summarize these findings in Table II.

V. COREGRAPH FOR TRAFFIC DATA MANAGEMENT

In this section, we present our case study. We deemed important to test our solution on a more domain-specific dataset that represents real-world use case and can be exploited to extract insights for researchers and industry practitioners. The use case focuses on the traffic data management, which is critical for improving urban and highway traffic conditions

to optimize traffic flow, detect congestion, and enhance overall transportation efficiency.

In this context, we extended the framework DIKCC, developed by our research team [40] [41] for traffic data management. The framework extracts knowledge from heterogeneous data sources and construct a knowledge graph characterized by high volume (300M edges and 4M edges) and high frequency of updates (10M updates/s).

Building on this foundational work, we integrate our framework CoreGraph into DIKCC framework, to provide high performance storage necessary in a context of high volume data and constantly evolving graphs. Our framework ensures efficient updates which are crucial in environments with real-time data stream. It also enables advanced analytic capabilities to address complex issues in traffic management. Moreover, CoreGraph outperforms graph databases or other state-of-the-art systems, that offer resource-consuming features that are not relevant to the traffic data discovery use case studied by our research team.

We utilized the same dataset as in the previous study [40], which consists of continuous views of three tables: Event, Route, and Intersection. The result of the knowledge construction from this data through is a property graph where the nodes are the intersections and the edges are the roads that link these intersections Fig. 7 shows the resulting graph.

We use the created mapping from relational-to-graph model, and we pre-process the datasets by converting them from CSV format as generated by the SQL queries, into file format that is supported by our framework, i.e, adjacency files, which does not require any additional schema definition and is consumed out of the box. Using this graph, our framework allows to recommend the optimal route to users to reach their destination by executing path traversal algorithms, which provide information about the state of the roads.

The updates to the graph are triggered from changes in the relational data by the creation of a new congestion event, that we process by updating the property value of edge of the corresponding road. Our framework supports topological mutation in addition to the updates to property values. Therefore, we extend the update workloads to the ones triggered by the creation of new roads between intersections, which we process as the insertion of new nodes and new edges. As for the new incoming updates, CoreGraph consumes continuous views to get the updates from the database as logs of edge lists, and performs the updates on the congestion status of roads (i.e. the edge property values) using our parallel batch updates API, and using our single update API for the insertions of new intersections and new roads (i.e. topological updates) since they are infrequent.

Fig. 7. Knowledge Graph for Traffic [40]. CoreGraph finds the shortest not congested routes by running BFS and setting the property values of edges accordingly.

We write a script to load the graph and measure the memory consumption. We find that the in-memory size is about 12 GB, which in principal can be supported on the same machine where the relational database resides.

After loading the graph, we run the path traversal algorithm namely BFS to find the shortest non-congested route from source to destination as depicted in Fig. 7. We then compare the output results to a validation data set for the top 10 nodes. After validating the correctness of our results, we measure the performance of the analytic workload which takes 2s to traverse the graph 300M of edges, which introduces minimal overhead to the end-to-end value chain process.

As for updates, since we store the adjacency of vertices in sorted order by id of intersections, we are able to locate the edge defined for the road by doing a binary search over the neighbour list using the identifier of the destination node which is the intersection. We use the index in that list to update the property value and set the congested state of the road. Moreover, for our extension to support high throughput topological updates, we use the prediction ML model from DIKCC to set the reallocation factor of the edge arrays, by predicting how much space we need to allocate for newly added intersections giving us an average throughput of 24M updates/sec.

We showed that our framework can be used as a vital component of the data discovery chain by demonstrating how our lightweight framework is easily integrated into a pre-existing framework with low overhead for traffic data management. We concluded that the performance gains from our integration are significantly higher than integration with a graph database

system especially, and our framework can be easily compiled as a C++ library and shipped with the end-to-end framework without requiring extra configuration.

VI. CONCLUSION

In conclusion, this paper introduced CoreGraph, a highly configurable graph framework designed to address the challenges of efficient graph storage, mutation, and analysis. CoreGraph's storage and update protocol designs offer superior performance in terms of memory efficiency and update throughput compared to traditional graph data structures while maintaining read performance within 10% of CSR. The framework's integration of advanced synchronization mechanisms and configurable memory allocators enhances its adaptability to diverse workloads, making it suitable for real-time applications such as traffic data management. Our case study demonstrated that CoreGraph not only improves update throughput and analytic performance but also seamlessly integrates with existing frameworks, highlighting its potential as a critical component in modern data discovery and management systems. This study lays the groundwork for future research and development in optimizing graph processing systems, emphasizing the importance of balancing performance, memory consumption, and update efficiency in real-world scenarios.

Detecting Malware on Windows OS Using AI Classification of Extracted Behavioral Features from Images

Nooraldeen Alhamedi, Kang Dongshik
University of the Ryukyus, Japan, Okinawa, Japan

Abstract—In this research, using dynamic analysis ten critical features were extracted from malware samples operating in isolated virtual machines. These features included process ID, name, user, CPU usage, network connections, memory usage, and other pertinent parameters. The dataset comprised 50 malware samples and 11 benign programs, providing a data for training and testing the models. Initially, text-based classification methods were employed, utilizing feedforward neural networks (FNN) and recurrent neural networks (RNN). The FNN model achieved an accuracy rate of 56%, while the RNN model demonstrated better performance with an accuracy rate of 68%. These results highlight the potential of neural networks in analyzing and identifying malware based on behavioral patterns. To further explore AI's capabilities in malware detection, the extracted features were transformed into grayscale images. This transformation enabled the application of convolutional neural networks (CNN), which excel at capturing spatial patterns. Two CNN models were developed: a simple model and a more complex model. The simple CNN model, applied to the grayscale images, achieved an accuracy rate of 70.1%. The more complex CNN model, with multiple convolutional and fully connected layers, significantly improved performance, achieving an accuracy rate of 88%. The findings from this research underscore the importance of dynamic analysis. By leveraging both text and image-based classification methods, this study contributes to the development of more robust and accurate malware detection systems. It provides a comprehensive framework for future advancements in cybersecurity, emphasizing the critical role of dynamic analysis in identifying and mitigating threats.

Keywords—Malware analysis; dynamic analysis; image classification; malware behavior extraction; text

I. INTRODUCTION

Recently, the number, severity, sophistication of malware attacks, and cost of malware inflicts on the world economy have been increasing exponentially. Attacks with these kinds of software have a disastrous effect and cause considerable material damage to individuals, private companies, and governments' assets. Thus, malware should be detected before damaging the important assets in the company [1].

The primary motivation for this research stems from the need to enhance existing detection mechanisms to keep pace with the constantly changing threat landscape with traditional analysis methods, we aim to significantly improve the detection and classification accuracy of malicious software.

One of the key advantages of our approach is the combination of dynamic malware analysis with AI-driven techniques. This allows for a more comprehensive understanding of malware behavior. This hybrid approach not only improves detection rates but also enhances the ability to accurately classify and understand the nature of malware. There are two main techniques for analyzing malware - static and dynamic analysis. Static analysis examines the malware code without actually executing it. This by integrating advanced artificial intelligence (AI) techniques can provide information about suspicious functions, network activity, impacted files, etc. Dynamic analysis executes the malware code in an isolated environment to observe its runtime behavior. This provides insight into the full impact of the malware. A key benefit of static analysis is the ability to thoroughly inspect malware code using techniques like disassembly and decompilation to identify suspicious functions related to replication, propagation, payload activation, and more [2]. Static techniques help reveal overall structure, dependencies, triggers for malicious events, and obfuscation attempts. However, lacking runtime behavior, static analysis cannot confirm real impact of suspected capabilities. Complex packing or encryption techniques also limit code inspection. Other hand, dynamic analysis provides direct observation of malware behavior in action by executing it and monitoring resulting activity.

Dynamic analysis confirms suspected functions based on static clues and captures full infection chains showing progression and end objectives of malware according to case studies by [3]. Dynamic monitoring of memory access, networks calls, system API usage, and more creates a comprehensive picture. Additionally, dynamic analysis is particularly effective in identifying and analyzing newly emerging malware strains. As it focuses on the runtime behavior, it is better equipped to handle polymorphic and metamorphic malware that may change its form to evade static analysis techniques. Leveraging AI models for the analysis of malware code or the study of malware behavior has significantly contributed to the detection of malware in recent years. Numerous AI models have been integrated into static or dynamic approaches to augment both the malware detection rate and feature extraction processes. Despite the notable progress in the field of AI, these models still face various challenges. This research will use many model of AI in order to detect malware.

A. Difficulties in Detecting Malware

Robust malware analysis faces numerous obstacles. The sheer volume of malware proliferating at a rapid pace presents a formidable challenge in comprehensively examining this ever-expanding threat landscape. Additionally, malware authors employ sophisticated obfuscation tactics, such as code interchange, amalgamation, register reassignment, null insertion, and subroutine reordering [3], purposefully designed to evade detection by anti-malware systems. Despite decades of development, these security solutions still exhibit high false positive rates, undermining their accuracy.

Moreover, certain malware strains possess the ability to identify virtualized environments, resulting in altered or ceased execution, hindering effective analysis. The evasion techniques employed by malware necessitate lengthy detection times, potentially ranging from minutes to hours depending on the specific malware variant, during which systems remain vulnerable to compromise. Furthermore, the ambiguity surrounding API calls, as both malicious and benign software may legitimately invoke common APIs, complicates the process of distinguishing malware based on API usage patterns.

These factors, including the immense scale, obfuscation methods, virtual environment detection capabilities, delayed identification timelines, and the dual usage of APIs, collectively contribute to the arduous nature of robust malware analysis, necessitating the development of advanced techniques to overcome these challenges effectively, juxtaposition of text classification and image classification in the analysis of extracted behavior. It underscores that a nuanced understanding of program nature, distinguishing between benign and malicious entities, can be achieved through thorough behavior analysis. The model primarily relies on the extraction of malware features. Within the developed script, two distinct observers play a crucial role. The first observer extracts the entirety of the process, encompassing its characteristics, as well as details related to internet connections. The second observer is tasked with monitoring any file creation specifically linked to the malware. While previous research has explored the use of AI in malware detection, there remains a need for a more robust and adaptive framework capable of effectively handling the diverse and rapidly evolving nature of modern malware threats. Our study aims to fill this gap by developing a hybrid model that can effectively detect and classify malicious software, even in the face of obfuscation techniques and emerging threats.

II. RELATED WORK

Artificial Intelligence (AI) has emerged as a powerfully tool in this ongoing struggle to detect and classify malwares offering advanced capabilities in identifying and mitigating malware threats.

In study [4], the third paper analyzes different classical machine learning algorithms for malware detection - Random Forest, Support Vector Machine (SVM), grid search optimized SVM, and K-Nearest Neighbors (KNN). The goal is to validate the effectiveness of these models for detecting zero-day malware attacks. The dataset from Kaggle contained 19,611 PE files, with 14,599 malicious samples and 5,012 benign files

with 77 numeric features. Three training/test splits were used. Various accuracy metrics were calculated: accuracy, F1-score, confusion matrix, precision, recall and Type I/II errors. Random Forest performed the best with 96% accuracy and 93% F1score, with low errors and fastest training time. Optimized SVM improved results significantly but slowed down execution. KNN also performed decently with simpler implementation. Analysis showed Random Forest has good prospects for realtime zero-day malware detection. The model can process 25,000 files per second. For deployment, more diverse input data covering different malware families is needed.

In study [5], the authors used convolutional neural networks (CNNs) for malware classification by visualizing malware programs as grayscale images. The images are generated from the bytecode of malware programs and classified using CNN architectures. They evaluate several well-known CNN models like AlexNet, ResNet, and VGG16 using transfer learning on a malware image dataset. They also propose a custom shallow CNN architecture that achieves 96% accuracy, but is faster to train than the other complex models. The customized CNN and transfer learning models are also tested as feature extractors, with the features fed into SVM and KNN classifiers. This achieves even better performance up to 99.4% accuracy. They set a new benchmark on the public BIG 2015 malware dataset. The proposed system combining CNN feature extraction + SVM classifier obtains state-of-the-art 99.4% accuracy in distinguishing between nine malware classes. Visualization and CNN-based classification is shown to be effective for malware detection. The approach is computationally efficient compared to static/dynamic analysis. Fusing different CNN model predictions can further improve performance.

In study [6], the authors used Support Vector Machines (SVMs) for malware analysis and classification. SVMs are supervised learning models that can analyze high-dimensional, sparse data and recognize patterns. The authors collect a heterogeneous malware dataset from a real threat database. The data has features like time, format, domain, IP address. They visualize the dataset using techniques like scatter plots and radius visualization to understand correlations and structure before classification. A SVM model with polynomial kernel is trained on the dataset to classify malware vs normal software. The model is validated using cross-validation, leave-one-out and random sampling. The SVM classifier achieves 93-95% accuracy, 97-98% sensitivity and 86-90% specificity on the malware dataset. Validation shows the model generalizes very well. The high performance highlights that SVMs can effectively classify heterogeneous malware data gathered from computer networks and security systems.

In study [7], the paper proposes a deep learning framework for malware visualization and classification using convolutional neural networks (CNNs). The key aspects are: Malware files are converted into three image types - grayscale, RGB color, and Markov images. Markov images help retain global statistics of malware bytes. A Gabor filter approach is used to extract textures and discriminative features from the malware images. Two CNN models are used for classification - a custom 13-layer CNN and a pretrained 71-layer Xception CNN fine-tuned for malware images. The framework is

evaluated on two public Windows malware image datasets, a custom Windows malware dataset, and a custom IoT malware dataset. Markov images provide the best results, with the fine-tuned Xception CNN achieving over 99% accuracy on multiple datasets. The computational efficiency is also better compared to prior works. The approach demonstrates effectiveness for real-time malware recognition and classification. The visualization and deep learning framework extracts features automatically without extensive feature engineering. The framework's resilience against adversarial attacks is also analyzed by adding noise to test images. Some drop in accuracy is noticed, indicating scope for improvement. The current landscape underscores the significance of AI models as powerful tools for the analysis, classification, and detection of malware. These models can seamlessly integrate with both static and dynamic analysis, yielding noteworthy results that underscore their pivotal role in shaping the future of this field.

Arabo et al. [8] analyzed CPU and RAM usage patterns as potential indicators for detecting ransomware processes. Their findings suggested that while not the primary factors, monitoring CPU and RAM could complement other behavioral characteristics in identifying malicious processes. Regarding CPU usage, they observed variations that showed potential for distinguishing ransomware activities. Specifically, for the ViraLock ransomware sample, the maximum CPU usage peaked at 25% [1]. Such CPU spikes could potentially signify the initiation of encryption or other malicious operations by the ransomware. As for RAM consumption, the study found that ransomware samples generally exhibited low and relatively stable memory usage patterns. In the case of ViraLock, the maximum RAM usage was only around 2% [1]. However, the authors noted that while low RAM usage alone may not be a definitive indicator, it could be considered in combination with other behavioral factors. The researchers highlighted that while CPU and RAM usage showed some differences between ransomware and benign processes, the most significant distinguishing factor was abnormally high disk read/write activity [1]. Nonetheless, incorporating CPU and RAM monitoring alongside disk usage analysis could potentially enhance the accuracy and robustness of ransomware detection systems based on process behavior analysis.

In study [9], the Integrated Malware Classification Framework (IMCFN) converts malware binaries into grayscale and color images for classification using CNNs. It outperforms models like VGG16 and ResNet50, particularly with color images, and proves effective on the IoT-Android dataset, highlighting its potential for improving malware detection in diverse environments.

In study [10], this research proposes a novel malware classification method using CNNs. Malware programs are converted into grayscale images and fed into various CNN architectures. Experimental results show impressive accuracy (up to 99.4%) using CNN-extracted features with SVM. The approach demonstrates robustness across different malware categories, offering a significant contribution to cybersecurity.

III. COMPARATIVE ANALYSIS WITH PREVIOUS WORKS

Our approach employs relatively simple models, which positively impacts the time and resource efficiency of the

learning process. This streamlined design not only enhances the speed of model training and inference but also optimizes resource usage, making our method more suitable for environments with limited computational power. This balance between simplicity and effectiveness further contributes to the practical applicability of our approach in real-world malware detection scenarios. Particularly, our use of CNNs for image-based classification demonstrates strong potential, achieving competitive accuracy with less reliance on extensive feature engineering. Additionally, our approach does not depend on information provided by external monitoring frameworks like Cuckoo. Instead, it leverages a native program developed using Python libraries, which enhances the reliability and accuracy of feature extraction. This self-contained method ensures more consistent and precise data collection, further strengthening the effectiveness of our malware detection process.

IV. METHODOLOGY

The current investigation is centered on the behavioral analysis within an isolated Windows environment in virtual machine for the purpose of detecting malware. To achieve this, a combination of Recurrent Neural Network (RNN) for text classification and Convolutional Neural Network (CNN) for image classification is employed to analyze the extracted data. Diverging from the methodologies outlined in previous studies [3], [6], and [7], the classification approach adopted here focuses on the inherent characteristics of the malware file itself. This is achieved through a comprehensive analysis of the malware binary file and, notably, by representing the malware file as an image utilizing various visualization techniques. In this research, the emphasis is on visualizing the malware's behavior and subsequently conducting analyses based on these extracted features. Visual representations and also analyze the extracted features as a text. The presented model offers a juxtaposition of text classification and image classification in the analysis of extracted behavior. It underscores that a nuanced understanding of program nature, distinguishing between benign and malicious entities, can be achieved through thorough behavior analysis. The model primarily relies on the extraction of malware features. Within the developed script, two distinct observers play a crucial role. The first observer extracts the entirety of the process, encompassing its characteristics, as well as details related to internet connections. The second observer is tasked with monitoring any file creation specifically linked to the malware. The experimental framework involves the extraction of 10 distinct features through the monitoring of behaviors within an isolated Virtual Machine. Python libraries such as psutil, subprocess, wmi, watchdog, time, json, and os were employed to develop functions responsible for observing malware behavior and subsequently extracting pertinent information to a JSON file. The extracted features encompassed critical aspects such as process ID, process name, username, CPU percentage. The modules for this research were developed using TensorFlow and Keras, leveraging the Sequential model architecture. These tools enabled efficient tools enable construction and training of neural networks for malware detection, facilitating both text-based and image-based classification with enhanced accuracy through deep learning techniques. Fig. 1 illustrates the flow chart of the methodology of this research.

Fig. 2. Sample of JSON file content connections details, parent process, child process, execution path, and created files.

Following the extraction of these features, the gathered information is stored in a JSON file for further next step. Fig. 2 shows a sample of JSON file.

A. Text Analysis

The analytical process for the extracted features unfolded across two phases. Initially, the data underwent textual analysis, leveraging a simple feedforward neural network (FNN) model designed for binary classification using the Keras library to create a fully connected dense layer with 128 nodes.

The output layer has 1 node and uses 'sigmoid' activation for binary classification.

Subsequently, a recurrent neural network (RNN) model was employed to classify the same textual data, creates an

embedding layer that transforms integer word indices to dense word vector representations.

B. Image Analysis

By transforming data into images, researchers can leverage the vast body of knowledge and advancements in image processing techniques, readily applicable to the analysis of the transformed data. This data-to-image transformation unlocks the power of CNNs for a wider range of analysis tasks, promoting deeper insights into complex datasets. So this research implement the power of CNN alongside with the behavior analysis Subsequent to the behavioral analysis, the extracted features underwent further evaluation through an image classification paradigm. A dedicated function was developed to transform these feature data into grayscale

images. This transformative process involved the removal of associated labels, conversion of the data into binary numerical representations, subsequent transformation of these binary values into hexadecimal equivalents, and, finally, depiction of these hexadecimal values onto a 30*30 grayscale canvas.

The 30x30 size was empirically determined to balance information preservation and computational efficiency. Representing features as images enabled the utilization of convolutional neural networks (CNNs), which excel at capturing spatial patterns. The extracted features underwent further evaluation through an image classification paradigm. This visual representation approach offered several key advantages. Firstly, it enabled leveraging powerful deep learning techniques like convolutional neural networks, adept at capturing spatial patterns invaluable for malware characterization. Secondly, transforming features into images facilitated uncovering intrinsic relationships and patterns obfuscated in the original data's raw representation. Thirdly, the image domain allowed seamless integration of transfer learning and pre-trained models, expediting the analysis process. Lastly, the visually interpretable nature of images could provide insights into the discriminative characteristics learned by the models, aiding explainability. By combining dynamic monitoring with visual analytics, this multi-pronged approach offered a potent framework for comprehensive malware analysis and classification.

The dataset employed for experimentation comprised 50 instances of .EXE malware sourced from diverse families, obtained from the Malware Bazaar database, a freely accessible online repository. Additionally, 11 benign programs were included for comparative analysis. The monitoring process lasted three seconds for every malware instance, during which the monitoring code ran in the background, observing the processes and file creation activities of the malware. After the monitoring period, the code produced a JSON file containing the captured information. The dataset has been divided into 40 malware behavior and 6 benign program behavior for the training and 10 malware behavior and 5 benign program behavior for testing Fig. 3 provides visual representation of the converting text to image. Fig. 4 is a sample of obtained image.

Fig. 3. Provides visual representation of the converting text to image.

Fig. 4. Provides a sample representation of the resultant images, offering a glimpse into their visual characteristics.

V. THE EXPERIMENT

A. Text Analysis

The described FNN model exhibited an accuracy rate of 56% with a corresponding loss rate of 0.78.

For the RNN model: It takes the vocabulary size equal to 32 and output dimensionality as arguments. Also LSTM layer models the sequential nature and long-range context of text. The output dense layers act as classifiers on top of LSTM representations. The model is compiled with binary cross entropy loss, adam optimizer and accuracy metric.

With epoch 100, yielding an improved accuracy rate of 68% with a reduced loss rate of 0.67.

B. Image Analysis

Convolutional Neural Networks (CNNs) have revolutionized image analysis due to their ability to extract intricate spatial features. However, their power can be extended to non-image data by transforming it into a suitable image representation. This approach offers several advantages:

CNNs excel at automatically learning relevant features from images, circumventing the need for manual feature engineering, a time-consuming and potentially error-prone step in traditional

analysis. Data transformation allows for the visualization of complex relationships between data points within the image domain. This empowers CNNs to identify subtle patterns that might be obscured in the raw data format.

The experiment has done using two suggested model. The first model is simple and the second model is more complex both models are based on CNN.

The simple model consists of:

- Conv2D layer: Performs 2D convolution with 32 filters and 3x3 kernel. Extracts spatial features from input image.
- MaxPool2D: Max pooling layer reduces dimensions to summarize the features detected by convolution layer.
- Flatten: Flattens the pooled feature map into a 1D vector to prepare for fully-connected layers.
- Dense layers: Fully-connected layers that act as classifier on top of the extracted features. 64 nodes in first dense layer.

Output layer contains single node with 'sigmoid' activation for binary classification. This model takes input images of shape (30, 30, 1) indicating 30x30 grayscale images. With epoch 30

Fig. 5 represent the structure of the first CNN model.

Fig. 5. The structure of the first model.

Using this simple Model over these grayscale pictures gives accuracy rate 70.1% with loss 0.67.

The second model also based on CNN with more complex architecture shown in Fig. 6.

The model then uses several convolutional layers (Conv2D) to extract features from the image. These layers apply filters (also called kernels) that slide across the image, detecting patterns and edges.

The first Conv2D layer has 256 filters, each of size 3x3. As the filter slides across the image, it performs element-wise multiplication between the filter weights and the corresponding pixel values in the image. The results are then summed and passed through an activation function (relu in this case) to introduce non-linearity. This process helps identify low-level features like edges, corners, and simple shapes.

The subsequent Conv2D layers follow the same principle but with a different number of filters (128 and 64 in this example). These layers extract progressively more complex features based on the lower-level features detected earlier.

MaxPooling2D layers are inserted after some convolutional layers. These layers downsample the feature maps by taking the maximum value within a specific window (2x2 in this example). This helps reduce the number of parameters and computational cost while potentially capturing the most important features.

The Dropout layer (commented out) randomly drops a certain percentage (25% in this example) of activations during training. This helps prevent the model from overfitting to the training data by forcing it to learn more robust features.

After the convolutional and pooling layers, the model uses a Flatten layer to convert the 3D feature maps into a 1D vector. This allows the fully-connected layers to process the extracted features. The model then uses several fully-connected layers (Dense) to classify the image. These layers work similarly to traditional neural networks, where each neuron receives input from all neurons in the previous layer, performs weighted sums, and applies an activation function.

The first three fully-connected layers (4096, 2048, and 1024 neurons) are responsible for learning complex, high-level representations based on the extracted features. The relu activation allows these layers to learn non-linear relationships between the features. The final dense layer has only one neuron with a sigmoid activation function. This neuron outputs a value between 0 and 1, representing the probability of the image belonging to a specific class.

As a summary for this model the convolutional layers act as feature detectors, extracting progressively more complex features from the input image. The pooling layers reduce the dimensionality of the data while retaining important information. The dropout layer helps prevent overfitting. The fully-connected layers learn high-level representations and produce the final classification probability.

Fig. 6. The structure of the second CNN model.

Using this complex Model over these grayscale pictures gives accuracy rate 88% with loss 0.31.

VI. RESULTS AND DISCUSSION

Comprehensive performance evaluation through bar charts illustrates accuracy and loss metrics for both text and image classification. The findings suggest that combining behavioral analysis with AI models, particularly in the image domain,

holds promise for effective malware detection. This multimodal approach provides a holistic understanding of malware behavior, potentially enhancing overall detection capabilities in the evolving cybersecurity landscape. The study contributes to advancing malware detection methodologies by leveraging the synergy between static and dynamic analyses, bolstered by AI integration, and offers insights into the promising potential of image-based classification for improved accuracy in identifying malicious behavior. The bar chart for accuracy and loss is given in Fig. 7.

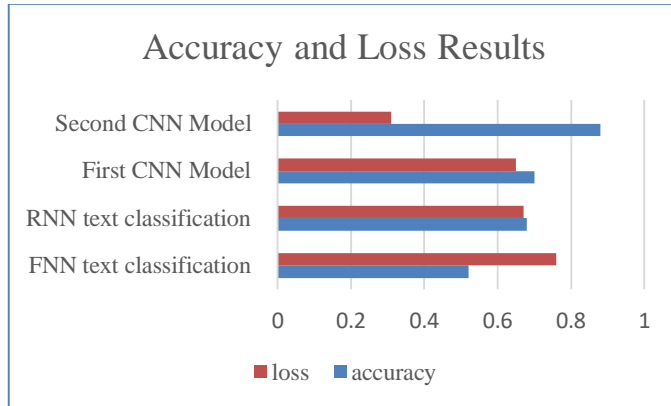

Fig. 7. Bar chart for accuracy and loss.

The Second Model with numerous convolutional and fully-connected layers grants high capacity for learning intricate features. While advantageous for complex datasets, it can lead to overfitting, particularly with limited training data. The model memorizes training data too well, hindering performance on unseen examples. Furthermore, training and running this deep model can be computationally expensive due to the high number of parameters. This translates to significant processing power and memory requirements, potentially limiting its use in resource-constrained environments. The results from the text classification and image classification shows that these methods of analyzing malware might be a good way to detect the malware using the extracted behavioral features.

Our primary objective was to enhance malware detection capabilities by combining dynamic analysis with AI techniques. The results of our image-based CNN model, achieving 88% accuracy, demonstrate significant progress towards this goal. Our image-based classification approach achieved 88% accuracy, which is comparable to the 96% accuracy reported by Sharma et al. [7] using a similar CNN-based method. However, our approach differs in that we focus on behavioral features rather than binary code visualization. The superior performance of our image-based CNN model (88% accuracy) compared to the RNN text classification model (68% accuracy) suggests that the spatial relationships captured in the image representation of behavioral features are particularly informative for malware detection. The superior performance of our image-based CNN model (88% accuracy) compared to the RNN text classification model (68% accuracy) suggests that the spatial relationships captured in the image representation of behavioral features are particularly informative for malware detection.

VII. CONCLUSION

This study successfully employs dynamic analysis within a virtual machine (VM) to extract crucial behavioral features from Windows malware. Integrating these features with advanced text and image classification models (RNN and CNN) shows promise for malware detection. Image classification, based on transformed feature data, achieves a superior accuracy of 88% compared to 68% in text classification. This multimodal approach, combining behavioral analysis with AI models, provides a nuanced understanding of malware behavior.

One significant limitation of this study is the relatively small dataset used, consisting of only 50 malware samples and 11 benign programs. This limited sample size may not fully represent the vast diversity of malware in the wild, potentially affecting the generalizability of our results. Future work should involve a substantially larger dataset, encompassing a wider range of malware families and benign software to validate and potentially improve the model's performance. Another limitation is the brief 3-second monitoring period used for each malware instance. While this duration was chosen to balance efficiency and data collection, it may not capture the full range of behaviors exhibited by more sophisticated malware that employs delayed execution or other evasion techniques. Extended monitoring periods in future studies could provide more comprehensive behavioral data, potentially improving detection accuracy. To enhance the robustness and generalizability of our model.

We recommend several areas for future exploration. First, increasing the diversity and quantity of the training data by including a wider range of malware families and benign samples is crucial. Additionally, exploring additional features, such as registry changes, could provide valuable insights into malware behavior. Second, experimenting with different visualization techniques for image generation and testing more complex CNN architectures or pre-trained models with fine-tuning could further improve accuracy and efficiency. Third, addressing the threat of adversarial attacks is essential. Incorporating noise resilience mechanisms into the model can help mitigate the impact of such attacks and ensure the model's reliability in real-world scenarios. By pursuing these enhancements, we can contribute to advancing malware detection methodologies and ensuring their adaptability in the ever-evolving cybersecurity landscape.

Abstract—Virtual collaboration tools have become increasingly important in STEM education, especially after the COVID-19 pandemic. These tools offer many benefits, including developing 21st-century skills and fostering scientific process skills and scientific creativity. However, there are concerns regarding their effectiveness across different genders and regions. This study evaluates the impact of the ExxonMobil Young Engineers (EYE) program, which uses the Zoom application, on enhancing 21st-century skills, scientific process skills, and scientific creativity among secondary school students in Malaysia. The participants primarily consist of 520 secondary school students, with teachers acting as facilitators and professional engineers from ExxonMobil serving as instructors. A pre-test survey was conducted to assess students' initial skill levels. The program consisted of three phases: briefing, breakout room activities, and final reflections. After the program, a post-test survey was conducted to evaluate changes in student skills. Data analysis was analyzed using SPSS software by employing descriptive statistics, MANOVA with Wilks' lambda, one-way ANOVA, and partial eta squared to measure the program's impact and the influence of gender and regional factors. The results showed significant improvements in all three skill areas post-intervention: 21st-century skills, scientific process skills, and scientific creativity. Gender differences were significant for 21st-century skills, while regional differences significantly affected scientific process skills. The EYE program could enhance students' STEM-related skills using virtual collaboration tools like Zoom. However, regional and gender differences highlight the importance of adapting programs to address specific challenges and ensuring equitable opportunities for all students.

Keywords—Virtual collaboration tools; 21st-century skills; scientific process skills; scientific creativity; STEM education

I. INTRODUCTION

Virtual collaboration tools have become more common in STEM education, offering many benefits for developing 21st-century skills and scientific process and creativity skills. Online collaborative learning through small group discussions has been shown to promote knowledge co-construction and higher-order thinking skills in STEM subjects [1]. Virtual environments provide opportunities for direct interactions, helping students build knowledge and develop the mental processes involved in learning [2]. These tools facilitate collaborative learning and improve the effectiveness of learning experiences, especially when properly supported [3]. During the COVID-19 pandemic,

the shift to virtual educational spaces raised concerns, especially in STEM education, where changes to lab work and online teaching practices are actively discussed [4]. Virtual simulation in teacher education has emerged as a method to provide opportunities for teachers to practice essential skills, such as parent-teacher collaboration, in a safe and controlled environment [5]. Even so, the effectiveness of these tools depends heavily on the technological infrastructure available to students and educators and their proficiency in using these technologies. There is a need for training programs to ensure that teachers can effectively integrate these tools into their teaching practices.

To effectively prepare students for success in the 21st century, educators must focus on teaching and look after 21st-century skills. These skills include collaborative problem-solving, critical thinking, creativity, communication, and digital literacy [6], [7], [8]. 21st-century skills include learning and innovation, information technology, and career skills, which are crucial for students' future [9], [10]. Teachers must integrate these skills into their teaching practices to ensure students have the necessary abilities to thrive in their future careers [11], [12]. By emphasizing these skills, educational institutions can also prepare students to meet the demands of the modern workforce requirement [13]. One major issue is the lack of school resources, leading to unequal access to the tools and training necessary for teachers and students. Schools in underprivileged areas may have issues with related infrastructure or funding to provide a conducive environment to develop these skills.

Scientific process skills are fundamental for conducting scientific research and advancing scientific knowledge [14]. These skills include a blend of physical, emotional, and thinking abilities used in scientific work [15]. Key process skills, such as identifying variables, forming hypotheses, and designing experiments, are vital for solving problems and creating new knowledge [16], [17]. Science process skills focus on knowledge transfer and problem-solving in real-life scenarios [18]. Developing these skills through activities like scientific questioning, experimental skills, and data interpretation enhances students' scientific literacy and attitudes toward science-based subjects [19], [20], [21]. Clear instruction helps learn science inquiry skills [22]. Metacognitive abilities support scientific process skills by helping students manage their

*Corresponding Author.

understanding and learning processes [23]. Again, the same issues will happen to schools with limited resources, which may struggle to provide hands-on experiences and experimental activities for developing these skills.

Scientific creativity includes understanding scientific phenomena, developing scientific knowledge creatively, solving complex science problems, enhancing product quality, and designing innovative scientific products [24]. These skills are connected with scientific process skills, where people who think and discuss, like scientists, show better scientific creativity [25]. Scientific creativity involves producing original and valuable outcomes with a specific purpose using available information [26]. It is a higher-order thinking skill essential for scientific thinking and differentiating between typical and exceptional scientific thinkers [27]. Enhancing scientific creativity often involves mastering creative thinking, which stimulates science process skills like observation, prediction, and hypothesis formation [28]. Scientific creativity relies on scientific knowledge and skills, combining a static structure with a developmental one [29]. Encouraging lifelong learning can improve individuals' scientific creativity skills [30]. One major challenge in nurturing scientific creativity is the need for professional development for teachers to help them recognize and nurture scientific creativity in their students. Many educators may lack the training or confidence to implement creative teaching strategies effectively.

Based on the issues related to these three skills. This study aims to evaluate the effectiveness of a virtual collaboration approach in improving 21st-century skills, scientific creativity, and scientific process skills in STEM education. Specifically, it will assess the impact of the ExxonMobil Young Engineers program, delivered through virtual collaboration tools, on enhancing these crucial skills among students. This paper comprises the following sections: a background study, a methodology section, results and discussion, and concludes with conclusions and future directions.

II. BACKGROUND STUDY

In STEM education, nurturing 21st-century skills, scientific process skills, and scientific creativity skills has become a focal point for preparing students for the demands of the modern workforce. STEM education, which integrates Science, Technology, Engineering, and Mathematics, cultivates problem-solving abilities in real-world contexts and adopts essential 21st-century skills [31]. These skills include logical reasoning, problem-solving, collaboration, critical thinking, creativity, and communication, which are crucial for success in the current related job market [32]. STEM practices have been increasingly emphasized globally to enhance students' competencies in mathematics and engineering, aiming to equip them with the necessary skills to survive and thrive in today's society [33]. By incorporating project-based learning approaches and activities that involve scientific inquiry and engineering design processes, STEM education can effectively develop 21st-century practices and other related skills [34]. Even so, there is a need for continuous professional development for educators to keep pace with the rapidly evolving STEM fields. Teachers must be proficient in STEM content and pedagogical strategies that promote active learning and critical thinking. Without adequate

training and support, educators may struggle to deliver STEM curricula that engage and inspire students effectively.

Virtual meeting tools enhance STEM education by promoting collaboration, engagement, and learning outcomes. Teachers highly value hands-on activities in STEM education [35], and platforms like Zoom have become crucial during the pandemic [36]. Digital tools have made STEM education more accessible [37], and online collaborative tools have been shown to improve learning outcomes and motivation [38]. Many tools are available and effective for virtual teaching [39], [40]. It can be used to enhance online presence whilst improving collaborative learning [41], [42]. The shift to remote instruction due to COVID-19 has led to exploring online resources for self-learning [43]. Universities are encouraged to cultivate self-regulated and peer-collaborative learning skills online [44]. However, the transition to virtual STEM education comes with challenges. One major issue is the digital divide, where students from low-income families may lack access to reliable internet connections and necessary devices, preventing them from fully participating in online learning. This gap worsens educational inequalities and limits the effectiveness of virtual meeting tools in improving STEM education for all students.

Various factors, including gender stereotypes, cultural norms, and personal interests influence gender disparities in STEM education. Studies have shown that gender differences in STEM careers can be traced back to early adolescence and are caused by societal expectations and decision-making processes [45]. Other than that, implicit gender-science stereotypes vary across countries and can contribute to gender differences in STEM achievement and representation [46]. Addressing gender differences in STEM fields is crucial not only for promoting gender equality but also for diversifying the workforce and creating a more competitive environment [47]. Efforts to bridge the gender gap in STEM education should consider the impact of cultural factors, traditional gender role beliefs, and the importance of providing equitable learning opportunities for all students [48]. Effective strategies in one country or community might not be applicable in another. Tailoring interventions to local needs and involving the community in developing and implementing programs can enhance their effectiveness.

Rural students often face challenges in STEM education due to limited access to resources and qualified teachers compared to urban areas [49]. Geographic differences in postsecondary STEM participation are influenced by students' demographics, aspirations, and academic preparation [50]. When given resources, rural educators can create strong systems for advanced STEM talent development [51]. Leadership practices, such as community relationships and empowering STEM teachers, contribute to STEM education success in rural schools [52]. To bridge the gap, it is crucial to engage diverse students in pursuing STEM fields [53]. Implementing STEM programs in rural schools, such as using the STEM Engineering Design Process, can produce positive outcomes [54]. This initiative should focus on inclusivity and diversity, ensuring that all students, including those from diverse urban backgrounds, have fair access and opportunities in STEM fields. This approach helps reduce the educational gap and encourages students to pursue STEM careers.

III. METHODOLOGY

The ExxonMobil Young Engineers Program utilizes the Zoom application as the medium for the virtual collaboration session, which involves 10 schools. The participants primarily consist of secondary school students, with teachers acting as facilitators and professional engineers from ExxonMobil serving as instructors, with an instructor-to-student ratio of 1:10. Each student is provided with STEM kits before the program starts. A pre-test survey was conducted before the program started to identify the students' initial levels of 21st-century skills, scientific process skills, and scientific creativity. The program has three phases: In Phase 1, instructors gather all participants in the main room to explain the program's structure and goals. In Phase 2, participants are divided into breakout rooms, one for each school, each with one instructor, up to five facilitators, and ten students. They conduct three educational modules, each lasting one hour, focusing on real jobs for oil and gas engineers and using a problem-based learning approach. The modules, adapted from energy4me®, are "Getting the Oil Out," "Core Sampling," and "Exploring Oil Seeps," which replicate real challenges in the oil and gas industry. In Phase 3, all participants return to the main room for a final discussion, where instructors and facilitators answer questions and provide final reflections on the program outcomes. This structured approach ensures comprehensive engagement and learning for all participants. After the program was completed, a post-test survey was distributed to evaluate the program's impact on the three main skills, which is the main objective of this study. Fig. 1 shows the overview of the EYE program structure and study phases.

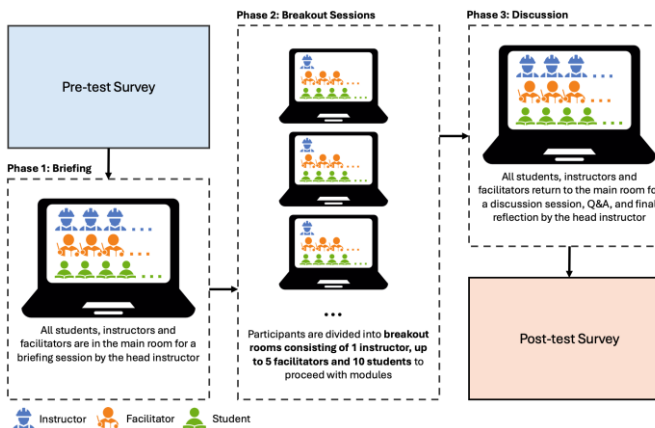

Fig. 1. Overview of the EYE program structure and study phases.

Fig. 2 shows the execution of the EYE program via Zoom. Instructors led the module through Zoom, while facilitators assisted students in following the instructors' instructions. Participants used STEM kits to accomplish the modules by following the instructions provided by the instructors.

A. Instrument

The data collection tool employed in this study was a questionnaire adapted from previous related studies, as shown in Table I. Minor modifications were made to customize it to achieve the research's specific objectives. This instrument was used to gather data to assess the program's impact on STEM literacy by conducting pre and post-surveys before and after the

program. The questionnaire comprised two main sections: the first focused on gathering demographic information about the respondents, and the second focused on the study's core constructs. These constructs related to STEM skills were categorized.

Fig. 2. Execution of the EYE program via ZOOM (own sources).

TABLE I. QUESTIONNAIRE ITEMS ON 21ST-CENTURY SKILLS, SCIENTIFIC PROCESS SKILLS, AND SCIENTIFIC CREATIVITY

Construct	Items	Item Source
21st-century skill	I will be optimistic about completing a given activity through Zoom.	[55]
	I always think of different methods from different perspectives in solving a problem.	[56]
	I always come up with something new when studying science.	[55]
	I am always optimistic about performing tasks using Zoom.	[57]
	I always think critically and rationally to complete tasks.	[56]
Scientific process skill	Before starting an activity, I must plan, make hypotheses and identify problems.	[58]
	I get information from the facilitator and the internet to carry out activities	[59]
	I will record all work steps and processes, and evaluate the activities I produce	[58]
	I keep all data, calculations, and activity sketches as evidence of the work.	[58]
Scientific creativity	I present and show the results of my activities to the facilitators and friends through Zoom	[59]
	I like to give views and suggestions to facilitators and friends about the activities carried out through Zoom	[60]
	I like to discuss the design of my activities with other friends through Zoom	[61]
	I always think about the effects and consequences of the activities that will be carried out	[61]
	I like associating the activities with the latest elements of science and technology.	[56]
I like to follow the example of activities given by the facilitator through Zoom	[60]	

B. Analysis

In this study, gender and region are the dependent variables, while 21st-century skills, scientific process skills, and scientific creativity are independent variables. The objective is to evaluate the ExxonMobil Young Engineers (EYE) program's impact on these skills and to explore how gender and regional factors influence skill development. Data were collected through pre- and post-test surveys administered to secondary school students in Malaysia, using a 5-point Likert scale. SPSS software was used for analysis, including descriptive statistics to summarize mean values and standard deviations. Multivariate Analysis of Variance (MANOVA) tested the significance of skill differences between pre- and post-test scores and examined the effects of gender and region. One-way ANOVA assessed the significance of differences by gender and region for each skill, with Partial Eta Squared measuring the effect size. Levene's test was performed to assess the assumption of homogeneity of variances across groups. Levene's test results were insignificant ($p > 0.05$), suggesting that the variances are approximately equal across the groups for the dependent variables. This indicates that the assumption of homogeneity of variances is met, supporting the validity of proceeding with the MANOVA. Therefore, the MANOVA was conducted assuming that the equal variances condition is satisfied." Stratified random sampling was employed to select students from both rural and urban areas.

IV. FINDINGS AND DISCUSSION

The table shows the demographic characteristics of the study's participants, giving information about their gender and where they live. The data shows that 196 participants were male, making up 37.7%. The majority, 324 participants, were female, making up 63.2%. 192 participants were from urban areas, accounting for 37.0%. A larger portion, 328 participants, were from rural areas, making up 63.0% of the total. This breakdown of participants by gender and location helps understand the study's sample, which can affect the generalizability of the research findings and any potential impacts of demographics on the study's results. Table II shows the demographic information of the study.

Table III shows the mean score values of the pre-test and post-test for 21st-century skills, scientific process skills, and scientific creativity. The data indicated increased scores in all three skill areas: 21st-century skills improved from a pre-test mean of 4.3304 to a post-test of 4.4423, scientific process skills from 4.2322 to 4.3495, and scientific creativity from 4.0635 to 4.2858. Statistical analyses confirmed these improvements, with significant p-values ($p < 0.05$) indicating the program's effectiveness.

TABLE II. DEMOGRAPHIC INFORMATION

Demographic Characteristics	Number of Participants
Gender	
Male	196 (37.7%)
Female	324 (63.2%)
Region	
Urban areas	192 (37.0%)
Rural Areas	328 (63.0%)

These results suggest that the ExxonMobil Young Engineers (EYE) program significantly enhances students' STEM-related skills. The improvements in post-test scores across all three areas indicate that virtual collaboration tools, such as the Zoom application used in the EYE program, can effectively support skill development. Zoom's use as a virtual collaboration tool has several advantages that contribute to these positive outcomes. Zoom allows for interactive sessions, where students can engage in real-time discussions, collaborative projects, and hands-on activities, which are crucial for developing 21st-century and scientific process skills. The platform's features, such as breakout rooms, screen sharing, and real-time feedback, facilitate a dynamic and engaging learning environment that can adapt to different teaching styles and learning needs.

While the findings are promising, several limitations must be considered. The sample size, though adequate, may not represent the entire population of secondary school students in Malaysia. Potential biases could arise from self-reported data and using a single program for analysis. The assumptions of the statistical tests, such as the normality of data distribution, were checked but could still affect the results. Comparing these findings with previous research, it is evident that virtual collaboration tools are becoming increasingly important in STEM education. The greater improvement in scientific creativity among female students observed in this study highlights the potential for virtual collaboration tools like Zoom to provide an inclusive learning environment that supports all students. This requires further investigation to understand the underlying factors better and tailor the program to benefit both genders equally.

TABLE III. MEAN SCORE VALUE OF THE PRE-TEST AND POST-TEST FOR 21ST CENTURY SKILLS, SCIENTIFIC PROCESS SKILLS, AND SCIENTIFIC CREATIVITY

Construct	Mean Value	
	Pre-test	Post-test
21st century skills	4.3304	4.4423
Scientific process skills	4.2322	4.3495
Scientific creativity	4.0635	4.2858

A. 21st Century Skills

The analysis presented in Table IV demonstrates significant improvements in 21st-century skills post-intervention, with Wilks' lambda = 0.982, $F = 9.181$, $p = 0.003$, and partial eta squared = 0.018. These results highlight the effectiveness of the ExxonMobil Young Engineers (EYE) program, which uses virtual collaboration tools, such as Zoom, to enhance students' competencies. The higher post-test scores indicate that integrating virtual collaboration tools effectively improves students' 21st-century skills, including critical thinking, problem-solving, collaboration, and digital literacy.

The analysis also found significant gender differences, with female students showing greater improvement in their 21st-century skills compared to male students (Wilks' lambda = 0.992, $F = 3.883$, $p = 0.049$, partial eta squared = 0.008). This suggests that virtual collaboration tools like Zoom may be particularly effective for female students, potentially due to the inclusive and flexible nature of virtual environments. These

platforms can accommodate different learning styles and preferences, which might help female students engage and excel more effectively. Further research should investigate the reasons behind these gender differences to tailor the EYE program more effectively for both genders.

Regional factors did not significantly affect skill development (Wilks' lambda = 0.999, F = 0.753, p = 0.386, partial eta squared = 0.001), indicating that the EYE program's effectiveness is consistent across different regions. This consistency suggests that virtual collaboration tools like the Zoom application can deliver high-quality education regardless of regional disparities [38]. The broad applicability of the EYE program across various geographical locations underscores the potential of virtual collaboration tools to provide equitable learning opportunities to students from diverse backgrounds.

The significant improvement in 21st-century skills emphasizes the potential of virtual collaboration tools as effective mediums for developing essential student competencies. Virtual collaboration tools like Zoom offer several advantages, including accessibility, flexibility, engagement, and collaboration [42]. These collaboration tools allow students to stay engaged with interactive content and real-time feedback and work together with peers and instructors through virtual platforms [40].

TABLE IV. MULTIVARIATE ANALYSIS OF 21ST CENTURY SKILLS, GENDER, AND REGION USING WILK'S LAMBDA

Effects	Wilks' Lambda Value	F	df1	df2	P	Partial Eta Squared
21st Century Skill	0.982	9.181b	1	504	0.003*	0.018
Gender	0.992	3.883b	1	504	0.049*	0.008
Region	0.999	.753b	1	504	0.386	0.001

B. Scientific Process Skills

The analysis in Table V shows a significant improvement in scientific process skills post-intervention, with Wilks' lambda = 0.964, F = 18.916, p = 0.000, and partial eta squared = 0.036. This indicates that the ExxonMobil Young Engineers (EYE) program, which uses virtual collaboration tools like the Zoom application, effectively enhanced students' scientific process skills. The significant increase in scores underscores the impact of virtual collaboration tools in providing a robust educational experience.

Gender differences were found to be insignificant (Wilks' lambda = 0.999, F = 0.273, p = 0.602, partial eta squared = 0.001), suggesting that both male and female students benefited equally from the program. This finding is important as it highlights the inclusive nature of virtual collaboration tools like Zoom, which can cater to diverse groups of students without gender bias. Zoom's flexibility and interactive features may create an equitable learning environment where all students can thrive [36].

However, regional differences significantly affected scientific process skills (Wilks' lambda = 0.992, F = 4.067, p = 0.044, partial eta squared = 0.008). This indicates that the program's effectiveness varied slightly across different regions.

These regional variations suggest that while virtual collaboration tools like Zoom are generally effective, there may be differences in how they are implemented or accessed in various areas [49]. Some schools involved in the EYE program have issues with technology infrastructure that affect the program's flow. Other factors such as internet connectivity, availability of digital devices, and local educational practices, could also influence the effectiveness of the EYE program across regions [51].

These findings highlight the potential of virtual collaboration tools, such as Zoom, to enhance scientific process skills among secondary school students. The effectiveness of the EYE program across gender lines suggests that it is a valuable tool for promoting STEM education for all students. The regional differences indicate a need for tailored approaches to address specific challenges that may arise in different areas. Ensuring consistent access to resources and support across regions can help maximize the benefits of virtual collaboration tools.

TABLE V. MULTIVARIATE ANALYSIS OF SCIENTIFIC PROCESS SKILLS, GENDER, AND REGION USING WILK'S LAMBDA

Effects	Wilks' Lambda Value	F	df1	df2	P	Partial Eta Squared
Scientific Process Skill	0.964	18.916b	1	504	0.000*	0.036
Gender	0.999	0.273b	1	504	0.602	0.001
Region	0.992	4.067b	1	504	0.044*	0.008

C. Scientific Creativity

The analysis in Table VI shows a significant improvement in scientific creativity post-intervention, with Wilks' lambda = 0.905, F = 52.836, p = 0.000, and partial eta squared = 0.095. This substantial effect size indicates that the ExxonMobil Young Engineers (EYE) program, which utilizes virtual collaboration tools such as Zoom, effectively enhances students' scientific creativity. The large improvement in scores underscores the impact of virtual collaboration tools in providing an engaging and stimulating educational experience.

Gender differences were found to be insignificant (Wilks' lambda = 0.992, F = 4.067, p = 0.804, partial eta squared = 0.000), suggesting that both male and female students benefited equally from the program. This finding is important as it highlights the inclusive nature of virtual collaboration tools like Zoom, which can cater to diverse groups of students without gender bias. The interactive features of Zoom, such as breakout rooms, real-time collaboration, and multimedia integration, may contribute to creating an equitable learning environment [38] where all students can develop their scientific creativity.

Regional differences also showed no significant effect on scientific creativity (Wilks' lambda = 0.999, F = 0.512, p = 0.474, partial eta squared = 0.001). This suggests that the EYE program's effectiveness in enhancing scientific creativity is consistent across different regions. The consistency of the program's impact across various geographical locations highlights the potential of virtual collaboration tools like Zoom to deliver high-quality education regardless of regional factors. This result indicates that the program can be broadly applied and

adaptable to various regional contexts, providing learning opportunities to students from diverse backgrounds.

The significant improvement in scientific creativity shows that virtual collaboration tools effectively develop important skills in students. Virtual tools like Zoom offer accessibility, flexibility, engagement, and collaboration. They allow students to access resources from any location, learn at their own pace, stay engaged with interactive content, and collaborate with peers and instructors, which is important in STEM education [35]. The EYE program effectively enhances scientific creativity using Zoom, demonstrating its potential to provide inclusive, high-quality education. These findings highlight the importance of integrating virtual collaboration tools in educational programs to prepare students for future challenges in a rapidly evolving digital world.

TABLE VI. MULTIVARIATE ANALYSIS OF SCIENTIFIC CREATIVITY, GENDER, AND REGION USING WILK'S LAMBDA

Effects	Wilks' Lambda Value	F	df1	df2	P	Partial Eta Squared
Scientific Creativity	0.905	52.836b	1	504	0.000*	0.095
Gender	0.992	4.067b	1	504	0.804	0.000
Region	0.999	0.512 b	1	504	0.474	0.001

V. CONCLUSION AND FUTURE IMPROVEMENT

The ExxonMobil Young Engineers (EYE) program has shown great promise in improving students' 21st-century skills, scientific process skills, and scientific creativity through virtual collaboration tools like Zoom. The program's structured approach, which includes interactive sessions, group projects, and real-time feedback, has effectively engaged students and helped them develop these skills. The overall improvements in all three skill areas highlight the program's success. Enhancing 21st-century skills shows virtual collaboration tools can improve critical thinking, problem-solving, collaboration, and digital literacy. Gender differences were noted, with female students showing greater improvement in their 21st-century skills than male students. This suggests that the inclusive and flexible nature of virtual environments, like those facilitated by Zoom, may be particularly effective for female students. Scientific process skills also showed significant improvement after the intervention. Both male and female students benefited equally, indicating that virtual collaboration tools can provide a fair learning experience. However, regional differences did affect scientific process skills, suggesting some variation in program effectiveness across different areas. The most improvement was in scientific creativity, with both male and female students benefiting equally, and the program's effectiveness was consistent across different regions. This indicates that virtual collaboration tools like Zoom have a broad and consistent impact on improving students' creative thinking and innovation skills. These findings highlight the importance of integrating virtual collaboration tools in educational programs to prepare students for the challenges of the modern workforce. The EYE program's success across gender and regional lines suggests that such initiatives can be scaled and adapted for broader educational contexts, providing high-quality, inclusive education.

While the EYE program has shown considerable success, several areas need enhancement to maximize its impact and ensure all students benefit equally. The regional differences observed in scientific process skills suggest a need for tailored approaches to address specific challenges in different areas. Ensuring consistent access to resources, such as reliable internet connectivity and digital devices, can help bridge these gaps. Additionally, training local educators to use virtual collaboration tools effectively can enhance the program's impact across all regions. The greater improvement observed among female students in 21st-century skills requires further investigation. Understanding the underlying factors contributing to these differences can help tailor the program to support both genders equally. Future research could also explore the elements of virtual collaboration environments suitable for female students to adapt to the program accordingly. Integrating more advanced technologies, such as augmented reality (AR) and virtual reality (VR), could also further enhance the learning experience. These technologies can provide immersive and interactive learning environments that stimulate students' creativity and critical thinking skills.

ACKNOWLEDGMENT

We would like to thank all participants, engineers from ExxonMobil, and teachers from the schools involved in this study. The work was supported by a university research grant PDE52.

The Impact of E-Commerce Drivers on the Innovativeness in Organizational Practices

Abdulghader Abu Reemah A Abdullah, Ibrahim Mohamed, Nurhizam Safie Mohd Satar
Faculty of Information Science and Technology, Universiti Kebangsaan Malaysia, Bangi, UKM 43600 Malaysia

Abstract—Innovation in e-commerce practices has revolutionized the way goods and services are purchased or sold online. This relatively new tool for online transaction provides range of access to wealth of information and knowledge needed to facilitate electronic commerce globally using internet network. The case is not the same in the developing countries where e-commerce innovation is deprived of key the components to drives developing economy. To clearly understand innovation in e-commerce diffusion, 375 quantitative data generated from e-commerce organizations in Libya. Statistically analysis of the key drivers of e-commerce innovations focused on the need for a shift in organizational attitude and knowledge through decision making that are committed to meeting customer's needs. The inter statistical covariance indicated a strong homogeneity between the drivers of e-commerce with mean value range of 4.09 to 4.82 (58.4 % to 68.8% of responses) indicating that 219 to 258 respondents out of 375 are of the same view. There is strong positive correlation between the drivers of e-commerce innovations except for e-commerce management style that has moderate relation and were statistically significant at 0.00 level. This study clearly explained the main factors of interest that are versatile in providing timely delivery of goods, efficient services and in meeting with e-commerce developmental trend.

Keywords—E-commerce innovation; e-commerce drivers; performance management; decision making; management style

I. INTRODUCTION

The progress in e-commerce represents a potential opportunity to enhance the growth of developing nations and to improve the effectiveness of business processes at the organizational level. The Organizations across developing countries can conveniently utilize open-ended opportunities to improve commercial activities globally. Innovation in e-commerce is transforming the developing economy because it drives commercial sectors to benefit from efficient and low-cost transactions [1], [2], [3]. E-commerce online platforms aid in the purchase or sale of goods and services and have contributed to building business networks and partnerships in most developing and developed countries, organizations and businesses have appreciated development innovations and the emergence of transitional changes in e-commerce practices. E-commerce has become an essential pillar off economic growth and internationalization to maximize the advantages of technology-driven commercial activities.

The easy access to e-commerce resources has significantly contributed to the integration of various technologically mediated media service frameworks for the sale of products and services. E-commerce innovations are at the forefront of transforming conventional commerce into an electronic-based business format [4], [5], [6]. Furthermore, the emerging experience of accessing e-commerce resources for online transactions

has added to the use of different electronic devices and gadgets for economic activities. The versatility of electronic devices such as hand phones, computers, gadgets, electronic media, and handheld devices has improved the way goods and services are handled over the years [7], [8].

However, there are issues limiting the wider use to e-commerce websites including the cost of electronic systems, internet infrastructure, online security for data and personal information [9], [10]. Other challenges include ease of access to online platforms, customer experience, cost of shipping purchased products, online customers support, sustainability, and frequent updates requiring larger storage for new features to support online sales of products and services [11]. To generate depth of insight into e-commerce advances, these factors were grouped as drivers of e-commerce innovations in the present study. The emerging new features and apps incorporated with e-commerce require specialized skill [12], [13] and are vital for improving online businesses [14]. A good understanding of how these drivers influence innovativeness within organizations is very important for enhancing the competitive edge of the digital marketplace [7].

However, the objectives of the present study are to identify the impact of the e-commerce drivers and to analyze how they influence e-commerce innovation. A clear understanding of the factors that have consistently contributed to the improvement recorded in e-commerce development could improve the competitive edge of e-commerce. This is important, as e-commerce has become a well-known branch of commerce that uses electronic systems for the purchase and sale of goods and services via online channels. The quality of e-commerce services will continue to improve over time as research efforts are targeted at meeting customers' needs [13], [15] As online businesses continue to widen with the inclusion of new innovative changes [16], retailers may be compelled to adapt certain changes to facilitate online transactions. The drivers of e-commerce could help drive e-commerce performance with insight into the potential influences on e-commerce innovations. The drivers of e-commerce innovation at the organizational level could further improve the effectiveness of different services and the competitiveness of online businesses.

II. LITERATURE REVIEW

The present study is based on the influence of the key drivers of e-commerce on innovative features from the literature. These variables have been widely recognized and used separately considering their impact on e-commerce activities at the organizational level. In the context of e-commerce practices, managerial and operational capabilities for organizational innovation have been validated based on management

style, decision making, people's development (also known as workers development), process management and performance management [1], [17]. [18] found that e-commerce development has been affected by technological and organizational attitudes toward innovation, as well as financial concerns. The management framework for assessing disruptive innovations by [19] found that decision making is a key driver of technological innovation in organizations. This could be because the decision to use a certain technology is based on management's decisions and approval. Decision-making has been referred to as an approach to improve technological innovation [20] and among drivers for the adoption of eco-design practices [21].

An empirical study that explored the interplay of managerial and operational capabilities to infuse organizational innovation in SMEs [1] provided a formal reflection on the role of innovation in transforming organizational practices. In [22], it was shown that e-commerce will continue to improve management practices with the emergence of new technological features that make transactions easier and faster. A study by [18] provided a depth of insight into the prevailing issues of concern regarding e-commerce practices, which are related to organizational practices, technological development, financial resources and external factors.

Previous research findings are foundational to the choice of instrument, used in this study, research approach, variables of interest, and the analytical method used in the present study. A literature study by [18], [21] found that e-commerce adoption has been severely affected by technological innovation, financial assets, management practices, decision-making, and organizational factors. Financial and technological factors have demonstrated a consistent influence over the years on organizational factors. E-commerce practices at the organizational level were demonstrated in a study by [1]. Important variables used include process management, management style, decision making, performance management, people's development, and organizational innovations. The study in [23] found that emerging economies have realized the benefits of e-commerce and are investing heavily in technology to fully explore e-commerce potentials. This study's structure is reflective of previous findings that represented a synergetic focus on factors that constrained innovation in e-commerce practices.

III. RESEARCH FRAMEWORK

This study examined contextual factors that have been identified as drivers of e-commerce innovation. The drivers include organizational management styles (eCMS) that provide insight into the need for a swift response to online customers and feedback to information and requests relative to sales of products and services. Decision-making in e-commerce (DM) provided a clear understanding of the plans to improve e-commerce practices. e-commerce worker development (eCWD) focus on training and employers' development to cope with innovative changes in technology and the application of e-commerce features. The e-Commerce management process (eCPM) explains activities and tasks to effectively improve e-commerce services. e-commerce performance management (eCPfM) sets clear business goals for e-commerce organizations. The e-Commerce Organization Attitude to Innovation (eCOAI) explained the commitment of thee-commerce management team to adopt new technology to efficiently

Fig. 1. The research framework of e-commerce drivers' effect on e-commerce innovations.

deliver e-commerce services. Knowledge of e-commerce technology (KeCT) focuses on the ability of innovative features to drive e-commerce activities. Financial concern refers to the capability to effectively manage financial resources to achieve healthy e-commerce services. External factors (extF) entail pressure from external entities, such as customers and suppliers. e-Commerce Innovation (eCI) explains new ways of conducting e-commerce business using improved features. These important e-commerce factors were collectively used in this study, and their effect on e-commerce innovation was hypothetically validated using statistical measurements. This study sets up a new conceptual and holistic view that contextually explains the variable themes that matter in the theoretical model of e-commerce innovation. The hypothesis of this study asserts that "e-commerce drivers have a positive relationship with e-commerce innovation". This study explores the key drivers of e-commerce practices and their overriding influences on e-commerce innovation. E-commerce innovations are embodied with potential opportunities to earn promising benefits from e-commerce features that support sales of goods and services via online websites [24]. The clear identification of e-commerce drivers and potential barriers in this study is a pathway to improve the effectiveness and versatility of online services. Reflecting on the work of [18], e-commerce has been constrained by knowledge of e-commerce technology, organizational management style, financial concerns, as well as external factors relative to supply and customer push. The research framework constituting the key drivers of e-commerce innovations are as shown in Fig. 1.

IV. RESEARCH APPROACH

The population of this study comprised 375 managers who have saved a minimum of five years on the most active 150 e-commerce websites across Libya. Participants ranging

from 20 to 65 years of age were selected to respond to structured research items that focused on the drivers of e-commerce innovations. Data collected from online and e-commerce employees willingly contributed to their practical experience in e-commerce transactions and management involvement to improve e-commerce practices. Employers' age, position and years of experience were major considerations for data collection and 384 data collected were carefully screened of which 375 were considered appropriate for this study. Incomplete questionnaires were excluded to improve the accuracy and reliability of the research findings. Participation in the survey was voluntary, and participant experience and organizational roles contributed to the overall quality of the research findings.

A. Measures

e-commerce organizational practices revolve around e-commerce innovations [19], [24], [25]. To improve e-commerce activities and competitiveness at all levels, this study statistically explored the participants' knowledge of e-commerce innovations and the types of devices used as well as the type of training and the issues that have constrained e-commerce progress. Pearson's correlation statistics were used to measure the strength of the relationship between the relative research variables based on r and p value. Inter-statistical analysis was used to provide a clear explanation on the variance and the mean value in the research items. ANOVA with Tukey's test for statistics was used to estimate the degrees of freedom based on the power of observation and the linear relationship of the hypothesized relationship. Multivariate analysis was used to explain the research hypotheses and address the null hypothesis of the study. A statistical test between the subject effect was used to support the hypothetical result.

V. CONTEXTUAL DESCRIPTION OF RESEARCH VARIABLES

The analysis reported in this section was based on numerous factors that support the e-commerce business including the need for timely communication and feedback with customers/clients also referred to as the e-commerce management style (eCMS). e-commerce organizational practices have been challenged by the difficulty of handling sensitive personal information, data and important software and innovative apps that have added value to the competitiveness of online businesses [26]. This is because the management style of e-commerce firms has failed to incorporate trends in technology into management practices. This could be because, decision making (DM) to improve e-commerce practices has not taken into consideration the need for adequate and timely training on e-commerce updates and innovations also referred to as e-commerce worker development (eCWD). In this study, all processes and tasks associated with e-commerce transactions is referred to as e-commerce process management (eCPM) and a clear business set goal for the e-commerce process is referred to as e-commerce performance management (eCPfM). Other important factors such as e-commerce organizations attitude towards innovation (eCOAI) have focused on making e-commerce more attractive to a range of online consumers into an effort to reduce shopping and delivery time. Organizations knowledge of the impact of e-commerce innovation has opened

doors to new outlets to make online sales easier and convenient [27], [28], [29]. It becomes imperative that e-commerce competitiveness e-commerce rotates around a transformative shift in innovation [30]. Knowledge of e-commerce technology (KeCT) has become a vital tool for e-commerce development. This is because insufficient knowledge about new developments in e-commerce practices poses greater challenges in positioning developing economies on a fast development path [31]. This is very visible from the emergence of relatively new technological innovations changes that have enabled organizations to tap new knowledge capabilities to foster the production and sales of products by extending service networks and providing timely services to larger numbers of online shoppers [32]. It is noteworthy to consider the financial capability of e-commerce organizations to acquire the necessary infrastructure to handle different services. Financial involvement (eCFin) to sustain e-commerce development is an important factor that determines e-commerce versatility to render efficient and timely services at a relatively lower cost. External pressure is another important factor (extF) in this study that focuses on customer and supplier commitment and respond to the business environment and is discussed in this study relative to new ways of doing online business, also referred to as e-commerce innovation (eCI).

VI. STATISTICAL ANALYSIS

A. Descriptive Statistics of e-Commerce Knowledge Across the Study Population

Proportion of Libyan using e-commerce platform to purchase products are denoted by "Yes and No device used for e-commerce transaction, type of training to adopt e-commerce innovations and problems with purchasing product and vices via e-commerce platform are as shown in Table I.

The mean distribution of the research variables ranged from 4.0880 to 4.8160 (58.4% to 68.8%), indicating that 219 to 258 out of 375 of the study population had the same view about the research outcome, as shown in Table II.

B. Correlation Matrix of the Research Variable

The correlation matrix shows the relationship levels of the variables ranging from moderate (only for eCMS) to strong positive relationships with other drivers of e-commerce innovation (Table III). Inter-item covariance explains the homogeneity of the tested variables. The mean value of the variable item was closely related (4.088 – 4.816) with a mean value of $M = 4.431$ (Table IV, Fig. 2, 3).

C. ANOVA Statistics with Tukey's Test for Nonadditivity

Tukey's estimated power to which observations must be made to achieve additivity = 2.056. The model analysis revealed the interaction effect between e-commerce drivers and e-commerce innovation at the organizational level (Table V).

D. Multivariate Analysis of the Research Hypotheses

- indent Variable: eCI.
- .581 eCMS(eCOAI)+.564 eCMS (KeCT)+.839 eCMS(eCFin)+.330 eCMS(extF) - 1.315 eCMS (Error).

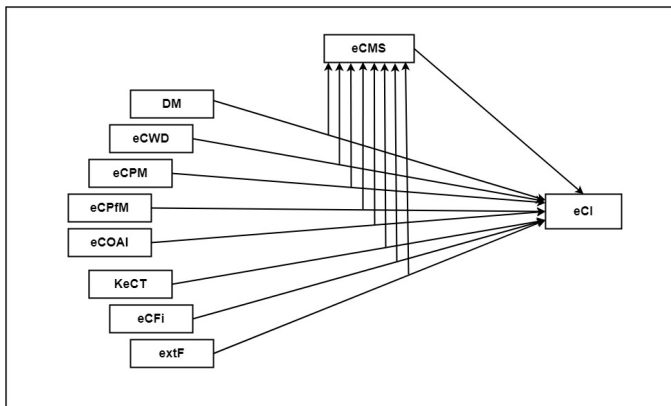

Fig. 3. Hypothetical path of the moderating effect of eCMS on the eCD influence on eCI.

- Cannot compute the appropriate error term using Satterthwaite's method.

With the intention of exploring different innovative ways to improve e-commerce practices at the organizational level, the partial sum of squares at an intercept with e-commerce innovation was .581 eCMS(eCOAI), .564 eCMS (KeCT), .839 eCMS(eCFin), .330 eCMS(extF), .771 eCMS(eCWD), .878 eCMS(eCOAI), .300 eCMS (DM), with - 1.315 eCMS (Error), indicating that e-commerce process management (eCPM) could not compute the appropriate error term. However, the hypothetical statement that eCMS(eCPM) has a positive relationship with eCI at the organizational level and was significant at 0.00 level (Table VII).

- Dependent Variable: eCI

A test of equality of error was conducted to confirm whether the variance of the dependent variable was equal across groups for the null hypothesis (Table VIII).

VII. DISCUSSION

The study population consisted of Libyans aged 20 years and above 65 years old who are eligible e-commerce users

and have a minimum of five years working as management staff in e-commerce organizations across Libya. results showed that 330 (88%) out of 375 of the study population purchased products and services via e-commerce websites. 306 (81.6%) users of e-commerce infrastructure accessed the website using smartphones, while others used tablets (30 users constituting 8%), laptops (27 users comprised of 7.2%), and desktop PC covering (12 users constituting 3.2%). Training of e-commerce is mainly by formal training and “on the job training” on-job training using facilities and infrastructures for e-commerce services. Majority of the e-commerce users (28.8%) were satisfied with the services, while others emphasized on the need to use identifiable location addresses (20.8), others focused on improving the delivery time (19.2%), product quality (15.7%), and to address delay in product and service delivery (Table I). Item statistics show that the mean value ranges from 4.09 to 4.82 (58.4 % to 68.8% of responses), indicating that 219 to 258 respondents out of 375 in the study population are of the same view about the research outcome. This finding shows that this study is reliable and can be used to generalize innovations in e-commerce practices across the developing countries, especially in the Middle East. The statistical results (Table II) show that eCI had the highest mean value (M = 4.82, SD = 1.54), followed by eCOAI (M = 4.66, SD = 1.65), KeCT (M = 4.53, SD = 1.58), eCMS (M = 4.47, SD = 1.69), eCFin (M= 4.46, SD = 1.67), extF (M = 4.41, SD = 1.67), eCPfM (M = 4.39, SD = 1.63), DM (M = 4.26, SD = 1.55), eCPM (M = 4.22, SD = 1.74), and eCWD (M = 4.09, SD = 1.86).

The correlation statistical result showed that eCMS has a moderate positive correlation ranging from $r .430-.488$, $p = .000$ level, with all e-commerce innovation drivers. Except for eCMS, the other drivers of e-commerce innovation have a very strong positive correlation. DM had a strong positive correlation, ranging from $r = .944-978$, $p = .000$. eCWD is strongly positively correlated at $r = .951 - 972$, $p = .000$, eCPM at $r = .958 - 978$, $p = .000$, eCPfM at $r = .953 - 977$, $p = .000$, eCOAI at $r = .952 - 976$, $p = .000$, keCT at $r = .951 - 967$, $p = .000$, eCFin at $r = .944 - 969$, $p = .000$, extF at $r = .951 - 967$, $p = .000$ and eCI at $r = .941 - 976$, $p = .000$. The strength of the relationship between variables varies. eCMS showed a stronger relationship with eCI and eCOAI, whereas DM showed a stronger relationship with eCPM, eCWD with eCPM, eCPM with DM, eCPfM with eCPM, eCOAI with eCI, KeCT with eCFin, eCFin with KeCT, extF with eCPM, and eCI with eCOAI (Table III).

An ANOVA one-degree Tukey's test for no additivity of freedom was used to test the hypothesized linear interaction across the research variables. The ANOVA model assumed no randomized treatment or additive block across the measured items. The interaction between the items and no additivity was statistically significant. The multivariate multiple responses of the variables were generalized using Hotelling's T-Squared Test. Significant differences between the multivariate means of the data sets shown in Table VI summarize e-commerce the significant relationship between e-commerce divers and

e-commerce innovations. The multivariate probability of F-distribution explained the hypothetical statement that the e-commerce drivers positively influenced e-commerce innovation were generalized by the statistics underlying t-distribution.

We reject H0 because α t2 (841.244) is greater than the critical value for F (91.472).

Analysis of variance based on a test of the between-subject effect was conducted to test the ability of the model to clearly explain possible variation. The displayed variable labels indicate that the values of all terms were significantly related at the intercept; eCMS, DM, eCWD, eCPfM, eCOAI, KeCT, eCFin, and extF computed similar error terms. However, larger values of the sum of squares, mean squares, and F values indicate a greater amount of variation accounted for by the model error term.

The p-values for the hypothetical relationship between eCMS, eCPfM, eCFin, and extF and eCI, while DM, eCWD, eCOAI, and KeCT were statistically significant at 0.00 level. The practical significance of each term was based on the ratio of the variation in the sum of squares accounted for by the term to the sum of the variation accounted for by the term, and the variation left to error. The tendencies of bias in standard errors, as well as t-statistics or F-statistics in drawing inferences, especially during model misspecification, were addressed by conducting heteroscedasticity tests to check for structural breaks. The heteroscedasticity test revealed that no single observation was dominant (Table VI). This has provided a clear understanding of the main factors requiring close attention in meeting the developmental innovations in e-commerce and how newly added features in online web shops have improved existing practices. It is clear that e-commerce innovations are versatile in providing timely delivery of goods and efficient services [33], [34].

This intriguing shift in e-commerce innovation has transformed digital commerce and provided multiple choices for

online customers to buy products that were previously available only in physical retail shops. This relatively new business opportunity is embodied in specific skills that require successive developments and updates. The adoption of e-commerce innovation is part of the digital transformation from remote sales, and the delivery of customer service is an open-ended business network [35]. With the recent surge in online shopping, e-commerce stands out as a potential tool for enhancing entrepreneurial capability and competitiveness in organizations.

VIII. CONCLUSION AND RECOMMENDATION

Recent innovations have widened e-commerce knowledge and its role in a developing economy. Various drivers have been identified as key factors in enhancing e-commerce performance at the organizational level. Identifying the key drivers of e-commerce innovation makes the future of e-commerce brighter, as they contribute to addressing the back-drop in e-commerce performance at the organizational level. E-commerce innovation has been acknowledged as the main factor driving online transactions. The development of e-commerce workers is an issue of concern that needs to be addressed to meet the growing trend in innovation. The management styles of e-commerce firms incorporate development trends in e-commerce innovations into the training of workers and services to improve workers' knowledge and e-commerce performance. This is because knowledge of e-commerce at the organizational level is affected by attitudes towards innovation. Decision-making at the management level should incorporate funding of e-commerce infrastructures, since formal training and on-the-job training are prevalent ways of equipping employees in e-commerce organizations.

The drivers of e-commerce innovation model design showed that, at the intercept (eCMS + DM + eCPD + eCPM + eCPfM + eCOAI + KeCT + eCFin + extF), the drivers of e-commerce innovations have a strong positive relationship. Multivariate analysis has quantified the moderating effect of e-commerce management style (eCMS) on the relationship between e-commerce drivers (eCD) and e-commerce innovation (eCI). eCD had a strong positive relationship with eCI. Management styles at various e-commerce organizations aim

to invest more effort and resources to improve the performance of e-commerce innovation drivers.

E-commerce companies selling and delivering goods and services across multiple online platforms have indicated that the potential of e-commerce is promising. e-commerce has made shopping easier and positioned e-Shop strategically to cater customers using fast and easy-to-handle electronic systems. Therefore, for further improvement, customer interest should be considered first. To facilitate online transactions, it is important to provide access to different product links and a clear description of product quality and price to potential customers.

E-commerce organizations should also partner with firms that can provide a reliable target for different customers, especially those that rate preferences and choice of online customers, to improve sales of products and services via e-commerce sites. This can be achieved by fine-tuning or providing a descriptive explanation of available products and services to potential customers using different media platforms that are actively used by many people. Efforts in this direction will further e-commerce processes and attract potential customers.

DECLARATION OF COMPETING INTEREST

The authors declare no conflicts of interest regarding the data and information reported in this study.

ACKNOWLEDGMENT

The authors acknowledge the funding support provided by the Faculty of Information Science and Technology, Universiti Kebangsaan Malaysia (under the research grant TAP). The support from a few professionals such as Associate Prof. Dr Nurhizam Safie Mohd Satar, Ts. Dr Ibrahim Mohamed and Prof. Dr Charles Ahamefula Ubani who enriched the paper and constructively enhanced the presentation. The Centre for Software Technology Management (SOFTAM) and Bani Waleed University of Libya for their mentorship and invaluable contribution. The commitment of the editor-in-chief, associate editor, and reviewers' comments for improvement is among the efforts to put this paper in the best shape it deserves.

This work was supported by funding from the TAP and the Faculty of Information Science and Technology Universiti Kebangsaan Malaysia. under Grant TAP.
